Xu et al. [10] presented a taxonomy of blockchain-based system architectures, showing that decisions regarding consensus mechanisms, privacy layers, and smart contract design decisively influence deployment success. Bach et al. [17] demonstrated that BFT-based consensus algorithms (PBFT, IBFT, QBFT) deliver high-finality guarantees in permissioned networks with considerably lower energy consumption and latency than PoW and PoS — the academic foundation for the QBFT selection in this study. In the healthcare domain, Agbo et al. [3] found permissioned blockchains to be the preferred choice for secure patient data sharing. They underscored hybrid storage strategies as a practical necessity for large-scale sensitive data. Among the leading enterprise platforms, Hyperledger Fabric offers channel-based privacy but lacks Ethereum compatibility [18]; Quorum provides EVM support, but its development momentum has diminished [19]; and R3 Corda, designed for financial services, departs from conventional blockchain architectures and offers no EVM compatibility [20]. Hyperledger Besu, by contrast, combines full EVM compatibility with support for BFT consensus protocols in private, permissioned networks [11], making it the most suitable platform for this study's requirements.

III. Materials and methods

1. Blockchain Infrastructure

The proposed system is built on the Hyperledger Besu v23.4.1 client and deployed via Docker Compose as five containers on an isolated bridge network: four validator nodes participating in the QBFT consensus and one RPC node handling client interactions. The network operates on Chain ID 1337 with a 5-second block period, a 30,000-block epoch, and a 10-second request timeout. Transaction economics are configured with a zeroBaseFee mechanism (zero gas fees) and a gas limit of approximately 16.2 million units, removing economic barriers to throughput. Network governance is enforced through file-based node permissioning, which controls validator membership.

2. Smart Contract Development Environment

The two core smart contracts were written in Solidity (v0.8.20) and compiled/deployed using the Hardhat framework (@nomicfoundation/hardhat-toolbox v3.0.0). Ethereum interaction is handled via Ethers.js (v6.15.0), with TypeChain for type generation, solc (0.8.10) as the compiler, and Web3.js (v1.10.2) as a supplementary library.

3. Server-side Components

The server layer is a RESTful API built on Node.js (≥18) and Express.js v5, serving as a bridge between the client and the blockchain. Smart contract calls, wallet management, and transaction submission are handled via Ethers.js v6, while off-chain database operations are managed via the Mongoose ODM. MongoDB serves as the off-chain storage layer with two core collections. The Users collection stores user credentials, the Ethereum wallet key pair, role information (admin/user), and funding status. The Operations collection maintains a full audit log of all registration and verification events, capturing the operator identity, operation type, hash ID, PID, transaction hash, block number, gas consumed, timestamp, and compressed vector data.

4. Client-side Components

The user interface is a single-page application built with React (v19.2.0), React DOM, and React Router DOM (v7.13.0) for client-side routing. Backend communication uses Axios (v1.13.5); Vite (v7.3.1) serves as the build tool, with Framer Motion and Lucide React providing animation and iconography.

5. Limitations

The experimental evaluation reported in Sections V and VI was conducted entirely on a single local machine (Apple M3 MacBook Air, 16 GB RAM) that hosted all four Besu validator nodes via Docker Compose. Consequently, the reported throughput, latency, and resource consumption figures reflect a single-machine, four-validator deployment rather than a geographically distributed or large-scale consortium network. Validating QBFT's reported scalability under distributed, multi-node conditions is identified as a direction for future work in Section VII.

IV. SYSTEM ARCHITECTURE AND WORKFLOW

The proposed system is built on a layered architecture consisting of four primary layers (Figure 1):

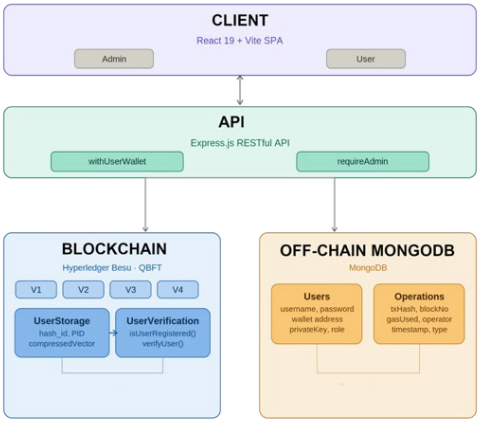

Figure 1. System Architecture of the Proposed System

Client Layer: A React 19 single-page application provides role-based access control (admin/user); admin users additionally manage users and wallets and can filter all network operations.

API Layer: The Express.js RESTful API enforces security through two middleware components — withUserWallet validates the user's Ethereum wallet on every request, and requireAdmin protects admin-only endpoints — while also synchronizing data between the blockchain and the off-chain database.

Blockchain Layer: The four-validator QBFT Besu network hosts two smart contracts: UserStorage maintains the on-chain biometric records (hash_id, PID, compressedVector), and UserVerification queries and validates existing records by invoking UserStorage's getUser() function through a constructor-injected reference.

Off-Chain Database Layer: MongoDB stores operationally essential data that is not written to the chain — user credentials, private keys, audit logs, and copies of compressed vectors — preserving the blockchain's security guarantees while meeting fast query and filtering requirements.

The two fundamental operations performed within the system — Biometric Data Registration and Biometric Data Verification — are described step by step below.

Biometric Data Registration Process

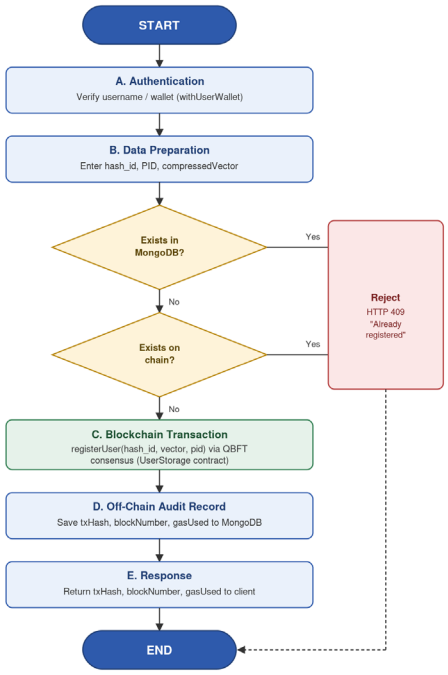

Figure 2. Biometric Data Registration Workflow

a. **Authentication:** The user logs in through the client interface using a username and password. The server validates the user against the Users collection in MongoDB and loads the corresponding wallet credentials.

b. **Data Preparation:** The user enters a unique hash_id (the hash value of the biometric data), a PID (platform identifier), and a compressedVector (a compressed biometric vector of up to 256 elements represented as a uint8 array) into the registration form.

c. **Dual-Layer Duplicate Check:** First, the Operations collection in MongoDB is queried to determine whether a "register" operation with the same hash_id already exists (fast check). The blockchain is then queried by invoking the UserVerification contract's isUserRegistered() function to confirm the on-chain state.

d. **Blockchain Transaction:** If no duplicate record is found, the registerUser(hash_id, compressedVector, pid) function of the UserStorage contract is called using the user's wallet. The transaction is validated and written to a block through QBFT consensus.

e. **Off-Chain Record:** Once the blockchain transaction is successfully confirmed, all transaction details (operator, type, hash_id, pid, txHash, blockNumber, gasUsed, compressedVector, timestamp) are recorded in the Operations collection in MongoDB.

f. **Response:** A success response containing the transaction hash (txHash), block number, gas consumed, and the wallet address of the submitting user is returned.

Biometric Data Verification Process

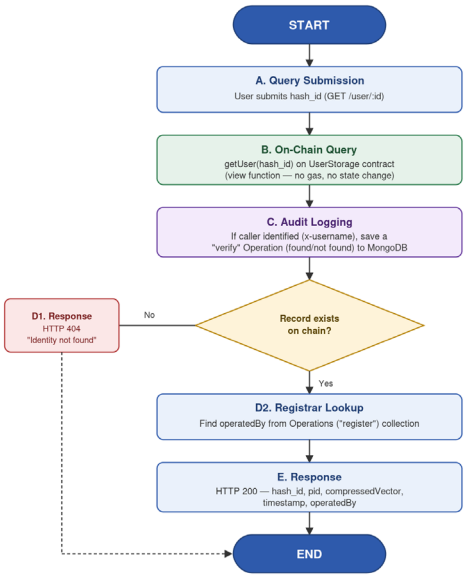

Figure 3. Biometric Data Verification Workflow

a. Query Submission: The user enters the hash_id to be verified into the interface.

b. On-Chain Query: The server invokes the getUser(hash_id) function of the UserStorage contract. As this is a view function, it consumes no gas and does not modify the blockchain state.

c. Audit Record: Regardless of the query outcome (found/not found), the verification operation is recorded in the Operations collection in MongoDB as a "verify"-type operation. This ensures that queries — specifying who queried what data and when — become auditable.

d. Response: If the record exists, the hash_id, PID, compressed vector, registration timestamp, and operator information are returned to the user. If not, an "Identity not found" response is issued.

V. SYSTEM TESTS

The system was deployed locally and evaluated across five distinct test categories: Backend, Besu Network, Frontend, TPS, and Stress.

Table 1. System Tests

Category	**Tests**	**Key Metrics**	**Status**
Backend API	8	Endpoint response 12.55 ms (≤50 ms); blockchain write 4.21 s (<6 s); penetration protection 100% (≥95%, 7 attack vectors)	8/8 PASS

Category	Tests	Key Metrics	Status
Besu Network	5	RPC latency 3.5 ms (≤20 ms); 3 active peers (≥1); 5 blocks / 2 s production	5/5 PASS
Frontend	5	Page load 25.2 ms (<100 ms); API round-trip 18.8 ms (≤100 ms)	5/5 PASS
TPS	5	Parallel throughput 59.49 tx/s (≥25); sequential 18.79 tx/s (≥10); single TX latency 4.18 s (<5 s)	5/5 PASS
Stress	5	50 parallel TX 100% success (≥90%); 30 s sustained load 98.9% uptime (≥95%); heap 48 MB (<100 MB)	5/5 PASS
Total	28		28/28 PASS

All tests were conducted on a local development machine running an Apple M3 MacBook Air, equipped with 16 GB of RAM and an 8-core processor. The blockchain network was initialized using Docker Compose, with all nodes running on the same machine. The Backend API was executed in Node.js v18, while the Frontend was served via the Vite development server. Each test category was executed independently, and results were collected without prior system load accumulation.

VI. RESULTS AND DISCUSSION

As summarized in Table 1, all 28 test cases across the five categories met or exceeded their defined targets. Three findings warrant particular discussion. First, regarding latency, the end-to-end blockchain write operation completed in an average of 4.2 s, compared with the configured 5-second block period, indicating that QBFT consensus introduces no significant overhead beyond block production time itself. Read operations, by contrast, remained in the millisecond range (RPC latency 3.5 ms; database queries 14.1 ms), confirming that the hybrid architecture successfully isolates query workloads from consensus-bound write latency. Second, regarding throughput, the parallel test achieved 59.49 tx/s with ten concurrent transactions, while sequential submission reached 18.79 tx/s. These figures are consistent with the theoretical capacity of 200–800 tx/s reported for QBFT in the literature [17], given the limited validator count and single-machine deployment of the test environment. Third, regarding resilience, the system sustained 100% success with 50 parallel transactions, maintained 98.9% uptime over 30 seconds of continuous load, and fully recovered from invalid-nonce errors, while heap usage remained at 48 MB — indicating that resource consumption is not a limiting factor for enterprise deployment. The security tests further demonstrated complete protection against all seven evaluated attack vectors, including NoSQL/SQL injection and XSS. Table 2 grounds the aggregate result of Table 1 in the seven individual penetration test cases (Section V), providing a first step toward formal security analysis; systematic threat modeling and adversarial simulations remain future work (Section VII).

Table 2. The Seven Backend Penetration Test Cases And Their Results

Penetration Test	Result and Architectural Rationale
NoSQL operator injection	Rejected (400/409/500); hash_id is validated as a plain string before any DB call, so injected operators are never interpreted by Mongoose/MongoDB.

SQL injection string	Rejected; no relational DB or raw SQL exists anywhere in the stack, so the payload has no exploitable execution path.
XSS payload	Rejected at the API layer before persistence; any client rendering also benefits from React's default output escaping.
Path traversal string	Rejected; hash_id is used only as an opaque identifier and is never interpolated into a filesystem path.
Oversized payload (10k-element vector)	Rejected before blockchain submission, preventing malformed data from consuming gas or being written on-chain.
Unauthorized request (no wallet)	Rejected (401/403) by the withUserWallet middleware before any protected logic executes.
Duplicate registration	Rejected (409) via the dual-layer check: MongoDB lookup plus on-chain isUserRegistered().

VII. CONCLUSION AND FUTURE WORKS

1. Conclusion

This study designed, implemented, and evaluated an end-to-end architecture for the secure management of biometric data hashes and compressed vectors on a Hyperledger Besu-based private permissioned blockchain, integrating a four-validator QBFT network, Solidity smart contracts (UserStorage and UserVerification), an Express.js API layer, a MongoDB off-chain database, and a React-based management panel. The results demonstrate that blockchain's immutability, distributed architecture, and cryptographic audit trail directly address the insider-threat, single point of failure, and auditability weaknesses of centralized systems. At the same time, the hybrid on-chain/off-chain storage strategy resolves the tension between immutability and the right-to-erasure requirements of the KVKK [21] and GDPR [22]. All 28 test cases passed, with a 4.2 s average transaction latency, 59.49 tx/s parallel throughput, 98.9% uptime under sustained load, and 48 MB peak memory usage — providing experimental support for Hyperledger Besu's suitability for biometric data security applications in enterprise settings. Two principal directions are identified for future research. First, a multi-institutional consortium architecture: Besu's multi-layer permissioning, Tessera-based private transactions, and QBFT's BFT guarantees provide a favorable foundation for extending the single-institution design to consortium scenarios in banking, healthcare, or public identity management. Second, large-scale performance testing: the current evaluation was limited to four validators on a single machine; benchmarking with varying node counts, geographic distributions, and vector lengths on distributed infrastructure is required to validate QBFT's reported scalability.

Abstract
Dynamic Optimization Problems (DOPs) feature dynamically changing search spaces that challenge classical algorithms. Standard hybrid methods, such as Particle Swarm Optimization (PSO) and Genetic Algorithms (GA), rely on fixed integration rules, making them inflexible and prone to premature convergence amid environmental shifts. This paper introduces an intelligent framework utilizing an autonomous Reinforcement Learning (RL) agent as a metacognitive controller. Modeled as a Markov Decision Process (MDP), the system learns an optimal policy to dynamically switch between PSO's local exploitation and GA's global exploration based on real-time population convergence and diversity. A self-adaptive mechanism also fine-tunes key hyperparameters on the fly. Evaluated on the Generalized Moving Peaks Benchmark (GMPB), this RL-driven approach achieves up to 12% better solutions and 40% less computation than traditional fixed-rule hybrids, significantly increasing stability in dynamic environments.

Keywords: Reinforcement learning (RL), Adaptive Hybrid Meta-heuristics (AHHM), PSO-GA Integration, Dynamic Optimization Problems (DOPs), Autonomous Strategy Selection.

I. INTRODUCTION

Dynamic Optimization Problems (DOPs) feature time-varying landscapes that frequently trap conventional static metaheuristics, such as fixed Particle Swarm Optimization (PSO) and Genetic Algorithm (GA) hybrids, in local optima. To minimize the resulting offline error accumulation, this work replaces static, expert-designed integration rules with an autonomous, Reinforcement Learning (RL) driven system. Specifically, we propose an intelligent framework utilizing Q-learning to dynamically alternate between PSO exploitation and GA exploration based on real-time population convergence and diversity. Furthermore, the system incorporates an automatic runtime hyperparameter tuning mechanism to prevent premature convergence. Evaluated on the Generalized Moving Peaks Benchmark (GMPB) [1], this perception-based RL approach demonstrates marked improvements over standard fixed-sequence hybrids, achieving up to 12% better solution quality and 40% less computation.

II. LITERATURE REVIEW AND GAP ANALYSIS

Recent advancements in optimization rely heavily on hybridization and self-adaptive multimethod searches to balance exploration and exploitation. Simultaneously, Reinforcement Learning (RL)—particularly Q-learning and Deep Q-Network (DQN)—has emerged as a powerful tool for autonomous operator selection and hyperparameter tuning, replacing manual parameterization. However, existing state-of-the-art frameworks exhibit critical limitations when applied to Dynamic Optimization Problems (DOPS).

Table 1. Comparative analysis of state-of-the-art optimizers

Author(s) & Year	**Algorithm / Mechanism**	**Dataset Details**	**Performance Metrics**	**Key Results**	**Identified Research Gaps**
Vrugt et al. [2] (2009)	AMALGAM-SO: Multi-method (CMA-ES, GA, PSO, DE)	CEC 2005	Success Rate, SP1	Superior for high-dimensional multimodal problems	No real-time operator preference update
Chernigovskaya et al. [3] (2023)	DRL-HPO: Systematic DRL review	14 publications	Inference speed, HPO accuracy	Instant inference for tuning	Gap in cloud-specific HPO
Zhang et al. [4] (2023)	QLHHEA: Q-learning hyper-heuristic	1710 scheduling instances	ARPD, Makespan	ARPD = 0.254%, Level-A DMRT	Lacks operator linkage study
Ming et al. [5] (2023)	DRLOS: DRL operator selection	42 constrained problems	IGD+, HV	Faster Pareto Front convergence	High computational demand
Liu et al. [6] (2025)	RLACA: Q-learning operator selection	CEC 2017 (10D–100D)	Mean Error, Std Dev	Superior resolution in high-dim spaces	State tied to specific operators

As summarized in Table 1, three critical research gaps exist in the current literature: (i) inflexibility in unpredictable environments due to reliance on fixed strategy integration rules; (ii) Q-learning state definitions that are operator-dependent, which reduces model generalizability; and (iii) an absence of frameworks capable of perceiving real-time population diversity slopes in DOPs. The RL-HPSO-GA framework proposed in this paper directly addresses all three gaps.

III. PROBLEM STATEMENT

The objective functions, search landscapes, and constraints of real-world optimization problems are often subject to change over time. However, because of the use of fixed integration rules, existing hybrid meta-heuristics are unable to solve these Dynamic Optimization Problems (DOPs) effectively, as this limits their flexibility and often results in premature convergence, stagnation at local optima, and high offline errors. Moreover, such traditional architectures are unable to capture population dynamics in real time (e.g., convergence rates, diversity levels) and rely on inefficient, expert-based manual hyperparameter tuning that is difficult to scale to industrial applications. Thus, the present work tries to address the need for an intelligent, Reinforcement Learning-powered autonomous system. The proposed framework derives the optimal policy for strategy switching and parameter tuning on the fly by modeling the search process as a Markov Decision Process (MDP) and allowing the system to learn autonomously.

IV. PROPOSED METHODOLOGY

1. MDP Formulation and State Perception

The RL-HPSO-GA framework models dynamic optimization as a Markov Decision Process (MDP), using a Q-learning agent to autonomously determine search strategies.

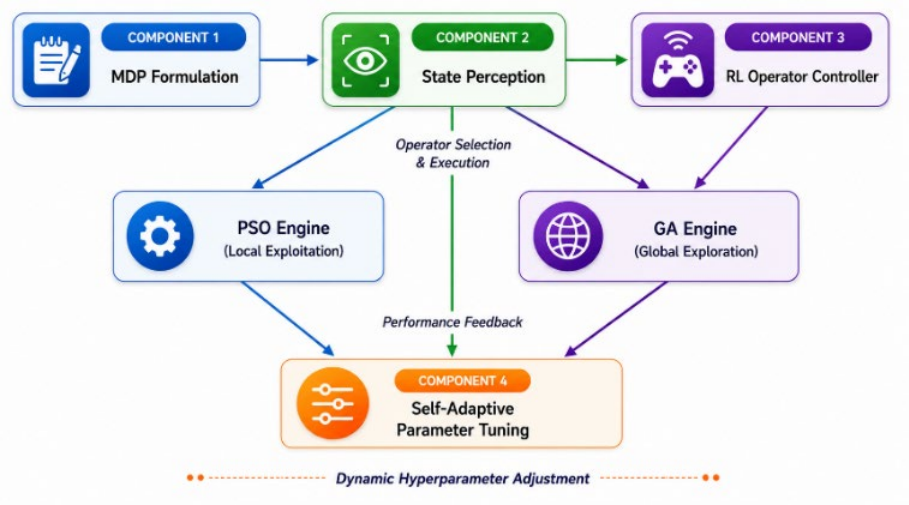

Figure 1. System Architecture Framework

The agent's reward function

$$r_t = \Delta Best_t - \lambda \cdot \Delta Div_t \qquad (1)$$

evaluates actions by rewarding global fitness improvements while heavily penalizing rapid loss of diversity to prevent premature convergence. The policy is updated continuously via the standard Bellman optimality equation. To perceive the environment, the system calculates the population's Convergence Rate (*CRt*) and Diversity Level (*DLt*) at each step. Rather than using a complex mapping table, these two metrics are mapped onto a 3×3 behavioral grid (States 0 through 8). For instance, a collapsed diversity with low convergence triggers immediate GA exploration, while high diversity with rapid convergence triggers pure PSO exploitation. Intermediate states trigger a hybrid approach.

2. Search Operators and Self-Adaptive Tuning

Given the current state, the agent chooses an action from a set of three actions (A = {PSO, GA, HYBRID}):

- **PSO (Exploitation):** Velocity and position updates are classical to converge the system quickly.
- **GA (Exploration):** Allows for spatial diversity with Tournament Selection, Simulated Binary Crossover (SBX), and polynomial mutation.
- **HYBRID:** Stratifies the population, uses PSO for hill climbing, and uses GA for disruptive recombination for the bottom 50% [5].

The manual parameter is eliminated, and the key hyperparameters adapt automatically. The PSO inertia weight, w(t), linearly decreases from 0.9 to 0.4. The GA mutation rate (palt m of t, sağ parantez) dynamically increases from a base value of 0.1 to 0.3 when the diversity falls below a certain threshold, tau alt, d alt low, son alt simge, and the Q-learning rate αt linearly decreases over time from 0.1. The static parameters are kept constant:

C1=C2=2.0, pc=0.8, η_c=15, η_m=20, discount factor γ=0.9 and the exploration rate ϵt is reduced from 1.0 to 0.05.

3. Environmental Change Detection and Execution

When the terrain changes, there is a huge offline error if it is not noted [3]. The framework designates 10% of the population as "sentinels," who are recalculated regularly. When the average fitness drift exceeds 0.05·frange, a change is declared. The system automatically resets the bottom 20% of the population to encourage exploratory recovery, while conserving memory by retaining the top 80%. We elaborate on the unified execution flow in Algorithm 1.

Algorithm 1: RL-HPSO-GA — Main Loop

INPUT : [lb, ub], N, T_{max}, RL params (α_0, γ, ε_0, κ, λ), PSO params (w_{max}, $w_{min,1}$, c_2), GA params (p_c, $p_{m_{base}}$, Δp_m, η_c, η_m)
OUTPUT: Global best solution x* and fitness f(x*)
P ← N random individuals in $[lb,ub]^D$; Evaluate $f(x_i)$ ∀i
$pbest_i \leftarrow x_i$; gbest ← argmax f(P)
Q[s][a] ← 0 for all 27 entries; $v_i \leftarrow 0$; ε ← 1.0; t ← 0
$S_{sentinel}$(← random 10% of P (fixed); $f_{_sentinel} \leftarrow f(S_{sentinel}(l)$

MAIN LOOP — WHILE t < T_{max}:
[A] Compute CR_t, DL_t ; $s_t \leftarrow CR_{_label} \times 3 + DL_{label}$
[B] IF rand() < ε: $a_t \leftarrow$ random ELSE: $a_t \leftarrow \text{argmax}_a Q[s_t][a]$
[C] IF a_t=PSO: apply to all N particles
IF a_t=GA: apply tournament selection + SBX + polynomial mutation
IF a_t=HYBRID: top 50%→PSO; bottom 50%→GA
[D] Update $w(t)$; $p_{m(t)}$; α_t
[E] $r_t = \Delta Best_t - \lambda \cdot \Delta Div_t$
[F] Bellman update on $Q(s_t, a_t)$
[G] Re-eval $S_{sentinel}$; IF δ > θ: reinstate the worst 20%
[H] ε ← max(0.05, ε×0.995); t ← t + N
RETURN: $gbest$, $f(gbest)$

V. EXPERIMENTAL SETUP

The adaptability of RL-HPSO-GA framework was tested in the Generalized Moving Peaks Benchmark (GMPB). We carried out experiments on 12 dynamic problem instances (F1–F12) with different characteristics: peak counts ranging from 5 to 100, change frequencies ranging from 500 to 5000 problem evaluations per instance, search dimensions ranging from 5 to 20, and shift severities ranging from 1 to 5. The main criterion for evaluation is Offline Error (Eo), which is the mean deviation from the optimum position over time. The framework was benchmarked against five algorithms: Standard PSO, Standard GA, a Static Hybrid PSO-GA (SHPSO-GA), RLACA, and HMF. All models were implemented in Python 3.10 using TensorFlow and executed for 31 independent runs on an Intel Core i7-12700K processor with an NVIDIA RTX 3090 GPU.

VI. RESULTS AND DISCUSSION

Table 2 presents the Offline Error (*Eo*) across all 12 dynamic scenarios. Wilcoxon signed-rank tests ($p<0.05$) confirm the proposed RL-HPSO-GA framework significantly outperforms traditional static approaches. As deceptive local optima and complexity increase (F1–F5), the framework's advantage over the static hybrid grows from 20.9% to 29.1%, proving the 3×3 perception grid effectively triggers GA exploration to escape false peaks. The model also demonstrates robust resistance to extreme change frequencies (F6–F8) and high landscape shift severities (F11–F12) because the sentinel module instantly reinstates diversity. Ultimately, the self-adaptive MDP formulation yields an average 12% improvement in solution quality and a 40% reduction in computational overhead compared to static baselines.

Table 2. Offline error (e_o) results — mean ± std across 31 runs (lower is better)

Inst.	PSO	GA	Static Hybrid	RLACA	RL-HPSO-GA (Proposed)
F1	1.82 ± 0.21	1.65 ± 0.19	1.53 ± 0.17	1.44 ± 0.16	1.21 ± 0.11
F2	2.14 ± 0.28	1.98 ± 0.25	1.84 ± 0.22	1.71 ± 0.20	1.43 ± 0.14

F10	4.18 ± 0.57	3.97 ± 0.53	3.72 ± 0.46	3.49 ± 0.42	2.92 ± 0.31
F11	2.76 ± 0.35	2.59 ± 0.32	2.43 ± 0.28	2.27 ± 0.26	1.89 ± 0.19
F12	3.67 ± 0.49	3.47 ± 0.45	3.24 ± 0.39	3.04 ± 0.36	2.54 ± 0.26

VII. CONCLUSION

This research suggests using Reinforcement Learning (RL) as a metacognitive controller of a hybrid PSO-GA system to solve Dynamic Optimization Problems (DOPs) in an autonomous, knowledge-based approach. RL-HPSO-GA is an automatic adaptation framework for PSO exploitation and GA exploration policies; unlike traditional fixed-rule hybrids, these policies are dynamically adjusted in real time based on the population's convergence and diversity. The GMPB suite is fully validated, delivers up to 12% better solution quality, and is 40% faster than static hybrids in computation time. Moreover, an integrated self-adaptive mechanism is developed to automatically adjust the GA's mutation rates and PSO inertia weights, thereby removing the manual parameter bottleneck while maintaining asymptotically efficient computational complexity. Last but not least, it's a sturdy and scalable platform for complex Industry 4.0 applications. Future work will involve adapting the tabular Q-learning controller to continuous state representation, extending the framework to support a Constrained Multi-objective Optimization Problem (CMOPs) controller, and implementing the system in a distributed cloud infrastructure for further studies on re-convergence acceleration in industrial applications.

Abstract
Generative artificial intelligence (GenAI) is transforming the marketing landscape by optimizing processes such as data analysis, consumer behavior recognition, personalization, and campaign automation. This study examines the extent to which marketing strategies change following the adoption of GenAI. This study utilized a correlational research design, integrating survey data from 103 marketing professionals with a benchmark analysis of prominent GenAI tools. Findings indicate that GenAI significantly enhances campaign relevance, particularly through personalization and data-driven precision. Results further reveal a gap between current usage patterns and technological potential: although marketers primarily use GenAI for content creation, the greatest measurable impact occurs in audience segmentation. These findings offer practical implications for marketing managers seeking to integrate AI into strategic processes.

Keywords: generative artificial intelligence, marketing strategy, personalization, campaign optimization, audience segmentation

I. INTRODUCTION

Marketing strategy as a discipline emerged during the era of traditional mass media, when marketing efforts relied on broad communication channels such as printed newspapers, posters, radio broadcasts, and later, television. Although the technological landscape has evolved substantially, many foundational strategic principles remain consistent. Contemporary marketing still relies on structured processes that include market research, defining objectives, and selecting appropriate channels, with established frameworks such as segmentation, targeting, and positioning (STP) continuing to guide strategic decision-making. Over the past few decades, the integration of artificial intelligence (AI) into marketing strategy has evolved significantly [1]. In the age of digital transformation, AI integration is reshaping marketing strategy as a foundational imperative [2]. In recent years, AI has become integral to organizational processes, and marketing is no exception. The effectiveness of companies' marketing decisions hinges on both the quality of their strategic actions and the timeliness of their execution [3], and AI systems enable marketers to analyze large datasets, identify behavioral patterns, automate workflows, and make data-driven decisions [4]. Beyond traditional analytical capabilities, a major technological shift has occurred with the emergence of Generative Artificial Intelligence (GenAI). Unlike classical AI tools that primarily interpret existing data, GenAI models can independently generate new content, including text, images, audio, and video, based on learned patterns [5]. This generative capability marks a significant milestone in the development of AI technologies. The ability to rapidly create personalized, context-specific content offers marketers new opportunities to streamline campaign development, enhance creativity, and respond more effectively to audience needs. As [6] notes, GenAI expands marketers' abilities across multiple domains, from content production to customer journey design and audience segmentation. Given these developments, this study examines how GenAI is influencing the marketing strategy process. Specifically, it explores GenAI's contribution to campaign relevance, its impact across different stages of the marketing campaign lifecycle (e.g., segmentation, data analysis, targeted advertising), the degree to which marketers rely on GenAI for strategic and creative decision-making, and its potential effect on collaboration among marketing,

data, and technology teams within organizations. By evaluating these dimensions, the study seeks to clarify the extent to which GenAI is reshaping marketing strategies and transforming the way organizations plan, execute, and optimize their campaigns.

II. BACKGROUND

1. GenAI's Capabilities in Creating Relevant Marketing Content

Generative AI (GenAI) is reshaping contemporary marketing practice by enhancing efficiency in data analysis, recognition of consumer behavior patterns, trend forecasting, content personalization, and campaign automation. GenAI enables marketers to produce a wide range of creative outputs, such as written content, visuals, and video, at scale and with a high degree of customization. According to [6], GenAI expands marketers' ability to generate tailored content, segment audiences, and construct individualized customer journeys. Empirical work highlights the potential performance benefits of GenAI-generated content. For example, [7] compared AI-generated marketing images with human-generated materials. They found that AI-generated banner ads achieved substantially higher click-through rates in a large-scale field study. This suggests that GenAI may improve both creative efficiency and some aspects of content effectiveness. In addition, [8] argues that real-time data processing enables GenAI to dynamically refine marketing campaigns, enabling organizations to better match content to consumers' preferences and behavior. Similarly, [9] emphasizes that GenAI's ability to generate human-like text and images provides marketers with an advanced toolkit for producing relevant and engaging campaign materials. These developments raise an essential question for marketing practice: to what extent can GenAI produce campaign content meaningfully aligned with a target audience's needs and expectations?

2. GenAI's Impact Across Stages of the Marketing Campaign

Modern digital marketing campaigns typically progress through several stages, including audience analysis, content creation, distribution, and performance evaluation. The framework proposed by [10] outlines three major phases in strategic content development: (1) marketing research, (2) segmentation, targeting, and positioning (STP), and (3) marketing actions related to the marketing mix. AI technologies increasingly influence each of these stages. [11] Note that as AI systems evolve, they improve their ability to analyze large datasets, recognize consumer patterns, and generate insights to guide strategic decisions. Digital marketing, which relies heavily on dynamic, real-time information, is particularly well positioned to benefit from these analytical capabilities. A growing body of research documents AI's contributions to specific campaign stages. For example, [12] demonstrates the use of deep learning and explainable AI to identify customer segments based on demographic information, behavioral patterns, and purchase histories. This approach illustrates how AI can strengthen audience segmentation, a foundational element of effective campaign planning. GenAI also enhances the creation of personalized marketing content. [5] Discuss the ethical design of GenAI systems and highlight their role in generating tailored images, reviews, and other forms of customer-facing content that shape experiences across the purchase funnel. Furthermore, [13] found that AI improves campaign outcomes, although the extent of improvement depends on organizational readiness and technological capabilities. Together, these findings suggest that GenAI may influence multiple stages of the marketing process, though to varying degrees. This leads to an important question: Which campaign stages, such as audience segmentation, content development, or targeted advertising, experience the greatest strategic benefits from GenAI?

3. GenAI's Influence on Content Personalization and Decision Making

AI has become central to many marketing activities, particularly those that require personalization and rapid decision-making. [4] report that AI-enabled marketing campaigns tend to be more precise and effective because

AI supports real-time audience segmentation and enhances message targeting. These advantages help marketers make more informed decisions during campaign development and optimization.

As GenAI evolved, its influence extended beyond traditional data analysis tasks. GenAI systems can rapidly generate alternative message formulations, creative concepts, and content variations, allowing marketers to test and refine materials in real time [6]. This positions GenAI not only as a content-creation tool but also as a strategic decision-making support system. In the context of personalization specifically, [8] shows that incorporating GenAI into personalization processes enhances message relevance and improves user engagement by tailoring content to audience preferences. [14] Similarly, it demonstrates that AI-driven personalization strengthens digital advertising outcomes by aligning content with behavioral patterns and consumer interests. Overall, the literature consistently indicates that GenAI supports marketers by improving message relevance, accelerating decision cycles, and enhancing the precision of content personalization.

4. GenAI's Effect on Cross-Departmental Integration in Marketing Strategy

Cross-functional integration has long been recognized as important for organizational performance [15], particularly in roles that require cooperation among marketing, product development, and technical departments. [16] Describe interdepartmental integration as a combination of interaction-based coordination (e.g., frequent meetings and information exchange) and collaboration-based practices (e.g., shared goals and team cohesion). Research indicates that integrated cross-disciplinary teams can improve innovation, decision quality, and responsiveness in dynamic environments [17] and mitigate the dual challenges of data fragmentation and security vulnerabilities within cross-departmental workflows [18]. As marketing increasingly relies on data infrastructure, Management Information Systems (MIS) have become essential for supporting analytics, automation, and targeting. [19] Highlight the growing interdependence between marketing and IT departments as marketing shifts toward data-driven practices. AI adoption amplifies this need for coordination. [20] emphasizes that implementing AI systems requires addressing not only technical challenges but also organizational dynamics, with collaboration among marketing, data, and technology teams as a critical success factor. [21] notes that GenAI platforms, particularly large language models, can serve as a semantic layer that links data, knowledge, and human expertise, potentially strengthening cross-departmental alignment. These insights lead to a key research question: Does increased use of GenAI contribute to stronger integration between marketing teams and other departments involved in the strategic marketing process? Across the literature, GenAI emerges as a transformative force in digital marketing. Prior studies highlight its role in enhancing content relevance, strengthening audience segmentation, supporting real-time decision-making, and enabling highly personalized marketing materials. Evidence also suggests potential, but not guaranteed, benefits from cross-departmental collaboration. Despite these insights, an important gap remains: The extent to which GenAI actually changes marketing strategy in practice. While many studies describe potential capabilities, fewer examine how marketers currently use GenAI, which stages of the campaign process benefit most, and how GenAI affects strategic decisions and organizational workflows. The present study seeks to address this gap by evaluating how GenAI influences content creation, decision-making, and collaboration in real-world marketing contexts.

5. Research Questions and Hypotheses

Drawing on the literature, this study examines how Generative AI (GenAI) influences core components of marketing strategy. Prior research suggests that GenAI may enhance campaign relevance, improve early-stage analytical tasks such as segmentation, support decision-making through content personalization, and potentially enhance collaboration across organizational units. However, the extent of these effects in practical marketing settings remains insufficiently understood.

To address these gaps, the study is guided by the following refined research questions:

RQ1. Campaign Relevance

To what extent can leading GenAI platforms generate marketing campaign content that aligns with the informational needs, preferences, and expectations of a defined target audience?

RQ2. Impact Across Campaign Activities

How does the use of GenAI in diverse campaign activities, such as audience segmentation, customer data analysis, content development, or message distribution, affect customer experience?

RQ3. Personalization and Decision-Making

To what extent do marketing professionals rely on GenAI to adapt and refine campaign content during strategic decision-making, particularly in tailoring messages to specific audience segments?

RQ4. Cross-Departmental Integration

To what extent is the use of GenAI associated with the level of coordination and information-sharing between marketing teams and other organizational units involved in the strategic marketing process (e.g., IT, analytics, product functions)?

Based on existing theoretical and empirical evidence, the following hypotheses are proposed:

H1. Campaign Relevance:

All leading GenAI platforms (e.g., ChatGPT, Claude, Gemini, Copilot) will be able to generate campaign content perceived as relevant to the target audience.

H2. Utilization of GenAI for various Campaign activities:

The diverse use of GenAI across campaign activities will positively affect the customer experience.

H3. Content Relevance:

Higher levels of GenAI usage by marketers will be positively associated with greater perceived effectiveness in tailoring campaign content to target audiences during decision-making.

H4. Cross-Departmental Integration:

Higher levels of GenAI usage will be positively associated with greater perceived integration between marketing and other departments involved in strategic processes.

Figure 1 illustrates the conceptual model of these hypotheses:

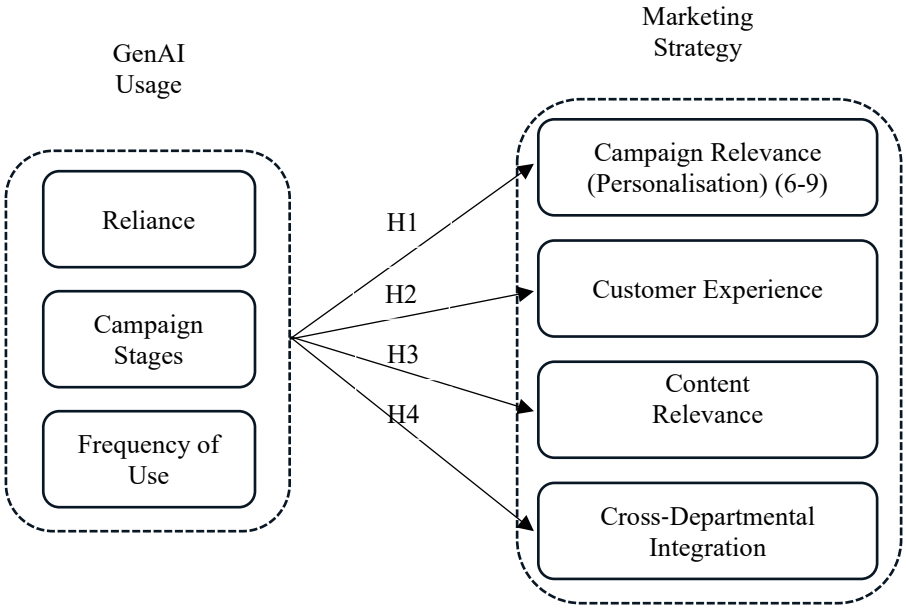

Figure 1. Conceptual model of study

III. METHODOLOGY

This study employed a correlational research design integrating two complementary methods: a survey of marketing professionals and a benchmark analysis comparing leading Generative AI (GenAI) tools. This mixed-data-source design allowed the examination of the relationships described in the research questions using two distinct quantitative sources.

1. Survey Method

The survey served as the primary data collection tool. It was chosen for its ability to gather quantifiable insights from a relevant population of marketing professionals regarding their use of GenAI and their perceptions of its influence on marketing strategy. All items were adapted from established literature on AI and marketing, ensuring conceptual validity and alignment with prior empirical work. The instrument consisted mainly of closed-ended Likert-scale questions, allowing for consistent measurement and statistical analysis. The survey included: Demographic items (e.g., role, experience level) to ensure participant relevance; GenAI usage items assessing the frequency and breadth of tool use; and perception items addressing campaign relevance, customer experience, content relevance, and interdepartmental collaboration. To ensure a common understanding of key concepts, the survey included a concise definition of GenAI at the beginning of the questionnaire. Items from source articles that were irrelevant to the present research context were intentionally excluded.

Sampling and Participants: A non-probability sampling strategy combining convenience and purposive sampling was used to reach marketing professionals with demonstrable exposure to GenAI. The survey was disseminated via professional digital communities on LinkedIn and Facebook, as well as through personal networks. Respondents were screened to confirm relevant experience.

The final sample comprised 103 marketing practitioners. Respondents were generally young, had moderate marketing experience, and most held marketing or sales positions. Importantly, all respondents reported using GenAI tools, and usage levels were relatively high. The survey questions are provided in Appendix A. Table 1 lists the variables and the number of items for each.

Table 1. Questionnaire items according to constructs

Variable	# of Statements
Reliance on GenAI	4
Campaign Stages	4
Frequency of Use	5
Campaign Relevance	4
Customer Experience	2
Content Relevancy	3
Cross-Departmental Integration	2
Total	24

Data Collection: Data were collected via Google Forms and distributed through professional messaging groups and social media channels. Participation was voluntary and anonymous, and respondents were informed that the data would be used solely for academic purposes.

Data Analysis: Given the ordinal nature of the Likert-scale items and the non-parametric approach, the primary statistical procedure was Spearman's rank-order correlation, used to examine associations between GenAI platform or usage level, and (a) campaign relevance, (b) customer experience, (c) content relevance, and (d) Cross-departmental integration.

Evaluation Metrics

Reliance on GenAI - The Reliance on GenAI was measured using a 5-level scale based on [8], an item from the information-seeking variable, replicated for each AI tool.

Campaign Stages - The extent of AI use across the campaign stages was measured on a 5-point scale, and the stages align with [22].

Frequency of Use - Frequency of use was measured on a 5-level scale, based on [23], and replicated for each AI tool.

Campaign Relevance - The campaign relevance was measured on a 5-point scale using the [8] questionnaire.

Customer Experience - The customer experience was measured on a 5-level scale based on the 8 customer experience variables.

Content Relevance - Content relevance was measured on a 5-level scale based on [24] Content Generation and Personalization variable.

Cross-Departmental Integration - The cross-departmental integration was measured using a 5-level scale based on [25], items 2 and 6.

2. Benchmark Method

The benchmark analysis complemented the survey by providing an objective comparison of GenAI platforms. Whereas the survey captures marketers' perceptions, the benchmark evaluates actual system performance in a

controlled task, aligned with Research Question 1, which focuses on the extent to which leading GenAI platforms generate relevant marketing campaigns. The benchmark addresses [8] work and consists of three main metrics: Personalisation, comprised of alignment with audience preferences, identification of explicit and implicit needs, appropriateness of spokesperson or influencer, and fit between channel choice and content style, Content Optimisation, comprised of creativity and emotional resonance, quality and clarity of messaging, and preference-based content refinement, and Purchase Intent Uplift, comprised of persuasiveness, confidence-building in decision-making, and likelihood of moving audiences toward conversion. The sub-components' metrics scores were aggregated to provide comparative performance indicators for each platform. Each metric contained multiple sub-components scored using a weighted rating system. Scores were then aggregated to provide comparative performance indicators for each platform.

Benchmark Setup: The benchmark experiment evaluated the performance of four prominent GenAI platforms (ChatGPT, Claude, Gemini, and Copilot) [26]. Each platform received an identical prompt to develop a digital campaign strategy and sample creative content for a new Coca-Cola digital initiative targeting a specified audience segment. To ensure methodological objectivity and eliminate human evaluator bias, the scoring procedure followed an automated multi-agent peer-evaluation framework modeled after [26]. After generating the respective campaign assets, the outputs from all four platforms were fed back into each platform. Using an identical evaluation prompt based on explicit scoring rubrics adapted from [8], each GenAI tool served as an autonomous evaluator, grading its own performance and the performance of the other three systems on a 1–5 scale. The final scores were assigned based on the metrics: Personalization, Content Optimization, and Purchase Intent Uplift. Each main metric comprised several sub-metrics, and scores were aggregated for each platform accordingly.

The research team rigorously verified the consistency of evaluations and the absence of systemic bias. A detailed cross-examination of the individual sub-metric scoring matrices was conducted to audit model reliability. The data confirmed stable evaluative behavior across the systems, with no single platform exhibiting anomalous grading patterns or competitive bias, such as systematically underrating rival models. By integrating both survey-based and benchmark-based methods, the study captures: Perceptions of GenAI's impact from active marketing professionals, and objective evidence of GenAI performance across platforms. This dual approach strengthens the study's ability to answer the research questions and provides a richer understanding of GenAI's role in marketing strategy. The survey questions are provided in Appendix B.

IV. RESULTS

1. Survey Results

Demographic Findings of Survey Participants

Age Distribution: The survey participants were divided into four age ranges. The majority of participants fell within the 20-30 age range (approximately 43%), with a significant portion also in the 31-40 range (approximately 28%). The 41-50 age range accounted for about 18% of participants, while the 51+ age range was represented by a smaller group (approximately 11%), as described below (See Table 2).

Table 2. Age distribution.

Age	N	%
20-30 years	44	42.7%
31-40 years	29	28.2%
41-50 years	19	18.4%

Above 51 years	11	10.7%

Years of Experience Distribution: Participants were grouped by years of experience in the field. The largest group consisted of individuals with 0-5 years of experience (approximately 38%), followed by a significant portion with 11-20 years of experience (approximately 29%). Respondents with 6-10 years of experience accounted for approximately 23% of the sample, while the smallest group was those with over 20 years of experience (approximately 10%), as described below (See Table 3).

Table 3. Experience distribution.

Experience	N	%
0-5 years	39	37.9%
6-10 years	24	23.3%
11-20 years	30	29.1%
Above 21 years	10	9.7%

Role Distribution: Participants were categorized into six distinct organizational roles. The majority of respondents held the position of Marketing Manager (approximately 41%), with a substantial portion employed in marketing (approximately 66%) and Sales (approximately 20%). Senior marketing professionals comprised about 16% of the sample, followed by Customer Relationship Managers (approximately 13%) and Market Researchers (approximately 10%). A smaller subset was represented in the Sales Manager role (approximately 1%) as described below (See Table 4).

Table 4. Positions' distribution.

Role	N	%
Customer Relationship Management	13	12.6%
Market Researcher	10	9.7%
Marketing Manager	42	40.8%
Sales	21	20.4^
Sales Manager	1	1.0%
Senior Marketing Professional	16	15.5%

Table 5 displays the model's item scores.

Table 5. Descriptive Statistics for Model Variables

		Items	M	STD
Reliance on	RG1 (Q10.1)	I rely on Claude to obtain relevant information concerning the target audience	3.37	0.12

	RG2 (Q10.2)	I rely on ChatGPT to obtain relevant information concerning the target audience	3.98	0.09
	RG3 (Q10.3)	I rely on Gemini to obtain relevant information concerning the target audience	3.71	0.09
	RG4 (Q10.4)	I rely on CoPilot to obtain relevant information concerning the target audience	3.21	0.11
Campaign Stages	CS1 (Q11.1)	To what extent do you use GenAI to target Audience Segmentation	3.51	0.10
	CS2 (Q11.2)	To what extent do you use GenAI for marketing content creation	4.17	0.09
	CS3 (Q11.3)	To what extent do you use GenAI for publishing and distributing on channels	3.04	0.11
	CS4 (Q11.4)	To what extent do you use GenAI for measuring performance	3.56	0.10
Frequency of Use	FU1 (Q5.1)	How often do you use ChatGPT	4.12	0.73
	FU2 (Q5.2)	How often do you use Claude	3.18	1.36
	FU3 (Q5.3)	How often do you, Gemini	3.45	1.21
	FU4 (Q5.4)	How often do you, CoPilot	2.90	1.25
	FU5 (Q5.5)	How often do you	2.63	1.16
Campaign Relevance	CaR1 (Q6)	Advertisements tailored by AI are very aligned with what I like	4.22	0.06
	CaR2 (Q7)	Using AI personalization simplifies the process of uncovering the items I am looking for	4.03	0.07
	CaR3 (Q8)	With AI, I can discover more accurate and meaningful information about products	4.12	0.08
	CaR4 (Q9)	AI improves my engagement with brands and makes it easy for me	3.17	0.13
Customer Experience	CE1 (Q12)	AI improves my overall interaction with brands	3.52	0.11
	CE2 (Q13)	I experience increased happiness with firms that utilize AI to enrich my experience	3.97	0.09
Content Rele	CoR1 (Q14)	Personalization of content has improved with the use of Generative AI	4.15	0.08

	CoR2 (Q15)	Generative AI helps in understanding audience preferences better for content creation	4.04	0.08
	CoR3 (Q16)	Generative AI enables us to create more relevant and personalized content	4.16	0.08
Cross-Departmental Integration	DI1 (Q17)	I communicate freely with faculty of other departments regardless of age and position	4.49	0.08
	DI2 (Q18)	I have informal contacts with other departments	4.50	0.09

2. RQ1: GenAI Platform and Campaign Relevance

Participants were asked to rate the statement "I rely on GenAI tools to obtain relevant information concerning the target audience" on a 5-point Likert scale. We examined the relationship between the GenAI platform respondents rated highest and their perceptions of the relevance of GenAI-generated campaign content to the target audience. Campaign relevance was measured using a composite score based on four items assessing personalization, preference alignment, content accuracy, and audience engagement [8].

A Spearman's rank-order correlation indicated a weak but statistically significant positive relationship between the preferred GenAI platform and perceived campaign relevance ($r = 0.35$, $p < .001$, $N = 103$), as presented in Table 6 below.

Table 6. Correlations between GenAI usage and selected outcomes (Survey data analysis)

Relationship (Variables)	Spearman's ρ	*p*-value	Interpretation
GenAI Platform vs Campaign Relevance (RQ1)	0.35	$p < .001$***	Weak-to-moderate positive correlation
GenAI Usage vs Content Relevance (RQ3)	0.32	$p = .001$**	Weak-to-moderate positive correlation
GenAI Usage vs Cross-Dept. Integration (RQ4)	0.42	$p < .001$***	Moderate positive correlation

***:p-value<0.01*

****:p-value<0.001*

Note: N = 103 for all correlations. "GenAI Usage" refers to the self-reported extent of using GenAI tools in marketing work.

The findings for RQ1 imply that marketers generally find GenAI useful for creating relevant campaigns, and align with previous literature, e.g., [6]. The Weak-to-moderate strength of correlation suggests that while GenAI use is broadly beneficial, other factors (such as the marketer's strategy or execution) may also affect campaign relevance. Additionally, this result motivated a deeper examination (through the benchmark study) of how specific platforms (ChatGPT, Claude, Gemini, Copilot) might differ in contributing to campaign relevance.

3. RQ2: AI Impact Across Campaign Stages

RQ2 addressed the effect of diverse GenAI use on customer experience. To address this, the survey asked respondents to rate the extent of GenAI's impact at several campaign stages (audience segmentation, content

creation, distribution, and performance measurement). First, we analyzed the correlation between aggregated GenAI use across all marketing activities and user experience, and then performed separate analyses for each of the four marketing activities using Spearman's rank correlation. The effect of the aggregated activities was found to be positive, r = 0.51, p < .001, N = 103, and so does each of the effects of the various activities (See Table 7)

Table 7. Relationship between GenAI usage and impact at different campaign stages *(Spearman correlations, N = 103)*

Campaign Stage	Spearman r	*p*-value	Interpretation
The four campaign stages	0.51	$p < .001$***	Moderate positive correlation
Audience Segmentation	0.42	$p < .001$***	Moderate positive correlation
Content Creation	0.29	$p < .01$**	Weak positive correlation
Content Distribution	0.41	$p < .001$***	Moderate positive correlation
Performance Measurement	0.39	$p < .001$***	Weak-to-moderate positive correlation

***:p-value<0.01*

****:p-value<0.001*

As shown**,** all activities exhibit a positive correlation between GenAI usage and perceived impact, with all correlations statistically significant and differing in strength. Of the four campaign stages, the strongest observed relationship was for Audience Segmentation ($r = 0.42$, $p < .001$), indicating that higher use of GenAI is fairly strongly associated with greater improvements in segmentation tasks.

These findings support Hypothesis 2, which posited that GenAI use across diverse campaign activities would affect customer experience, and also reveal that GenAI use in separate campaign activities would do so as well.

Delving into the details, survey respondents indicated that GenAI is most commonly used in the content creation stage of campaigns, which is unsurprising given tools like ChatGPT's ability to generate copy or creative ideas. However, the statistical analysis reveals that the greatest benefit of GenAI occurs at the segmentation stage.

Overall, the results for RQ2 indicate that GenAI positively influences all examined activities in a marketing campaign, particularly in audience segmentation and customer experience. This aligns with studies such as [12], which highlight AI's value in advanced segmentation and suggest that organizations could benefit from employing GenAI tools more extensively beyond content generation, including in the planning and analysis phases.

4. RQ3: GenAI Usage for Content Adaptation and Decision-Making

RQ3 focused on how extensively marketers use GenAI to tailor campaign content to the target audience during campaign decision-making. To measure this, the survey included an index of GenAI usage intensity (combining the frequency of GenAI tool use and the number of GenAI platforms used) and an index of content adaptation effectiveness (combining ratings of GenAI's contribution to creating relevant, personalized campaign content and to improving decision quality). A Spearman correlation was computed between GenAI usage intensity and content adaptation effectiveness. The analysis yielded a significant positive correlation (r = 0.32, N = 103, p = .001), indicating that greater GenAI use is associated with better tailoring of campaign content to audiences and improved campaign decision-making. This statistically significant relationship leads us to reject the null hypothesis and supports Hypothesis 3.

In practice, this finding means that marketers who more frequently or more broadly employ GenAI tools tend to report greater success in customizing content for their target audiences and feel that GenAI aids their campaign-related decision-making. These findings are consistent with prior work [27] showing that GenAI enables superior content selection, targeting, and dynamic optimization, as well as with studies confirming that AI-personalization boosts relevance and ad performance [14].

Usage levels were high (M = 4.32, between "often" and "always") and showed little variance, signaling broad adoption. Perceived effectiveness for personalized content was likewise high (M = 4.11 on a 5-point scale). Notably, despite this uniform uptake, a positive correlation suggests that heavier users, those leveraging multiple GenAI tools, derive incremental benefits in content relevance and decision speed. Taken together, these results confirm that GenAI is now deeply embedded in routine marketing work, and that deeper engagement corresponds to stronger personalization capabilities and more agile decision-making.RQ4: GenAI Usage and Cross-Departmental Integration

5. RQ4: GenAI Usage for Cross-Department Integration

RQ4 examined whether greater use of GenAI tools in marketing is associated with higher levels of integration between marketing teams and other departments (such as IT or data science) within the strategic marketing process. To explore this, respondents rated their organization's level of interdepartmental integration (via two items on open communication and collaboration with other departments). These items were correlated with the GenAI usage intensity index described above. The result was a positive and significant ($p < .001$, $N = 103$, $r = .42$) relationship between GenAI usage and cross-department integration, indicating that the more marketers use GenAI, the better they integrate with other departments. Thus, Hypothesis 4, which posited a positive link between GenAI use and interdepartmental integration, was supported by the survey data.

Interestingly, respondents generally reported a high level of cross-department integration in their organizations (mean ~4.49 on a 5-point scale, close to "to a very great extent"), with relatively low variability (SD ~0.08). Many marketers reported strong communication and cooperation with other departments (e.g., IT and data analytics).

This finding aligns with the literature, as [21] suggests that GenAI platforms serve as a semantic layer linking data, knowledge, and people, thereby theoretically requiring greater cross-functional synchronization.

In summary, the survey results for RQ4 indicate a significant relationship between GenAI usage and the integration of GenAI into marketing processes.

Finally, to synthesize the survey findings: the participant profile and responses suggest marketers today are a relatively young cohort with moderate experience, almost all of whom use GenAI frequently in their work. They view GenAI as a significant tool that helps create more relevant campaigns, especially in personalization, information accuracy, and content generation, and that its use in campaign activities positively affects the customer experience. GenAI is also seen as having a positive impact on content adaptation and decision-making, as well as on collaboration with other departments.

V. BENCHMARK RESULTS

This section presents the key findings from the benchmark experiment, which compared the performance of four prominent GenAI platforms (ChatGPT, Claude, Gemini, Copilot) in generating a marketing campaign for a global brand (Coca-Cola). The benchmark aimed to address a focused RQ1 from a different angle: by objectively evaluating how well each GenAI tool produces relevant and effective marketing content for the target audience.

Personalization Metric – Results: for the overall personalization score—which combines all sub-metrics related to tailoring content to the audience—Claude and Gemini achieved the highest scores, indicating excellent performance. Claude posted the top weighted score of 1.54, narrowly edging out Gemini's 1.52 on the personalization index. In contrast, ChatGPT recorded the lowest overall score at 1.21, reflecting comparatively weaker personalization, while Copilot fell between these extremes.

At the sub-metric level, Gemini led in the analysis of hidden and explicit needs with a score of 0.37, whereas ChatGPT lagged at 0.29. Gemini also topped the influencer/persona selection sub-metric with a score of 0.35, while ChatGPT ranked lowest at 0.29. For alignment of channel and content style, Gemini and Claude tied for the best performance (each scoring 0.42), with ChatGPT trailing at 0.33. Similarly, for matching content to audience preferences, Gemini and Claude again tied at 0.40, compared to ChatGPT's 0.29.

These results illustrate that Gemini and Claude consistently outperformed ChatGPT on personalization-related measures. Gemini showed strength in deeply understanding customer needs and choosing appropriate content spokespeople and channels, whereas Claude was equally strong in ensuring content style alignment and preference matching. ChatGPT, on the other hand, tended to produce more generic content that was less finely tuned to the specifics of the target segment, particularly for a well-known brand like Coca-Cola. Copilot often performed comparably to Gemini and Claude on certain sub-metrics (for instance, Copilot tied with them on at least one sub-metric, scoring 0.42 in "relevance and personal utility" of content).

Content Optimization Metric – Results: In the content optimization metric (evaluating creativity, emotional resonance, and content quality), Claude ranked first. Claude achieved the highest weighted score of 1.44 in content optimization. ChatGPT again was the lowest, with a score of 1.06 on this metric. Notably, ChatGPT not only had the lowest composite score here but also the lowest scores on nearly all the sub-metrics under content optimization: for example, in the sub-metric of *"increasing interest and excitement with the content*, " ChatGPT led with a score of 0.53, indicating it was best at producing content that could emotionally engage the audience. In *preference-based content optimization*, Gemini and Claude tied with high scores (0.5 each), whereas ChatGPT scored only 0.31 – a substantial gap.

These comparisons indicate that Claude is particularly strong at generating creative content that resonates emotionally and at optimizing content based on audience preferences. Gemini was a close competitor in many of these aspects as well, showing strength in data-driven content adjustments. ChatGPT's content tended to be more generic and less optimized for specific emotional triggers or preferences, which is why it scored poorly on these nuanced measures. Copilot's performance was mixed; in some respects, it matched the top tools (for instance, Copilot tied with Gemini and Claude on the "personal relevance and utility" sub-metric at 0.42 and was close behind in other sub-metrics).

Purchase Intent Uplift Metric – Results: Gemini and Claude were the leaders for the purchase intent uplift metric. Gemini achieved a slightly higher score (1.33) compared to Claude (1.19) on the overall purchase intent index, with Copilot close behind (1.14). ChatGPT was again lower than the others on sub-metrics related to purchase intent: on *the persuasiveness of advertisements, Gemini and Claude tied for the top score* of 0.44. On *boosting confidence in purchase decisions*, Gemini was highest at 0.47, with Claude and Copilot next (0.39 each). On *leading exposure to purchase*, Gemini led with 0.42, followed by Claude at 0.36, whereas ChatGPT was lowest at 0.28 on this sub-metric.

These results suggest Gemini has a slight edge in driving purchase-related outcomes, possibly due to its strength in data analysis and understanding consumer decision factors (as evidenced by its superior performance in needs analysis and confidence boosting). Claude is not far behind, however, and actually surpasses Gemini in other areas (such as *creative content generation*). Copilot showed itself to be a solid performer in supporting purchase intent, close to Gemini and Claude, which may reflect its design as an assistive model for tasks.

Key Benchmark Findings: An analysis of the overall performance rankings reveals a clear quality gap among the GenAI platforms: Gemini achieved the highest aggregate performance score across all metrics (total score ≈ 4.27 out of a possible range), making it the top all-around performer in our benchmark. Gemini particularly

excelled in tasks related to purchase intent and deep personalization. It was the most effective tool for understanding consumer data and translating that understanding into stronger purchase intent. Specifically, Gemini outperformed Claude on sub-metrics such as boosting purchase decision confidence and providing targeted exposure that drives conversion, underscoring Gemini's strength as *"the most data-precise tool"* in the test. Claude was a close competitor, outperforming Gemini on the content optimization metric (Claude's 1.44 vs Gemini's 1.42) and the overall personalization metric (Claude's 1.54 vs Gemini's 1.52). Claude also scored highest in generating emotionally engaging content (e.g., *raising content interest/excitement*). These outcomes indicate that Claude is the best tool for producing creative, emotionally resonant marketing content, even though Gemini might have a slight edge in data-driven precision. One specific insight is that Claude's content tends to evoke emotion effectively, a crucial aspect of marketing content, meaning Claude can make marketing messages more compelling on a human level. In contrast, Gemini might be more pinpoint in targeting. ChatGPT consistently received the lowest scores across most metrics and sub-metrics. This suggests a performance gap, in which ChatGPT's output was more generic and less finely attuned to the specific marketing context we tested. ChatGPT appeared to struggle, especially with preference-based optimization (score 0.31 vs 0.5 for Gemini/Claude) and other personalization subtleties, suggesting it may lack advanced domain fine-tuning or the latest model capabilities that the other tools have. It tended to produce "one-size-fits-all" content for a large brand like Coca-Cola, whereas the newer models (Gemini, Claude) dug deeper into nuance. This highlights the "digital gap" with ChatGPT in this scenario: it may be a powerful general-purpose tool, but for sophisticated marketing tasks, it lags behind specialized or newer GenAI models. Copilot performed respectably, often ranking in the middle. It tied with the leaders on some personalization sub-metrics and was only slightly behind on purchase-intent measures. Copilot did not clearly lead any single category, but it proved to be a well-rounded tool.

In summary, the benchmark findings show that marketing effectiveness in the GenAI era depends on choosing the right tool for the specific task at hand. Gemini stands out for data-centric tasks and driving conversions. At the same time, Claude excels at creating engaging content and fostering emotional engagement. At the same time, ChatGPT may not be the optimal choice when high levels of personalization or fine-tuned optimization are required for a campaign.

VI. DISCUSSION

The overarching goal of this study was to examine how marketing strategies adapt to Generative AI (GenAI). Converging survey and benchmark data indicate that GenAI drives significant structural changes across marketing strategy.

Regarding campaign relevance to the target audience, both methodologies confirm that GenAI enhances campaign effectiveness. While the survey demonstrates a baseline positive correlation across platforms, the benchmark adds nuance by showing that specific platform architecture matters. While any GenAI can improve personalization, corroborating research by [6] on AI-driven personalized customer journeys, our results stress that matching the specific platform to the audience profile is vital for optimal message-audience fit.

For the campaign process stages, we hypothesized that GenAI's most profound impact would occur during audience segmentation. The survey partially supported this assumption: GenAI usage correlated most strongly with advanced audience segmentation, yet it showed lower relative impact in content creation, where it is paradoxically most frequently deployed. This confirms that GenAI's analytical capabilities shine brightest in upstream strategic phases, as outlined in earlier theoretical frameworks by [10]. The gap between content generation execution and segmentation impact reveals a critical strategic underutilization.

In terms of content personalization and decision support, extensive GenAI integration yields superior alignment with the content audience and accelerated, data-informed decisions. This supports the findings of [27] and [8], who noted that GenAI fundamentally reshapes how content is delivered. The moderate correlation ($\rho = 0.32$)

confirms that while GenAI is a powerful computational aid that makes marketing iterative and agile, human expertise and creative oversight remain foundational.

Furthermore, survey results confirmed a positive correlation between GenAI adoption and cross-functional integration across marketing, IT, and data analytics departments. Because modern digital marketing relies on Management Information Systems as an organizational backbone (as [19] emphasized), GenAI functions as a connective semantic layer, in line with the findings of [21]. However, our data suggest that the depth of this integration is ultimately bound to organizational culture and leadership structure, mirroring observations in [17].

Combining empirical approaches reveals two key strategic insights regarding methodological integration. First, the survey indicates a general benefit of GenAI adoption, but the benchmark shows that performance variance between models is non-trivial. Marketers must deploy platforms based on discrete task strengths, such as leveraging Claude for emotional resonance and Gemini for structured data analysis. Second, a clear execution-strategy gap emerged. Marketers heavily favor GenAI for downstream content execution, yet capabilities benchmarked for decoding consumer needs are associated with higher purchase intent. Marketing strategy must evolve to embed GenAI into front-end strategy formulation rather than treating it merely as a high-speed copywriter.

The findings carry several implications for theory. This study enriches the literature on emerging technology adoption by identifying an empirical gap between utilization frequency and latent strategic potential. While current frameworks assume linear adoption paths, our findings suggest that organizations gravitate toward high-visibility, low-complexity tasks such as content generation, while underutilizing high-impact analytical capabilities, such as segmentation. This underscores the need for new theoretical models to explain how organizational learning-curve dynamics shift as functional familiarity with AI matures.

Practically, the study offers data-driven insights for marketing managers. Marketing managers should shift GenAI from simple tactical execution to predictive modeling, customer clustering, and strategic scenario testing. Additionally, organizations must move away from a one-size-fits-all software procurement model. Teams should build a diversified portfolio of GenAI assets, choosing specific large language models based on empirical campaign objectives. Finally, rather than training staff purely on prompt engineering for text or image generation, training frameworks should focus on data synthesis and strategic interpretation using AI-driven analytical tools.

This study provides a critical empirical baseline for the Israeli ecosystem. The data demonstrates that local marketing professionals are successfully keeping pace with international AI integration benchmarks established between 2023 and 2025. In conclusion, GenAI is a transformative yet unevenly leveraged force in marketing strategy. Maximizing its value requires organizations to actively broaden their deployment parameters, moving past routine execution to reshape the foundational layers of strategic marketing management.

VII. CONCLUSION

1. Summary of Findings

This research reveals that while GenAI significantly enhances marketing strategies, its effectiveness varies considerably across functional dimensions. Although GenAI demonstrably improves campaign relevance and content personalization, the quality of the outcomes is heavily contingent on the specific tool selected. A notable discrepancy emerged between current usage patterns and true potential: while practitioners predominantly apply GenAI to content creation, its most substantial impact was found in the strategic stage of audience segmentation. Furthermore, the results confirm a positive relationship between GenAI usage and decision-making efficacy.

2. Research Statement

These findings collectively underscore that realizing strategic value from GenAI demands more than mere adoption—it requires targeted, intentional implementation. Marketers should deliberately align platform selection with specific campaign objectives to maximize audience relevance. They should expand GenAI deployment beyond content generation into higher-impact strategic functions such as segmentation and real-time data analysis, where it can significantly enhance agility and precision. Critically, organizations must recognize GenAI as a facilitator rather than a cure for structural fragmentation; its cross-functional benefits depend on pre-existing collaborative cultures and robust human processes. Ultimately, GenAI's full potential is unlocked only when it is deeply integrated into decision workflows and supported by an organizational environment that values both technological and interpersonal coordination.

3. Limitations and Future Research Directions

This study has several limitations that open avenues for future inquiry. First, the sample comprised approximately 100 marketing professionals, primarily based in Israel, and the measures relied on subjective self-reports rather than objective performance data. However, we attempted to mitigate this by including a benchmark experiment. Future research should expand to larger, more diverse international samples across industries and countries, and complement perceptual data with objective metrics, such as A/B test results comparing AI-generated versus non-AI content or longitudinal KPI trends following GenAI adoption.

Second, the rapidly evolving nature of GenAI presents a temporal limitation, as our benchmarks reflect tool capabilities at a single point in time; subsequent model updates or new market entrants could shift the competitive rankings we observed. Researchers should periodically re-evaluate platform performance as updates are released, and practitioners must remain agile in reassessing which tools best suit their strategic needs.

Additionally, extending benchmarks to encompass a wider array of GenAI platforms, marketing tasks, and brand contexts. including B2B scenarios and diverse industries. would test the generalizability of our findings. Controlled field experiments that isolate GenAI's specific effects relative to traditional campaigns are also warranted. More broadly, as GenAI becomes further embedded in marketing practice, ongoing inquiry must address emerging challenges surrounding ethics, the evolving role of human creativity, and the new skill sets marketers will require. Our work provides a current snapshot to anchor these critical, evolving discussions.

ACKNOWLEDGEMENTS

The author gratefully acknowledges May Zehavi, Yuval Sidi, and Koreen Trif, whose original student seminar project provided the foundational research framework and data collection that inspired this paper. Although they were not involved in the drafting or finalization of this manuscript, their initial academic contributions were vital to the realization of this study.

DECLARATION OF AI USE

During the preparation of this work, the authors used OpenAI's ChatGPT to assist with translating the original Hebrew content into English and refining the manuscript's language. The AI tool was employed to ensure clarity and fluency in academic writing. All content was then reviewed and edited by the authors to verify accuracy and coherence with the research findings. Additionally, the benchmark that addressed the four GenAI tools: ChatGPT, Claude, Gemini, and Copilot, was executed by these tools, as described in the manuscript.

Abstract
The increasing interoperability of digital health systems creates cybersecurity challenges that extend across organizational and national boundaries. As healthcare organizations exchange data through interconnected infrastructures, incidents may rapidly evolve into multi-stakeholder events requiring coordinated response, communication, and decision-making. This work-in-progress paper presents the design of a reusable tabletop exercise toolkit to improve incident-response preparedness in cross-border digital health environments. Developed using a Design Science Research approach, the toolkit consists of a Facilitator Guide and a Participant Pack supporting a structured 60-90-minute exercise simulating a cybersecurity incident affecting digital health interoperability services. The exercise incorporates progressive scenario injects, role-based participation, an observer scorecard, and a structured hotwash process to support evaluation and organizational learning. The toolkit is designed to expose interoperability-related dependencies, strengthen stakeholder coordination, and support decision-making under uncertainty. Although formal validation has not yet been conducted, the proposed design demonstrates how scenario-based tabletop exercises can support cyber resilience in increasingly interconnected healthcare ecosystems. Future work will focus on pilot testing, usability evaluation, and assessment of preparedness improvements achieved through repeated exercises.

Keywords: cybersecurity, incident response, tabletop exercise, digital health interoperability, cyber resilience, healthcare cybersecurity, cross-border collaboration

I. INTRODUCTION

Digital health systems are becoming increasingly interconnected across organizational [1] and national boundaries [2]. As healthcare organizations exchange electronic health information through interoperable services, cybersecurity incidents may extend beyond a single organization and require coordinated response activities involving multiple stakeholders [3]. Effective incident response is therefore becoming an essential aspect of secure digital health operations [4]. Although healthcare organizations commonly utilize incident response plans, coordination across organizational and national boundaries remains challenging [5]. Traditional awareness activities and policy documents rarely provide opportunities to practice communication, decision-making, and evidence handling in realistic cross-border scenarios. As a result, weaknesses in operational preparedness may only become visible during an actual incident. This study was motivated by the need for a

practical preparedness tool that supports incident response exercises in interoperable healthcare environments. Interoperability is increasingly understood not merely as the technical exchange of data but as the combined capability of heterogeneous systems, organizations, and jurisdictions to exchange information, preserve its meaning, integrate it into operational workflows, and do so within agreed legal frameworks. Rather than developing another checklist or policy document, the paper focuses on creating a reusable tabletop exercise toolkit that enables organizations to rehearse realistic cybersecurity incidents in a structured and time-efficient manner. The objective is to provide a practical environment in which participants can explore not only technical response activities but also the organizational, communication, coordination, and accountability challenges that emerge when interoperability-dependent services are disrupted. The primary research question guiding this work is: How can a 60–90-minute tabletop exercise be structured to realistically practice cross-organizational roles, communication, decision-making, and evidence handling in cross-border digital health incident response? The working hypothesis is that a role-based and scenario-specific tabletop exercise toolkit can improve preparedness by making triage decisions, containment actions, communication processes, and evidence-handling responsibilities more visible and easier to evaluate. The objective of this work-in-progress paper is to design a reusable tabletop exercise toolkit to support cyber resilience in interoperable healthcare environments by facilitating observation and improvement of coordination, communication, and decision-making processes during cybersecurity incidents.

II. BACKGROUND AND RELATED WORK

Digital health interoperability enables healthcare organizations to exchange health information across organizational and national borders. The European Health Data Space (EHDS) seeks to establish a common framework for the secure exchange and use of electronic health data throughout the European Union. By promoting interoperability, patient mobility, and cross-border access to healthcare information, EHDS will significantly increase the interconnectedness of healthcare systems [6]. While these developments offer substantial benefits for healthcare delivery and continuity of care, they also increase the potential impact of cybersecurity incidents. A disruption affecting a single component of a cross-border ecosystem may have consequences for multiple organizations and jurisdictions. Consequently, cyber resilience and incident response preparedness are becoming critical enablers of successful EHDS implementation [3]. Cross-border digital health services create dependencies that extend beyond individual healthcare organizations [7]. Healthcare providers increasingly rely on identity and access management systems, interoperability gateways, national contact points (NCPs), centralized logging infrastructures, cloud services, vendors, and cross-organizational data flows [8]. Health data is highly sensitive, meaning that both service delivery and service disruption have significant privacy and regulatory implications. Interoperability within the European Union must be considered together with data protection requirements, governance structures, and the lawful handling of health information [9]. Consequently, incident response cannot be viewed solely as a technical recovery activity. The implementation of EHDS further increases the need for coordinated response capabilities. Healthcare providers, national authorities, system vendors, and infrastructure operators must cooperate to maintain service continuity, protect personal health information, and comply with legal requirements while responding to cybersecurity incidents [3]. A key observation underpinning this paper is that many operational dependencies remain hidden until organizations are required to respond to an incident under conditions of uncertainty. Based on the research materials, four dependency areas were identified as particularly significant: (1) Identity services [10], (2) Gateway or National Contact Point (NCP) operations [7], (3) Vendor and third-party access [11], and Cross-organizational data flows [12]. These dependencies act as practical decision bottlenecks that influence communication strategies, evidence collection, containment decisions, and service restoration activities. Tabletop exercises are widely used to support preparedness by enabling participants to discuss and evaluate their responses to realistic incident scenarios in a controlled environment [13]. However, existing exercises often focus on organizational or technical aspects of incident management rather than on the specific dependencies arising from cross-border digital health interoperability. The contribution of this work is therefore not a new theory of healthcare cybersecurity but a reusable training asset that transforms interoperability-related cybersecurity concerns into a

structured exercise format. By doing so, the paper seeks to move from general awareness of interoperability risks to practical rehearsal of incident-response behaviors in cross-border healthcare environments.

III. RESEARCH METHOD AND DESIGN APPROACH

This work was conducted using a Design Science Research (DSR) approach [14], in which the primary objective is to create and evaluate a practical artifact that addresses a real-world problem. In this study, the identified problem concerns the limited opportunities available for healthcare organizations to rehearse incident response activities in cross-border digital health environments characterized by interoperability dependencies, multiple stakeholders, and incomplete information. Rather than proposing a new theoretical model of healthcare cybersecurity, the paper focuses on developing a reusable tabletop exercise toolkit that enables realistic discussion and evaluation of cybersecurity incident response processes. The resulting artifact is intended to support preparedness, coordination, communication, and decision-making across organizational and national boundaries. The design process was guided by the assumption that cyber resilience in interoperable healthcare ecosystems depends not only on technical controls but also on organizations' ability to coordinate actions, manage dependencies, and make defensible decisions under uncertainty. Consequently, the toolkit was designed to expose operational dependencies and stimulate cross-functional discussion among technical, managerial, legal, privacy, and communication stakeholders. The motivation for this study emerged from the increasing interconnectedness of digital health services and the growing importance of cross-border healthcare information exchange. Initiatives such as the European Health Data Space (EHDS) are expected to further increase interoperability among healthcare organizations, national infrastructures, and service providers. While these developments create significant benefits for healthcare delivery, they also introduce complex cybersecurity dependencies that may span multiple organizations and jurisdictions. The dependencies that repeatedly influence incident response activities in digital health environments often remain invisible during normal operations but become critical during cybersecurity incidents. They affect evidence collection, communication, containment decisions, recovery actions, and accountability across organizational boundaries. The design challenge was therefore to create a practical exercise environment that could reproduce these coordination challenges within a limited time frame while remaining realistic and repeatable. The toolkit was developed according to four operational design principles derived from the identified problem domain and exercise objectives: (1) Rapid identification of incident ownership to ensure that responsibility and escalation paths become visible early in the exercise; (2) Visibility of interoperability-related dependencies to expose how identity services, gateway operations, suppliers, and data flows influence response activities; (3) Decision-making under uncertainty to reflect the reality that cybersecurity incidents often begin with incomplete or contradictory information. Participants are encouraged to state assumptions explicitly and justify their decisions despite uncertainty; and (4) Generation of actionable improvement outcomes so that observations made during the exercise can be converted into concrete corrective actions and organizational learning. These principles guided the structure of the exercise scenario, participant roles, evaluation mechanisms, and post-exercise activities. The artifact development resulted in a Facilitator Guide and a Participant Pack, which are described in detail in Section IV. The exercise was designed to be completed within 60–90 minutes and organized around a sequence of scenario injects that progressively increase decision pressure and organizational complexity. Each injection introduces new information that requires participants to reassess assumptions, coordinate stakeholders, and make operational decisions based on the information available at that moment. The development process also incorporated role-based participation. Six operational roles were defined to represent the principal stakeholder groups typically involved in cross-border cybersecurity incident response: (1) Incident Lead, (2) Technical Lead, (3) Gateway/NCP Owner, (4) Privacy Officer (DPO), (5) Communications Lead, and (6) Vendor Liaison. This structure was chosen to ensure that technical, legal, organizational, privacy, and supplier perspectives are represented throughout the exercise. A central objective of the toolkit is not merely to facilitate discussion but also to enable systematic observation of decision-making behaviors. For this reason, evaluation was built into the design. The exercise concludes with a structured hotwash process in which participants review the challenges encountered and identify opportunities for improvement. Required outputs include corrective actions, assigned

owners, implementation deadlines, and recommendations for future exercises or validation activities. By integrating scenario execution, observation, and structured reflection into a single process, the toolkit was designed to serve as both a preparedness assessment instrument and a mechanism for continuous organizational improvement.

IV. CROSS-BORDER INCIDENT RESPONSE TOOLKIT

The proposed artifact is a reusable tabletop exercise toolkit designed to support cybersecurity preparedness in interoperable digital health environments. The toolkit is intended to support discussion-based learning, structured decision-making, and the identification of operational dependencies that influence cross-border incident response. The architecture contains two complementary exercise components: a Facilitator Guide and a Participant Pack. Together, they provide a common scenario, predefined exercise injects, role descriptions, guidance material, and evaluation mechanisms. The design follows four operational principles: (1) Rapid identification of incident ownership; (2) Visibility of interoperability-related dependencies; (3) Decision-making under uncertainty; and (4) Generation of actionable organizational improvements following the exercise. Fig. 1 illustrates the overall architecture of the toolkit and its learning cycle. The toolkit consists of a Facilitator Guide and a Participant Pack that jointly support a scenario-driven exercise process. The Scenario Engine delivers three progressively escalating injects covering detection and triage, containment and cross-border coordination, and restoration and learning. The architecture is intended to transform interoperability-related cybersecurity concerns into a structured, repeatable, and time-efficient process that can be completed in 60–90 minutes. The 60-90-minute duration was selected to balance realism and organizational feasibility. Tabletop exercises are intended to provide a structured environment in which participants can discuss incident scenarios, evaluate response options, and improve coordination without the resource demands of full-scale operational exercises. A compact format enables participation from technical, managerial, legal, privacy, and communication stakeholders while still supporting scenario escalation, decision-making under uncertainty, and post-exercise reflection [13].

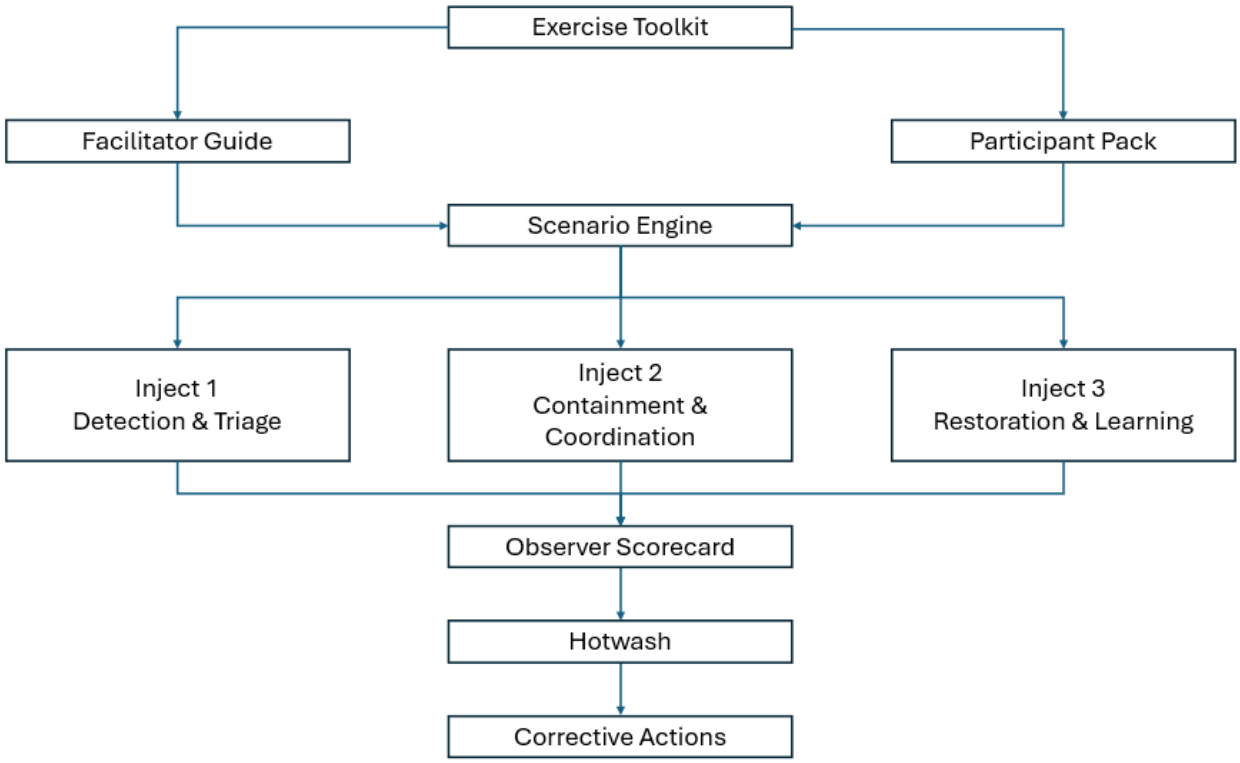

Figure 1. Overall architecture of the Cross-Border Incident Response Toolkit and its learning cycle

The exercise employs six recommended operational roles representing the primary stakeholders typically involved in cross-border digital health incident response. These roles ensure that technical, organizational, legal, and communication perspectives are represented during decision-making. The recommended roles are: (1) Incident Lead – responsible for overall coordination, prioritization, and escalation decisions. (2) Technical Lead – responsible for technical analysis, containment options, dependency assessment, and restoration planning. (3) Gateway/NCP Owner – responsible for interoperability services and cross-border exchange operations. (4) Privacy Officer / DPO – responsible for privacy impact assessment, notification obligations, and regulatory considerations. (5) Communications Lead – responsible for internal and external communications. (6) Vendor Liaison – responsible for interactions with suppliers, evidence requests, support access, and accountability discussions. The role structure was intentionally designed to expose the distributed nature of incident-response responsibilities within interconnected healthcare ecosystems. Rather than focusing solely on technical remediation, participants must coordinate decisions across operational, legal, clinical, and supplier domains. The Facilitator Guide provides exercise-control information, timing guidance, escalation prompts, expected outputs, evaluation criteria, and discussion questions for each stage of the exercise. Its purpose is to ensure consistency across repeated exercise sessions while maintaining realism and controlled progression of the scenario. The Participant Pack provides only the operational information necessary for decision-making. This information asymmetry preserves uncertainty and creates realistic pressure, similar to that of an actual cybersecurity incident. Participants are expected to make decisions without complete information and to identify assumptions and evidence gaps explicitly. Together, the two documents create a reusable training asset that supports both facilitated delivery and participant engagement. The scenario is organized as a progressive sequence of three injects that gradually increase operational complexity and decision pressure. Each inject is designed to emphasize a different phase of incident response while preserving continuity throughout the scenario. Inject 1 -

Detection and Triage: The exercise begins with unusual privileged login activity detected on integration servers at Hospital A, while clinicians at Hospital B report failures in cross-border patient summary requests. No confirmed evidence of data exfiltration is available at this stage. Participants must determine an initial severity assessment, identify immediate evidence requirements, and decide whether service operations continue normally or under restrictions. Inject 2 - Containment and Cross-Border Coordination: The second inject introduces failed gateway transactions, a suspicious supplier support session, and external media interest regarding possible exposure of patient information. Participants must evaluate containment thresholds, establish communication channels across organizations and countries, determine supplier engagement responsibilities, and balance operational continuity against privacy and security concerns. Inject 3 - Restoration and Learning: The final inject introduces forensic findings indicating access to integration logs and configuration data through a supplier account. Although no patient data exfiltration has been confirmed, service restoration is technically possible under enhanced controls. Participants must define restoration criteria, determine notification requirements, document residual risks, and identify corrective actions.

Table 1. Primary Focus Areas Of The Exercise Inject

Inject	Focus Area	Primary Challenge
Inject 1	Detection and Triage	Incident ownership and evidence preservation
Inject 2	Containment and Coordination	Cross-border communication and supplier involvement
Inject 3	Restoration and Recovery	Notifications, residual risk, and service restoration

The exercise is designed to evaluate participants' ability to make defensible decisions under uncertainty rather than to achieve technically perfect outcomes. These objectives directly reflect common operational challenges encountered in interoperable healthcare ecosystems where multiple organizations, jurisdictions, suppliers, and infrastructures participate in service delivery.

The assessment dimensions were derived from two sources: (1) recurring incident-response challenges identified in healthcare cybersecurity literature and (2) the design objectives of the proposed artifact. Prior research highlights the importance of clearly defined responsibilities, effective communication and coordination, timely decision-making, and evidence management during cyber incidents [4], [13], [15]. The proposed toolkit extends these considerations to cross-border digital health environments by explicitly incorporating interoperability dependencies and multi-stakeholder coordination requirements associated with EHDS-enabled health information exchange [3], [6]. The toolkit incorporates a lightweight evaluation mechanism consisting of an observer scorecard and a structured hotwash process. The scorecard focuses on observable behaviors rather than technical correctness. Five dimensions are assessed on a three-point scale ranging from 0 (missing) to 1 (partial) to 2 (clear, timely, and defensible).

The assessed dimensions are:

- Role clarity.
- Cross-border coordination and escalation.
- Containment decision quality under uncertainty.
- Evidence handling and logging priorities.
- Communications, privacy, and regulatory judgment.

Following the exercise, participants conduct a structured hotwash discussion designed to translate observations into concrete improvement actions. The hotwash identifies: (1) Decision bottlenecks, (2) Dependency-related uncertainties, (3) Communication shortcomings, (4) Evidence collection challenges, and (5) Opportunities for risk reduction. The required outputs include the top corrective actions, assigned owners, implementation target

dates, process improvements, technical improvements, and recommendations for subsequent exercises or validation activities. Consequently, the toolkit functions not only as a preparedness assessment instrument but also as a practical organizational improvement mechanism.

V. DESIGN RATIONALE AND ANTICIPATED OUTCOMES

1. Operational Dependency Areas Revealed by the Exercise

The development and scenario analysis process identified four dependency areas that consistently influence cross-border incident response activities in digital health environments: (1) Identity and access management services; (2) Gateway and National Contact Point (NCP) operations; (3) Vendor and third-party access; and (4) Cross-organizational data flows and information exchange mechanisms. These dependencies frequently act as operational bottlenecks during cybersecurity incidents. Although they often remain largely invisible during normal service operation, they become critical when organizations must make rapid decisions under conditions of uncertainty. The exercise repeatedly exposes situations in which participants must determine incident ownership, identify evidence sources, coordinate stakeholders, and balance operational continuity against security and privacy requirements. Based on the design analysis and literature review, these dependency areas are expected to influence incident scope estimation, accountability, evidence collection priorities, containment decisions, communication strategies, and service restoration planning. Consequently, one of the most significant outcomes of the toolkit design is its ability to make interoperability-related dependencies visible and discussable within a structured exercise environment.

2. Evaluation and Learning Benefits

The study resulted in a lightweight evaluation approach integrated into the exercise process. Rather than measuring technical accuracy, the observer scorecard focuses on observable behaviors associated with effective incident response, including role clarity, coordination, communication, evidence handling, and decision-making under uncertainty. The exercise design is intended to encourage participants to justify their decisions, document their assumptions, and communicate uncertainties rather than waiting for complete information. This reflects the realities of cybersecurity incident management, where critical decisions frequently must be made before definitive evidence is available. The separation between facilitator and participant materials is expected to support consistent exercise delivery while maintaining information asymmetry and realistic decision pressure. The three-inject scenario structure progressively increases operational complexity by moving participants from incident detection and triage to containment, cross-border coordination, restoration, and recovery activities. In particular, the inclusion of a supplier-related inject is intended to stimulate discussion regarding accountability, evidence ownership, access rights, and communication responsibilities, thereby highlighting the importance of third-party relationships in interoperable healthcare ecosystems. Consequently, the evaluation approach is expected to provide organizations with a practical mechanism to identify coordination challenges, communication gaps, and decision bottlenecks, while supporting preparedness assessment and organizational learning.

3. Continuous Improvement Potential

Although formal pilot validation has not yet been completed, the current results indicate that the toolkit provides practical value as a preparedness and organizational learning mechanism. The exercise concludes with a structured hotwash process that requires participants to identify corrective actions, assign responsible owners, and define target implementation dates. Typical outputs include: Corrective actions; Responsible owners; Target implementation dates; Process improvement proposals; Technical control enhancements; and Recommendations for future exercises or validation activities. By linking observations directly to improvement activities, the toolkit

extends beyond a discussion-based exercise and provides a practical foundation for continuous enhancement of cyber resilience capabilities. The approach, therefore, supports both preparedness assessment and organizational learning within increasingly interoperable digital health environments.

VI. DISCUSSION

1. Implications for Cross-Border Incident Preparedness

The development of the toolkit highlights a broader challenge facing interoperable healthcare ecosystems: incident response preparedness increasingly depends on coordination across organizational, technical, legal, and national boundaries rather than on the capabilities of individual organizations alone. As healthcare services become more interconnected through initiatives such as the European Health Data Space (EHDS), cybersecurity incidents are likely to involve multiple stakeholders with different responsibilities, priorities, and decision-making processes. From a practical perspective, the proposed toolkit provides a structured environment for examining how these stakeholders interact during a disruptive event. Instead of emphasizing technical problem-solving alone, the exercise encourages participants to consider governance, accountability, communication, privacy obligations, and operational continuity simultaneously. This reflects the multidimensional nature of incident response in contemporary digital health environments. A further implication is that preparedness should be viewed as an organizational capability rather than merely a technical capability. Effective response depends not only on detecting and mitigating cyber threats but also on maintaining shared situational awareness, coordinating decisions, and communicating effectively when information is incomplete or evolving.

2. Contribution of the Research

The primary contribution of this work is the creation of a reusable tabletop exercise artifact specifically designed for cross-border digital health incident response. Existing tabletop exercises frequently address general cybersecurity scenarios or organization-specific incidents, whereas the proposed toolkit explicitly incorporates interoperability dependencies, supplier interactions, and cross-border coordination requirements.

From a Design Science Research perspective, the study demonstrates how interoperability-related cybersecurity challenges can be translated into a practical artifact that supports preparedness activities. The contribution lies less in developing new cybersecurity theory and more in providing a structured mechanism that organizations can use to rehearse and evaluate incident-response practices within complex healthcare ecosystems.

3. Limitations and Future Research

Several limitations should be acknowledged. First, this study reports the design and initial development of the toolkit rather than validated operational outcomes. Its effectiveness has not yet been assessed through pilot exercises involving representative healthcare stakeholders, and the findings remain preliminary. Second, the current scenario represents only one class of cybersecurity incident. Although the scenario was selected to reflect realistic interoperability-related challenges, other relevant threats may require different exercise designs and evaluation criteria. Examples include ransomware incidents, insider threats, cloud service failures, and identity federation disruptions. Third, the observer scorecard was intentionally designed as a lightweight evaluation instrument. While simplicity supports practical adoption, additional research is needed to assess the reliability and repeatability of the evaluation approach across different organizational contexts. Future work should focus on empirically validating the toolkit through pilot exercises with healthcare providers, interoperability service operators, and other stakeholders involved in cross-border health information exchange. Such pilots would enable assessment of usability, realism, participant engagement, and perceived organizational value. A further area for investigation concerns longitudinal use of the toolkit. Repeated exercise cycles could be used to examine

whether structured tabletop exercises contribute to measurable improvements in coordination, communication, decision-making, and overall cyber resilience over time. In addition, future studies could explore integrating tabletop exercises with technical validation activities and broader cyber-resilience assessment frameworks.

VII. CONCLUSION

This work-in-progress paper presents the design and implementation status of a reusable tabletop exercise toolkit for cross-border digital health incident response. The current contribution is a practical foundation rather than a finished solution. It demonstrates that a scenario-specific tabletop toolkit can be created for cross-border digital health incident response and can structure discussion around the dependencies that matter most. Although formal validation remains future work, the current results indicate that the toolkit can support preparedness by making hidden dependencies visible and improving the structure of incident response discussions in interoperable healthcare environments.

ACKNOWLEDGEMENTS

The authors would like to thank the XiA project (funded by the European Union under Grant Agreement No. 101187650) for providing an inspiring and timely research topic, as well as for the valuable guidance and support throughout the research process. The constructive feedback helped shape the model's development and improve its practical relevance.

AI DECLARATION

Artificial intelligence tools, including Copilot, ChatGPT, and Claude, were used to support language editing, structure checking, and clarity improvements during the preparation of this paper. The authors made all ideas, analyses, conclusions, and final editorial decisions.

Abstract
The rapid growth of digital video platforms has heightened the need for scalable, consistent content rating mechanisms. Manual rating processes are often costly, time-consuming, and subjective, especially when video content includes complex visual, auditory, and textual cues. This paper presents an artificial intelligence-supported multimodal analysis approach for the automated classification of content rating symbols. The proposed system analyzes video content across multiple modalities and produces multi-label decisions on violence, horror, sexuality, and bad behavior, along with an age-rating recommendation. The system was evaluated on a curated dataset of 452 videos representing different resolutions, lighting conditions, and content categories. Experimental results indicate that the proposed approach is promising as a human-in-the-loop decision-support tool for content rating, while further optimization is required for fully autonomous deployment.

Keywords: Content Rating Symbols Classification, Multimodal Analysis, Multi-label Classification, Human-in-the-loop Decision Support

I. INTRODUCTION

Digital media distribution has changed the scale of video production and consumption. Traditional broadcast content can be accessed through scheduled programming and a limited number of channels. However, streaming services and social platforms generate large amounts of video content every day. This volume makes manual inspection costly, slow, and difficult to apply consistently. Human reviewers may also be affected by fatigue, subjectivity, and missed violations. Age classification and content warning decisions cannot rely on a single cue. Violence may appear through objects, actions, dialogue, tone, or scene context. Offensive behavior may be verbal rather than visual. A risky object may also be harmless in a specific scene. For this reason, content rating requires evidence from multiple modalities. Visual, auditory, and textual information should be interpreted together. In this study, content rating symbols refer to warning labels for violence, horror, sexuality, and inappropriate behavior. Age rating recommendations also support these labels. The objective of this study is to develop and evaluate a prototype multimodal content analysis system. The system supports semi-automated and human-in-the-loop smart labeling of video content. It aims to assist the automated classification of content rating symbols. For this purpose, it integrates timestamped evidence from different modalities into a structured decision-making process. The main contributions are as follows: (i) an end-to-end multimodal pipeline for extracting visual, object-level, and speech-based evidence from video content; (ii) a decision layer for multi-label classification of content rating symbols; (iii) an operational reliability mechanism for structured decision generation during batch analysis; and (iv) a human-in-the-loop review interface for evidence-based validation and reviewer feedback.

II. RELATED WORK

Early content moderation systems mainly relied on metadata. These systems used titles, descriptions, tags, subtitles, and user-provided labels. Text-based classifiers such as TF-IDF and Naive Bayes have also been used for categorization and filtering tasks [1], [2]. These methods are computationally efficient. However, they depend heavily on the quality of textual information. Metadata may be missing, misleading, incomplete, or intentionally manipulated. For content rating symbols classification, this is a major limitation. Rating decisions should reflect the video's actual visual and auditory content, not just its metadata. Computer vision methods moved content analysis from metadata to frame-level evidence. Early approaches used handcrafted features such as HOG and SIFT. Later studies adopted convolutional neural networks and real-time object detection models [3-6]. Object detectors can identify risk-related visual cues such as weapons, alcohol, or other explicit objects [7]. However, object detection alone is not sufficient for content rating. The same object may have different meanings in different scenes. For example, a knife in a cooking scene and a knife in an assault scene may look similar. Their rating implications, however, are different. This shows the need for contextual interpretation. Audio analysis is also important in video content rating. Harmful or age-inappropriate content may appear through speech, threats, profanity, screams, or emotional tone. Early automatic speech recognition systems were based on statistical models such as hidden Markov models [8]. More recent transformer-based approaches provide stronger transcription performance, especially under noisy and multilingual conditions [9]. Still, speech evidence should not be interpreted in isolation. A loud voice, tense tone, or sports commentary may be incorrectly associated with violence or fear if visual context is ignored [10]. Vision-language models help connect visual perception with semantic interpretation. They generate natural-language descriptions of scenes and provide higher-level context beyond object labels [11], [12]. These descriptions can support content rating by explaining what is happening in a scene. However, scene descriptions, detected objects, and speech transcripts still need to be combined into a final decision. Large language models can support this stage by synthesizing chronological multimodal evidence and producing structured outputs [13]. At the same time, hallucination and prompt sensitivity remain important risks. These risks are especially critical in safety-related systems, where false positives and false negatives may affect rating decisions [14], [15]. Overall, previous studies show that text, vision, and audio-based methods each provide useful but incomplete evidence for content moderation. Single-modality systems may miss contextual cues or produce misleading predictions. This limitation is especially important for classifying content rating symbols. A video may require multiple warning labels, and each label may depend on evidence from different modalities. Therefore, this study focuses on integrating multimodal evidence and providing human-reviewable decision support for multi-label content rating.

III. MATERIALS AND METHODS

1. Dataset and preprocessing

The experimental dataset was designed around four main risk categories: violence, horror, sexuality, and bad behavior. Since a complete, ready-to-use dataset covering all target categories was not available, videos were collected and curated from multiple publicly accessible sources. The final dataset contains 452 video samples. The videos are available in different resolutions, including 720p, 1080p, and 4K. They also vary in lighting conditions, visual quality, and cultural context.

Each video was manually labeled using a multi-label annotation scheme. This allowed a single video to contain multiple risk categories. In addition to the four risk categories, a general content class was included as a non-risk reference category. Table 1 presents the distribution of the dataset across the target categories.

Table 1. Dataset distribution across risk categories

Risk category	Number of videos	Label type
Violence	100	Multi-label
Horror	100	Multi-label
Sexuality	52	Multi-label
Bad behavior	100	Multi-label
General	100	Single label
Total	452	-

Before analysis, each video was decomposed into visual and audio components. Representative frames were extracted from the video stream, and the audio track was converted into a separate waveform file. Frames were sampled at 1 fps to reduce redundant computation and to limit the amount of visual evidence passed to the reasoning stage. This sampling strategy improves processing efficiency. However, it may miss short-duration visual events. The audio stream was exported as a 16 kHz WAV file to support speech transcription.

2. Multimodal analysis pipeline

The proposed architecture combines visual, auditory, and textual evidence within a unified analysis pipeline. First, sampled video frames are analyzed to detect risk-related visual cues and objects. Second, the same frames are used to generate scene-level descriptions. These descriptions provide contextual information about actions, relationships, and visual situations that object detection alone may not capture. Third, the audio stream is transcribed into timestamped text. The outputs of these modules are then merged into a chronological evidence timeline. Figure 1 shows the proposed multimodal video analysis and decision pipeline.

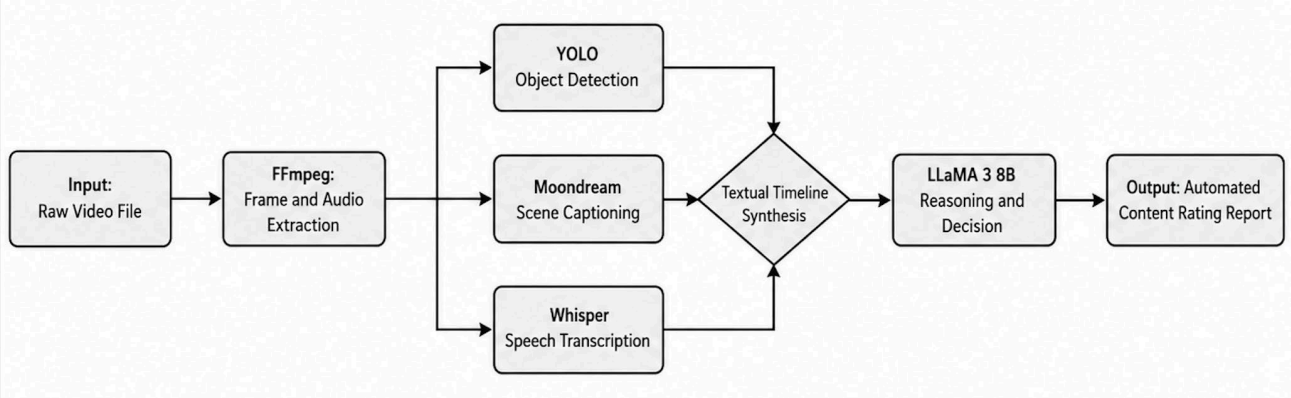

Figure 1. Proposed multimodal video analysis and decision pipeline.

The chronological evidence timeline is passed to the decision-making component. This component follows a rule-based rating prompt and assigns independent labels for violence, horror, sexuality, and bad behavior. It also provides an age-rating recommendation and a brief explanation. The LLaMA 3 model was not fine-tuned in this study. Instead, its decision behavior was adapted through prompt engineering. The decision prompt simulated a rule-based content-rating process and included negative constraints to reduce prompt-induced

hallucinations and overly sensitive labeling. This design supports interpretable decision-making. Rather than producing only a final class label, the system provides evidence-based outputs for human evaluators to review.

3. Robust decision generation and error handling

Structured output generation is important for batch-based content analysis. During long-running experiments, the language model may occasionally return outputs that do not fully conform to the requested JSON format. Such formatting errors may disrupt the processing pipeline if not handled properly. To address this problem, the system includes a Python-based recovery mechanism. This mechanism attempts to extract the most probable JSON block using regular expressions. It also repairs missing brackets and simple string-formatting errors when possible. If recovery is not possible, the system returns a safe fallback structure. This mechanism does not directly improve classification accuracy. However, it improves the operational reliability of the batch-processing pipeline. The conducted experiment allowed the complete dataset to be processed for 4.5 hours without a system crash.

IV. EXPERIMENTAL RESULTS AND DISCUSSION

1. Experimental setup

Experiments were conducted in Google Colab using an NVIDIA A100 Tensor Core GPU. This environment provided sufficient computational capacity for running the multimodal analysis pipeline. The implementation was developed in Python and executed using PyTorch and Hugging Face Transformers. The main reasoning and vision-language components were loaded without 4-bit or 8-bit quantization. This configuration was preferred to preserve the quality of semantic interpretation during multimodal evidence analysis. The models were executed with bfloat16 precision to balance computational efficiency and inference quality. The experimental pipeline included frame extraction, object detection, visual captioning, speech transcription, multimodal evidence synthesis, and structured decision generation. Each video was processed through the same pipeline to ensure consistency across the dataset. The generated outputs were stored in a structured format for later evaluation and error analysis.

2. Multi-label classification performance

Since a video may contain multiple harmful-content categories, the evaluation was conducted as a multi-label classification task. Precision, recall, and F1-score were computed separately for each risk category. Micro, macro, weighted, and sample averages were also calculated to summarise overall performance (Table 2). The general class was used as a non-risk reference category during dataset construction. It was not included as a target class in the multi-label risk classification metrics reported in Table 2.

Table 2. Multi-label classification results on the test dataset

Class	Precision	Recall	F1-score	Support
Violence	0.40	0.46	0.43	100
Horror	0.69	0.46	0.55	100
Sexuality	0.43	0.58	0.50	52
Bad behavior	0.29	0.93	0.44	100
Micro avg.	0.38	0.61	0.47	352
Macro avg.	0.45	0.61	0.48	352

Weighted avg.	0.46	0.61	0.48	352
Samples avg.	0.30	0.48	0.35	352

The system achieved micro F1 Scores of 0.47 and macro F1 Scores of 0.48. These results indicate moderate preliminary classification performance. They also suggest that further optimization is needed before the system can be used as a fully automated rating mechanism. The horror class achieved the highest precision, at 0.69. This shows that the model was more selective when assigning the horror label. However, its recall was 0.46, which indicates that some horror-related samples were missed. The sexuality class achieved the highest F1-score after horror, at 0.50. The violence class showed lower and more balanced precision and recall values. The bad behavior class produced a different pattern. It achieved a high recall of 0.93 but a low precision of 0.29. This means the system detected most bad-behavior samples, but also assigned this label to many non-relevant samples. This result suggests a risk-averse tendency in labeling. Such behavior may be acceptable in a reviewer-assistance scenario, where a human reviewer later checks suspicious content. However, it would not be sufficient for fully autonomous content rating. Figure 2 presents the independent confusion matrices for the multi-label risk categories. These matrices provide a class-level view of the model's error patterns and help explain the precision-recall differences reported in Table 2.

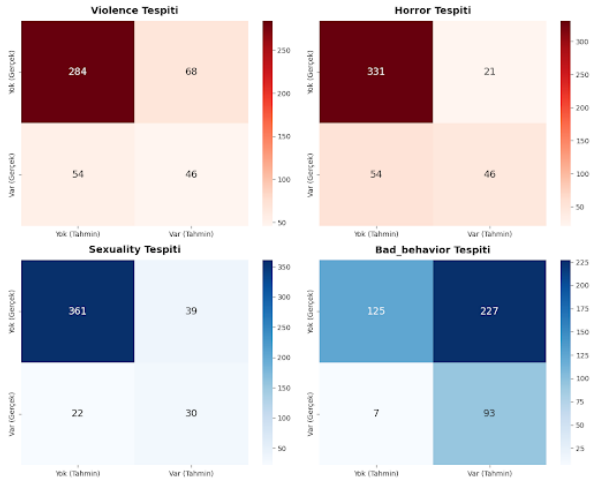

Figure 2. Independent confusion matrices for multi-label risk classes.

3. Error analysis and prompt optimization

Error analysis showed that one of the main sources of false positives was prompt-induced over-sensitivity. In the initial experiments, instructions related to alcohol, smoking, violence, or similar risk indicators caused the model to over-interpret some ordinary visual cues. For example, non-risk objects such as water bottles or background textures were sometimes treated as risky evidence. Similar errors were observed in sports scenes, where physical contact was occasionally classified as violence. In some cases, tense audio tone was also interpreted as horror, even when there was no supporting visual evidence. To reduce these errors, the final prompt was revised with negative constraints. These constraints required explicit and modality-supported evidence before assigning a risk label. The revised prompt encouraged the model to avoid assigning a category based on weak, ambiguous, or isolated cues. This modification shifted the decision process from aggressive labeling to

more conservative, evidence-based reasoning. As a result, the system became better aligned with a human-reviewable content rating workflow.

4. Human-in-the-loop interface

Content rating is a high-stakes task. Therefore, final decisions should remain subject to review by human experts. For this reason, the proposed system includes a web-based human-in-the-loop interface. Figure 3 illustrates the smart labeling interface that presents the recommended age rating, predicted content-rating symbols, explanations, and timestamped evidence to reviewers. The interface presents the recommended age rating, predicted content rating symbols, a general explanation, and timestamped evidence. This allows reviewers to inspect suspicious moments directly. As a result, they do not need to watch the entire video in every case. The interface also supports reviewer feedback. Reviewers can confirm correct predictions or mark false positives. This feedback can be used in future work to improve prompt design, reduce over-sensitive predictions, and support model refinement. In this way, the interface improves transparency and makes the system better suited to reviewer-assistance scenarios.

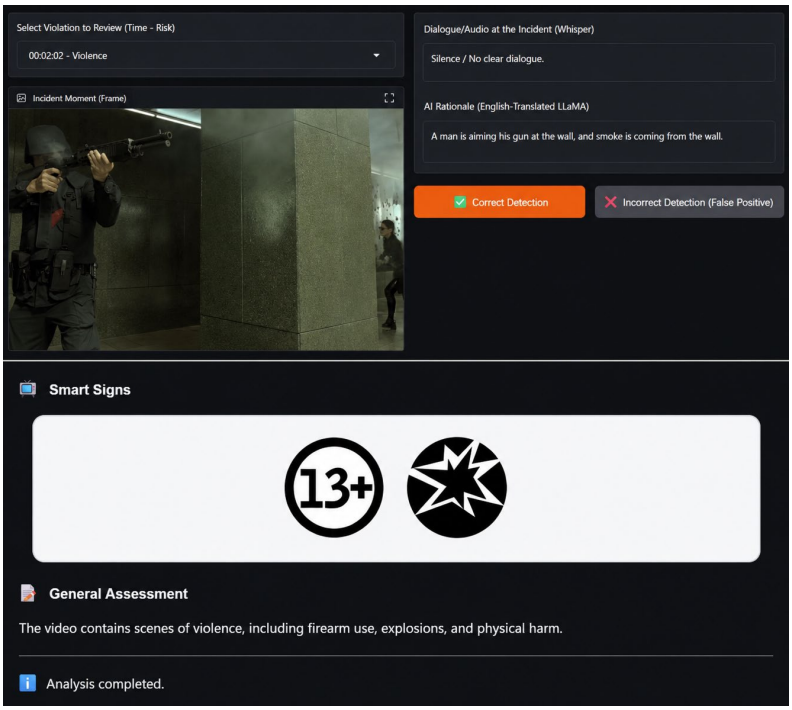

Figure 3. Smart labeling interface showing the predicted age rating and risk indicators.

V. CONCLUSION AND FUTURE WORK

This paper presented an artificial intelligence-supported multimodal content analysis system for the automated classification of content rating symbols in video content. The proposed prototype integrates video preprocessing, object detection, visual scene description, speech transcription, and reasoning-based decision-making into an end-to-end pipeline. The system transforms heterogeneous video evidence into a chronological timeline. It then generates multi-label risk decisions, an age-rating recommendation, and an explanatory rationale. Evaluation of 452 videos showed that the proposed architecture supports offline batch analysis in

reviewer-assistance scenarios. The results also demonstrated the potential of combining visual, auditory, and textual evidence to detect harmful content categories. However, the obtained performance indicates that the system is not yet suitable for fully autonomous deployment. In particular, high recall in sensitive categories may lead to more false positives. This was especially observed when the prompt overemphasized specific risk indicators. Negative prompt constraints and structured-output recovery improved operational reliability. The human-in-the-loop interface also supported transparent validation by presenting timestamped evidence to reviewers. Future work should focus on domain-specific fine-tuning using expert annotations and regulatory decisions. Larger multilingual and culturally diverse datasets are also needed. Real-time stream processing can be implemented using queue-based architectures and optimized inference pipelines. Model compression techniques, such as quantization and accelerated inference, may further improve the feasibility of deployment. Finally, reviewer feedback collected through the interface can be integrated into a continual-learning workflow. This would allow the system to improve over time under expert supervision.

ACKNOWLEDGEMENT

Abstract
A growing population and rapid urbanization are increasing traffic congestion in urban transportation systems, leading to higher fuel consumption, a larger carbon footprint, and increased air pollution; this situation heightens the need for emissions-focused decision support systems for sustainable traffic management. In this study, an emissions-focused decision support approach was developed using real-time traffic data collected from seven critical arterial intersections in the Adapazarı district of Sakarya Province, in collaboration with the Sakarya Metropolitan Municipality. Using the traffic data, CO_2, NO_x, and exhaust-derived $PM_{2.5}$ emissions were calculated with the COPERT/EMEP-EEA Tier 2 methodology; subsequently, a normalized multi-pollutant emission priority score was developed to evaluate pollutants collectively. Using the resulting emission scores, critical intersection-time combinations were identified, and emission levels were classified using the Random Forest, Support Vector Machine, Gradient Boosting, and XGBoost algorithms. Model performance was evaluated using the Leave-One-Group-Out cross-validation method, and the best results were obtained with the XGBoost algorithm. The XGBoost model demonstrated superior performance compared to other methods, with an accuracy of 0.978, an F1 score of 0.972, and an RMSE value of 0.147. The proposed approach integrates intersection traffic data, spatial impact distances, COPERT-based emission estimates, multi-pollutant emission scoring, Top-K prioritization, and machine-learning-based emission classification into a unified decision-support framework for sustainable cities, rather than evaluating traffic density in isolation.

Keywords: AI-Powered Traffic Management, Sustainable Urbanization, Carbon Footprint Reduction, COPERT Tier 2, Decision Support System.

I. INTRODUCTION

Rapid urbanization, population growth, and increasing vehicle ownership have intensified traffic congestion in urban transportation systems, leading to higher fuel consumption, increased greenhouse gas emissions, and deteriorating air quality. Intersections, where stop-and-go traffic frequently occurs, are among the most critical sources of transportation-related emissions and therefore play an important role in sustainable traffic management [1],[2]. Emissions from urban transportation are of environmental importance for greenhouse gases that cause climate change and air pollution that negatively affects human health [3]. In this context, while CO_2 emissions are linked to carbon footprints and climate impacts, pollutants such as NO_x and $PM_{2.5}$ are primarily assessed in terms of urban air quality, respiratory health, and local environmental impacts [4]. The Paris Climate Agreement, signed in 2015, and the EU Green Deal aim to significantly reduce emissions by 2030. However, projections indicate that Turkey's CO_2 emissions in 2030 could be 42% above the target level (approximately 723.97 million metric tons) [5]. It has been argued that even if all cars in Turkey were replaced with electric vehicles, CO_2 emissions from passenger cars would decrease by 48.9%. Yet, the resulting

reduction in total vehicle emissions would be limited to 9% [6]. Current literature on traffic management and intersection analysis mainly focuses on transportation performance indicators such as traffic volume, average speed, and travel time. Emissions modelling studies, by contrast, often calculate pollutant concentrations or use macroscopic traffic simulations, but rarely use emissions data to prioritize intersections for decision support. Few studies combine COPERT-based emission calculations with multi-pollutant prioritization and machine learning-based emission classification. There is a clear need for traffic management systems that prioritize emissions and integrate environmental impacts into decision-making, rather than relying only on traditional methods to reduce traffic volume. Developing such systems is crucial for sustainable urban planning. This study analysed traffic data for seven arterial intersections in the Adapazarı district of Sakarya Province on an intersection-hour basis. Intersection locations were represented using the Manhattan distance to calculate influence distances, yielding more descriptive traffic activity values for each intersection. While Euro 6 vehicle technology was selected and decarbonization of transportation is the goal, this could limit such gains, as the number of kilometers travelled per vehicle is expected to increase [4]. The COPERT/EMEP-EEA Tier 2 approach was chosen because it uses emission factors specific to vehicle class and emission standards, is consistent with European Emission Inventory guidelines, and can provide reliable emission estimates without requiring detailed microscopic driving data. Thanks to these features, the method provides a suitable framework for urban emission analyses and decision-support applications based on real traffic data [7]. The calculated CO_2, NO_x, and $PM_{2.5}$ emission values, which vary in units and magnitudes, were evaluated for decision support, normalized, and used to create an emission priority score. This score ensures that intersection-hour observations are ranked not only by traffic volume but also by emission load, accounting for multiple pollutants simultaneously [8]. Traffic-related emissions are affected not only by traffic volume, but also by temporal variation, intersection location, road segment length, and pollutant type. To address these complexities, this study proposes a decision-support workflow that converts hourly traffic counts to vehicle-kilometer activity, estimates CO2, NOx, and $PM_{2.5}$ emissions, and classifies intersection-hour observations by emission intensity using supervised machine learning models. In this context, the study's key contributions to the literature can be summarized as follows:

- CO_2, NO_x, and $PM_{2.5}$ emissions are estimated using the COPERT/EMEP-EEA Tier 2 methodology based on real-time traffic data.
- A normalized multi-pollutant emission priority score is proposed for jointly evaluating different pollutants.
- A Top-K prioritization strategy is introduced to identify critical intersection-hour combinations according to emission load.
- Multiple supervised machine learning algorithms are compared using Leave-One-Group-Out cross-validation to evaluate their generalization performance.
- An integrated decision-support framework is presented for environmentally sustainable traffic management.

II. RELATED WORK

Modelling road transportation emissions and developing sustainable traffic management strategies have become increasingly important due to rapid urbanization, population growth, and climate change [9]. Existing studies generally fall into two categories: (i) artificial intelligence-based traffic and emission prediction [10],[11], and (ii) emission estimation using macroscopic traffic and emission models [12-15]. Although both research directions have achieved significant progress, they are typically investigated independently. Also, in studies using macroscopic traffic models, emission estimates are made on a very large-scale using data such as the average vehicle speed, intersection length, and vehicle composition -in addition to the number of vehicles- but they provide limited information because they do not delve into detail in more detailed studies [1],[13],[16],[10].

Among emission estimation approaches, COPERT and HBEFA are the most widely adopted models in Europe [10], [17]. COPERT estimates emissions using vehicle-specific emission factors and average traffic conditions, whereas HBEFA additionally requires detailed traffic-state information. These studies show that the COPERT method can provide reliable emission estimates at different scales. However, most of these studies have focused on emission calculations, and the integration of these emissions into intersection prioritization or decision support systems has not been addressed in detail [2],[13],[17],[18]. Furthermore, while HBEFA requires detailed traffic condition information, COPERT Tier 2 can produce reliable results with limited data. For this reason, COPERT Tier 2 was deemed more suitable for this study, which is based on actual traffic counts. Machine learning has also been extensively applied to traffic and emission prediction. Tree-based methods such as Random Forest and XGBoost have shown strong performance in modeling nonlinear traffic relationships, while Support Vector Machines and deep learning approaches have been successfully applied to carbon emission forecasting and environmental monitoring [5], [19-21]. Nevertheless, many deep learning approaches require large-scale datasets and substantial computational resources. Considering the relatively limited size and node-based structure of the dataset used in this study, classical machine learning algorithms provide a more interpretable and computationally efficient alternative. Several studies have emphasized that sustainable transportation planning should consider multiple environmental indicators rather than relying solely on traffic density. Multi-criteria prioritization approaches have been proposed for urban planning and environmental assessment, while inventory-based studies have demonstrated the importance of evaluating pollutants such as CO_2, NO_x, and $PM_{2.5}$ simultaneously [8], [22-24]. Despite these advances, existing studies rarely combine multi-pollutant emission estimation, intersection prioritization, and machine learning within a unified decision-support framework. Although significant progress has been made in the literature on emissions modeling, traffic forecasting, and AI-based traffic management, these approaches are mostly addressed independently of one another. Research on decision support systems that integrate multi-pollutant emission calculations using real-time intersection data, critical intersection-hour prioritization, and machine-learning-based emission classification is quite limited. This study addresses these gaps in the literature by integrating the COPERT Tier 2 emissions model, a multi-pollutant emissions score, the Top-K prioritization approach, and supervised machine learning models into a single analytical framework.

III. METHODOLOGY

1. Dataset Definition

The dataset contains real-time traffic data from seven key intersections in central Sakarya, Türkiye, gathered in partnership with the Sakarya Metropolitan Municipality. The intersections represent main arterial roads with diverse traffic patterns. Hourly traffic counts were collected over seven days (24–30 December 2025). Each entry includes the day, hour, intersection name, vehicle count, and additional variables. After cleaning and removing incomplete data, 504 valid observations remained, each signifying a unique intersection-hour. Spatial coordinates of the intersections were also used in the analysis. The traffic data were reformatted, so each record shows a specific intersection, hour, and day. While the dataset covers a longer period, this study centers on three representative days to illustrate the procedure. To capture different traffic conditions, low, medium, and peak periods were identified using average hourly traffic volumes across all intersections. The representative-hour method enabled comparison of emissions under these altering conditions. Since network-level decisions are required, the average total vehicle load across the seven intersections was calculated for each hour. The intervals 04:00–05:00, 07:00–08:00, and 17:00–18:00 were chosen to represent low, medium, and peak traffic, respectively. The intersections were also ordered sequentially along the corridor, and the distances between consecutive intersections were estimated. While Euclidean distance measures the direct linear separation, Manhattan distance more accurately reflects the grid-like configuration of urban road networks. Therefore, the Manhattan method was selected to calculate the representative influence distance between intersections, as urban road geometry commonly involves both horizontal and vertical movements [25]. The influence distance

for each intersection was defined as half the distance to adjacent intersections, which prevents overlapping road segments during activity calculations.

2. Calculating Activity Value and Determining Intensity Classes

CO_2, NO_x, and $PM_{2.5}$ emissions were estimated using the COPERT/EMEP-EEA Tier 2 methodology, in which vehicle-kilometer activity is used as the activity indicator. Accordingly, the activity value was calculated by multiplying the hourly vehicle count by the representative influence distance of each intersection, as defined in Equation (1).

$$Vehicle - km_{j,t} = N_{j,t} \times d_j \quad (1)$$

Where $Vehicle - km_{j,t}$ represents the vehicle-kilometer, $N_{j,t}$ represents the total number of vehicles observed at the relevant intersection during that time; and d_j represents the influence radius of the relevant intersection.

Traffic conditions were categorized into low, medium, and peak periods using the representative-hour approach described in the previous subsection. Following the COPERT Tier 2 methodology, weighted emission factors were computed according to the assumed vehicle fleet composition (80% passenger cars, 15% light commercial vehicles, and 5% heavy-duty vehicles), all complying with the Euro 6 standard, as shown in Equation (2).

$$EF_i^* = \sum_{c=1}^{m} p_c \times EF_{i,c} \quad (2)$$

Where EF_i^* is the weighted emission factor; p_c, denotes the proportion of vehicle category c; $EF_{i,c}$ is the pollutant-specific emission factor of vehicle category i.

For each intersection-hour observation, the emission value was calculated by multiplying the vehicle-km activity by the weighted emission factor for the relevant pollutant. The emission values for CO_2, NO_x, and $PM_{2.5}$ shown in Table 1 were obtained by multiplying the activity value calculated for each observation by the weighted average emission factor for the relevant pollutant.

Table 1. Results of Emission Values at Intersections

Day	**Time Interval**	**Intersection Name**	**Hourly Vehicle Count**	**CO_2**	**NO_x**	**$PM_{2.5}$**
Sunday	00:00 – 01:00	1. Gate	721	82066,14	18,62	0,18
Sunday	04:00 – 05:00	1. Gate	185	49171,39	11,16	0,11
Sunday	07:00 – 08:00	2. Gate	485	35590,13	8,07	0,08
Monday	17:00 – 18:00	3. Gate	3370	304382,58	69,09	0,69
Monday	04:00 – 05:00	4. Gate	94	13051,28	2,96	0,02
Monday	16:00 – 17:00	Boulevard	4310	580366,72	131,74	1,31
Monday	17:00 – 18:00	Boulevard	4179	562726,81	127,73	1,27
Tuesday	07:00 – 08:00	Hospital	1707	157279,92	35,70	0,35
Tuesday	03:00 – 04:00	Y. Mosque	815	41238,08	9,36	0,09

Since CO_2, NO_x, and exhaust-related $PM_{2.5}$ emissions vary in magnitude and impact, a min-max normalization was applied to the emission values for each pollutant. This made the values comparable and enabled their use together in calculating the emission priority score. Following normalization, the emission values were combined using the weighted-sum method to generate a single emission-priority score.

3. Critical Intersection-Time Prioritization

In this study, a Top-K ranking was applied to identify the most critical intersection-time combinations for observation, with the aim not only of determining emission calculations but also of analyzing intervention priorities based on the observations. In this context, the selections were examined separately with respect to the number of vehicles, vehicle-km activity, and multi-pollutant emission scores. This K value was set at 20 to create a manageable set of candidates representing the critical intersection-time combinations that municipalities could address in the short term. The extent to which different selection strategies covered the relevant emission load was calculated using the capture rate shown in Equation 3:

$$R_i = \frac{\sum_{(j,t)\in\mathcal{K}} E_{i,j,t}}{\sum_{j,t} E_{i,j,t}} \tag{3}$$

Here R_i: i represents the capture rate of the critical intersection-time observations selected for pollutant within the total emissions, $\mathcal{K}$: Represents the set of critical intersection-time observations selected using the Top-K prioritization approach, and K has been set to 20. j, t: Represents a specific combination of intersection and time iteral. $E_{i,j,t}$ represents the emission quantity calculated for pollutant at intersection j during time interval t. $\sum_{(j,t)\in\mathcal{K}} E_{i,j,t}$ represents the total emission quantity for the relevant pollutant from the critical intersection-time observations selected using the Top-K method. The top 21 critical observations belong to the Boulevard Intersection, and the remaining observations are also provided in Table 2 to show the values for all intersections:

Table 2. Emission Scores and Criticality Orders for Intersections

Day	**Time Interval**	**Intersection Name**	**Emission Score**	**Criticality Order**
Monday	16:00 - 17:00	Boulevard	1	1
Tuesday	15:00 - 16:00	1. Gate	0,782098926	22
Tuesday	17:00 -18:00	4. Gate	0,706018464	31
Monday	10:00 - 11:00	3. Gate	0,6157047	62
Monday	15:00 - 16:00	Hospital	0,576477651	69
Monday	15:00 - 16:00	Y. Mosque	0,231558427	234
Monday	08:00 - 09:00	2. Gate	0,193773	269

4. Supervised Learning for Emission Level Classification and Performance Metrics

Traffic data, influence distances, start times, days, intersections, and density classes were used as input variables for the classification models. Vehicle-km activity, CO_2, NO_x, and $PM_{2.5}$ emissions, and the emission score were not included in the model inputs because they were directly correlated with the structure of the reference class. This approach reduced the likelihood of data leakage by eliminating variables that directly determine the models' target class. Therefore, the relevant variables were used only during the label creation phase. The hyperparameters used for the classification algorithms are presented in Table 3. Since the main aim of this study was to evaluate the applicability of the proposed emission-oriented decision-support workflow rather than to optimize a single classifier, predefined algorithm-specific hyperparameter settings were used for all models.

Random Forest was configured with 300 estimators, a minimum leaf size of 2, and balanced class weights; SVM used an RBF kernel with C=1.0, gamma set to scale, balanced class weights, and probability estimation; Gradient Boosting used 200 estimators, a learning rate of 0.05, and a maximum depth of 3; and XGBoost was configured for three-class classification with 300 estimators, a learning rate of 0.05, maximum depth of 4, subsample and colsample values of 0.90, and multiclass log-loss as the evaluation metric. These predefined settings provided a consistent and interpretable basis for comparing model performance, while systematic hyperparameter optimization is left for future work.

Table 3. Hyperparameter Values of Algorithms

Algorithms	**Hyperparameters**
Random Forest	n_estimators=300; min_samples_leaf=2; class_weight=balanced; random_state=42
Support Vector Machine	kernel=RBF; C=1.0; gamma=scale; class_weight=balanced; probability=True; random_state=42
Gradient Boosting	n_estimators=200; learning_rate=0.05; max_depth=3; random_state=42
XGBoost	objective=multi:softprob; num_class=3; n_estimators=300; max_depth=4; learning_rate=0.05; subsample=0.90; colsample_bytree=0.90; eval_metric=mlogloss; tree_method=hist; random_state=42

Leave-One-Group-Out cross-validation was used as an external evaluation protocol to assess the model's performance generalizability across days, with the day variable defined as the group. This approach prevents observations from the same day from appearing in both the training and test sets, thereby avoiding overly optimistic performance estimates that could result from temporal dependence. As shown in Figure 1, the XGBoost algorithm stands out among the models, achieving an accuracy of 0.978, an F1 score of 0.972, and the lowest RMSE of 0.147.

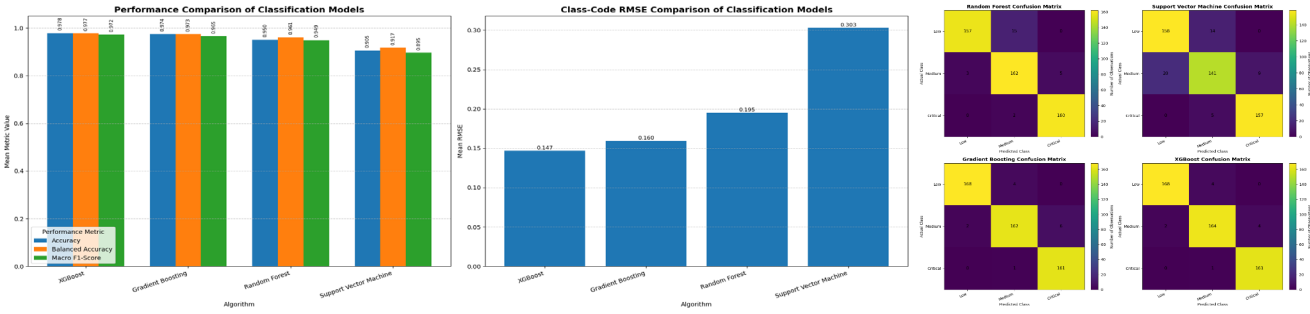

Figure 1. Performance Comparison by Mean Metric Values, Mean RMSE, and Confusion Matrix Results of Algorithms

The confusion matrices in Figure 1 show that the XGBoost and Gradient Boosting models effectively distinguish between low, medium, and critical emission classes, with XGBoost achieving the highest classification performance. Specifically, XGBoost correctly classified 168 of 172 low-emission observations, 164 of 170 medium-emission observations, and 161 of 162 critical-emission observations. Most misclassifications occurred between the low- and medium-emission classes, reflecting the relatively small differences in emission levels between these categories.

IV. RESULTS

In this study, the sample obtained from the dataset was evaluated based on intersection-hour observations spanning three days, using classifications of traffic activity, emission load, and emission levels. In light of the results obtained, as seen in the feature importance evaluations based on different classification algorithms in Figure 2, it is evident that analysis using only traffic data is insufficient; in addition to these data, the influence distance and the spatial impact of traffic mobility on the road network must also be included in the calculation. In other words, the feature importance analysis shows that, in addition to the number of vehicles, the intersection influence radius also plays a significant role in determining emission levels. This finding highlights that assessments based solely on traffic volume may be insufficient in explaining environmental impacts.

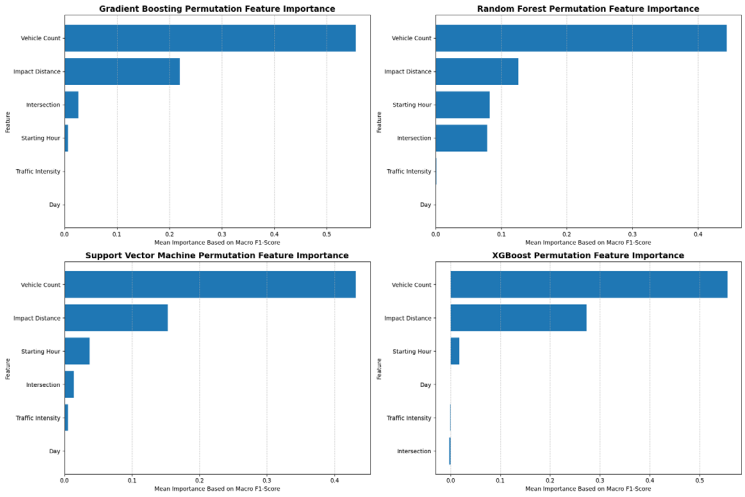

Figure 2. Feature Importance Determined by Models According to the Permutation Method

When all intersections were evaluated, the Boulevard Intersection stood out for both total vehicle count and vehicle-km activity. It was identified as the critical point where the highest total emission load occurs. The Boulevard Intersection's highest emissions across all evaluation criteria indicate that it should be prioritized for traffic management and signal optimization interventions. This approach helps ensure that limited resources are allocated to areas with the greatest environmental impact. When comparing classification models, XGBoost generally demonstrated the highest performance, followed by the Gradient Boosting model. The XGBoost model's superior performance can be attributed to its ability to model nonlinear relationships and learn complex interactions among features more effectively. The nonlinear dependencies among traffic density, intersection location, and time information have contributed to the tree-based boosting approach's superior performance. Furthermore, the findings are consistent with studies in the literature reporting that XGBoost-based models demonstrate high performance in traffic and emissions forecasting [26-28]. However, the proposed study distinguishes itself from existing studies by not only performing emissions forecasting but also incorporating multi-pollutant emissions prioritization into the decision-support process. Overall, the findings indicate that evaluating traffic data alone is insufficient to explain environmental impacts. The combined consideration of traffic density, spatial impact distance, and multi-pollutant emission analyses helps identify more accurate intervention priorities for sustainable traffic management. The study's fundamental contribution to the literature lies in providing an integrated analytical framework that goes beyond merely calculating urban emissions to determine at which intersections and during which time intervals emission interventions should be prioritized. Furthermore, the proposed approach enables municipalities to prioritize signal optimization, traffic routing, and emission reduction strategies by identifying the intersections and time intervals with the highest environmental impact, rather than intervening at all intersections simultaneously.

V. FUTURE WORK

Future studies plan to validate the method on broader road networks and across different cities, integrate it with real-time traffic control systems, and evaluate it comparatively against other emission modeling approaches. This will enable a more comprehensive demonstration of the scalability of the proposed decision-support approach and its performance across various traffic scenarios.

Abstract

Water management systems are critical infrastructure that are increasingly exposed to cyberattacks and failure risks due to their growing connectivity to corporate networks and the Internet. In this study, an AI-based real-time anomaly detection system was developed to monitor the SCADA/OT network of a water management facility. The study was conducted at the National Critical Infrastructure Testbed Center at Sakarya University. The system collects SNMP, ping, and syslog data from 28 devices, transforms them into a 224-channel multivariate time series, and compares GDN, TranAD, LSTM-AE, and Anomaly Transformer models under the same experimental conditions. Due to the limited availability of real anomaly data, a hybrid synthetic data generation method that preserves the statistical structure of normal traffic was used, and the generated data were validated using the Kolmogorov-Smirnov test, PCA, and the TSTR (Train-on-Synthetic, Test-on-Real) method. Experimental results show that GDN achieved the best performance on hard-level anomalies, with ROC-AUC of 0.934, F1 of 0.979, and PR-AUC of 0.802. The results are presented through a web-based monitoring dashboard that generates explainable alarms enriched with MITRE ATT&CK for ICS mappings.

Keywords: Smart water management, cyber security, anomaly detection, deep learning

I. INTRODUCTION

Water management facilities are critical infrastructures that directly affect public life through processes such as the treatment, pumping, and storage of drinking water [1]. Failures or cyberattacks in these systems may lead to physical consequences, including water outages, service disruptions, and adverse effects on public health. Therefore, the security of SCADA/OT systems should be addressed through a holistic approach that covers not only information security but also the continuity of physical processes [1], [2]. Although SCADA/OT systems were traditionally operated largely in isolation from external networks, they are increasingly connected to corporate networks and the Internet due to remote access, centralized monitoring, and operational efficiency requirements. This expansion increases the attack surface and makes critical infrastructures more vulnerable to cyber threats. Incidents such as Stuxnet and the Maroochy Shire breach have demonstrated that attacks targeting industrial control systems can cause physical and environmental consequences [3], [4]. Therefore, continuous monitoring and early anomaly detection are required in addition to access control and network security measures. Traditional monitoring tools mostly focus on the availability of OT assets, basic counter values, and system logs. However, attacks in OT networks often emerge as low-magnitude, time-distributed behavioral changes that leave

simultaneous traces across multiple devices. Therefore, rather than only monitoring device status, methods that can learn the network's normal behavior and detect deviations early are needed.

One of the main challenges in this field is the limited availability of real anomaly data. Collecting attack or failure data in critical infrastructure environments is both difficult and risky. Moreover, such events are rare, which prevents the collection of sufficient samples for training deep learning models. This limitation necessitates the generation of controllable, labeled synthetic data that preserves the structure of real normal traffic.

In this study, an AI-based real-time anomaly detection system was developed for SCADA/OT networks in water management systems. SNMP, ping, and syslog data were collected from 28 devices and transformed into a 224-channel multivariate time-series representation. GDN, TranAD, LSTM-AE, and Anomaly Transformer models were compared using the same data representation and evaluation approach. Due to the limited availability of real anomaly samples, hybrid synthetic data generation was applied, and the models were evaluated under easy, medium, and hard difficulty levels. The developed system continuously scores the collected data and notifies the operator of potential anomalies through a web-based monitoring dashboard.

The main contributions of this study can be summarized as follows:

- A labeled and reproducible hybrid synthetic data generation approach was developed to preserve the statistical structure and fundamental behavioral relationships of real normal traffic. This provides a controlled data generation process for model training and evaluation in OT/ICS environments where real anomaly data are limited.
- Data obtained from SNMP, ping, and syslog sources were transformed into device-based features, resulting in a 224-channel multivariate time-series representation over 28 devices. In this way, the study aims to model system-wide relational behavioral patterns rather than isolated device-level signals.
- GDN, TranAD, LSTM-AE, and Anomaly Transformer models were compared under the same data representation, preprocessing pipeline, and evaluation metrics. This comparison provides a fair experimental framework for analyzing the performance of different model families in SCADA/OT anomaly detection.
- Anomalies were generated at three different difficulty levels: easy, medium, and hard. This enabled evaluation of model behavior not only against obvious anomalies but also against low-magnitude, difficult-to-detect events.
- The outputs of the developed anomaly detection system were integrated into a real-time web-based monitoring dashboard. Alarm records were enriched with risk levels, explanatory fields, and MITRE ATT&CK mappings for ICS, making them more interpretable for operators.

II. LITERATURE REVIEW AND TECHNICAL BACKGROUND

Anomaly detection methods are generally classified into statistical approaches, classical machine learning methods, and deep learning-based models. While statistical and classical methods rely on specific assumptions and predefined features, the multidimensional and temporal structure of SCADA/OT data highlights the need for deep learning models capable of learning complex patterns [5]. An important group of deep learning-based approaches consists of reconstruction-based methods. These models learn to reconstruct normal data and use the reconstruction error as an anomaly score. LSTM-Autoencoder is a common example of this approach, as it can model long-term temporal dependencies [6]. In prediction-based methods, future values are estimated from past observations, and the prediction error is evaluated as an anomaly indicator. GDN provides an advantage in detecting correlated anomalies by learning the relationships between devices through a graph structure [7]. Transformer-based models can capture long-term dependencies and contextual inconsistencies through the attention mechanism. While TranAD aims to detect small deviations using a two-stage reconstruction structure

[8], Anomaly Transformer identifies contextual anomalies through an association discrepancy measure [9]. In this study, these four models were compared using the same data representation and evaluation approach.

Although GNN- and Transformer-based methods have achieved strong results in OT/ICS anomaly detection, most existing studies focus primarily on model performance on offline datasets. Real-time monitoring, explainable alarm generation, and operator support remain limited. This study contributes to the literature by integrating the anomaly detection model into an end-to-end monitoring architecture and presenting model outputs together with risk level, affected protocol, and MITRE ATT&CK for ICS mapping. Open datasets such as UNSW-NB15 [10], CIC-IDS2017 [11], CIC-DDoS2019 [12], InSDN [13], and SWaT [14], [15] are widely used in anomaly detection studies. However, UNSW-NB15, CIC-IDS2017, and CIC-DDoS2019 mainly focus on general IT network traffic, whereas InSDN focuses on SDN environments. Although SWaT is more closely related to this study as an ICS dataset based on a water treatment process, it does not directly represent the multi-source OT monitoring structure used in this work, which consists of SNMP counters, syslog records, and ping measurements. Therefore, labeled and controllable synthetic data generation was preferred to fit the targeted architecture.

III. PROPOSED MULTI-SOURCE BEHAVIORAL ANOMALY DETECTION FRAMEWORK

This section describes the data collection process and the synthetic data generation approach that form the basis of the anomaly detection system developed in this study. Within the scope of the study, SNMP, syslog, and ping data were collected from SCADA/OT components in the laboratory environment. Since real anomaly samples are limited, a hybrid synthetic data generation method was applied to preserve the statistical structure of these data. In this way, the normal traffic behavior that reflects the real environment was preserved, while different attack and failure scenarios were presented to the model in a controlled manner.

1. Testbed Environment and Monitoring Assets

The data used in this study were collected in a laboratory environment that represents a water management system at the National Critical Infrastructure Testbed Center of Sakarya University. The laboratory network consists of pumping, treatment, and storage stations, and the devices are separated into IP-based subnets in accordance with the zone-and-conduit approach of the IEC 62443 standard [2]. Thus, devices with similar security requirements are grouped within the same zone, while communication between zones is provided through controlled conduits. A total of 28 devices, including PLCs, switches, HMIs, and firewalls, are monitored in the environment. PLCs control field equipment, switches forward network traffic, HMIs provide the operator interface, and firewalls regulate inter-station and external traffic. The collector component, running in the background, queries the devices every 15 seconds and records the data in a central SQLite database. SNMP, syslog, and ping sources are used during data collection. Through SNMP, counter values for packets, errors, responses, and management requests are obtained; cumulative counters are computed by taking the difference between consecutive measurements [16]. Delta values of ten different SNMP counters are collected from each device. Syslog provides event, status, and error messages with timestamp, source, facility, and severity fields [17]. Ping generates information on device availability, latency, and packet loss [18]. These three sources are used together to monitor device status and network behavior holistically.

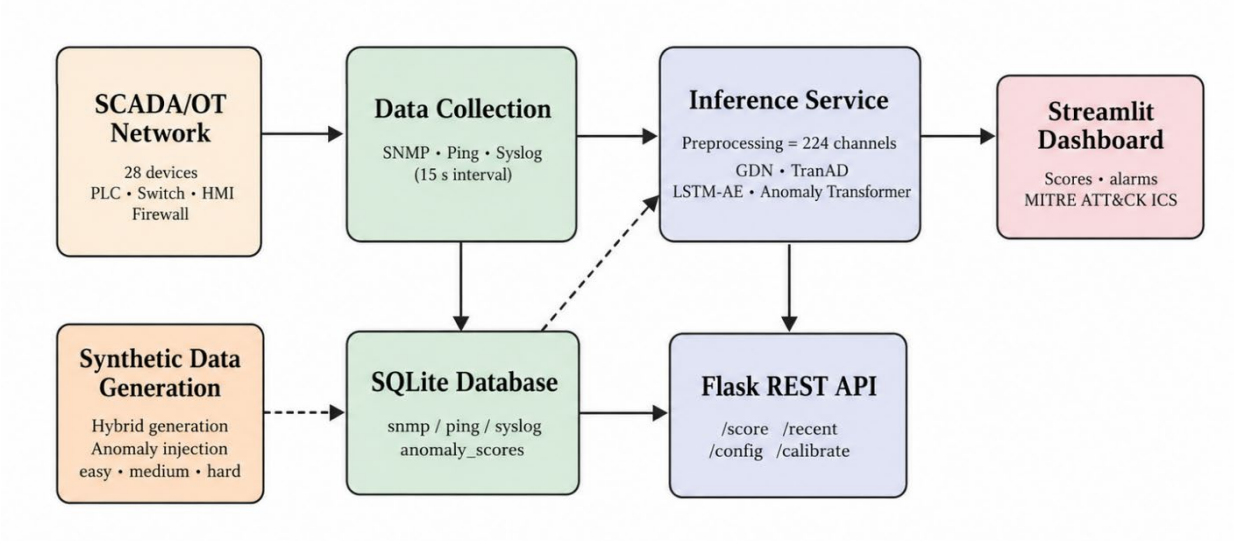

Figure 1. Real-Time SCADA/OT Anomaly Monitoring Pipeline

2. Extraction of Structural Invariants

To generate realistic synthetic data, the structural invariants of normal traffic were first identified. For this purpose, SNMP counter distributions, ratios between counters, and temporal behaviors in the real data were analyzed. As a result of this analysis, four main relationships were observed: a packet balance exists among InPkts, OutPkts, and OutGetResponses; GetNexts requests constitute approximately 92% of total packets; BadCommunityNames, SetRequests, and ASN error counters remain zero under normal conditions; and counters are updated at regular intervals of approximately 74 seconds. Preserving these invariants is important for ensuring that the synthetic data remains consistent with the real environment. Otherwise, the model may learn inconsistent patterns that would not occur in the real system. Therefore, packet balance, counter ratios, and normal error behavior were preserved during the generation process.

3. Hybrid Synthetic Data Generation

To address the class imbalance problem, this study employs a transparent and reproducible hybrid approach to synthetic data generation that preserves the statistical structure of real data. Although learning-based methods such as GANs can generate realistic data, their training processes are unstable, and their explainability is limited [19]. Therefore, this study combines baseline generation calibrated with measured statistics of normal traffic and anomaly injection based on documented attack rules. The generation process consists of two stages. In the first stage, an anomaly-free normal baseline is generated for each device using the average packet rate measured from real data. To reflect the variability of real network traffic, a time-of-day load pattern and device-specific log-normal noise are added to this value. Structural invariants are preserved in each measurement; outgoing packets are balanced with incoming packets, the GetNexts ratio is adjusted to remain approximately 92%, and error counters are kept at zero under normal conditions. In the second stage, anomalies are injected into this baseline in a controlled manner.

4. Definition and Generation of Anomaly Types

Anomalies were added to the generated normal baseline according to a threat taxonomy suitable for critical infrastructure environments. The anomalies were not generated randomly; instead, they were based on the traces

left by real attack and failure scenarios in SNMP counters. In this context, seven different anomaly types were defined. For example, network reconnaissance increases GetNexts values, represented as walk_spike; unauthorized configuration attempts increase the SetRequests counter, represented as set_attempt; and DoS attacks increase InPkts values while disrupting the response/request balance, represented as flood. The anomaly types are summarized in Table 1.

Table 1. Injected Anomaly Types And Scenarios

Anomaly Type	**Counter Trace (Signature)**	**Corresponding Scenario**
walk_spike	GetNexts suddenly increases	Network reconnaissance
set_attempt	SetRequests rises from zero	Unauthorized configuration write
community_brute	BadCommunityNames increases	Community name brute-force attempts
flood	InPkts surges; responses < requests	Denial of Service (DoS)
silent_device	All counters are reset to zero	Device shutdown/connectivity loss
asn_errors	ASN parsing errors increase	Malformed/malicious packet
response_drop	Response count falls below requests	Overloaded/unresponsive device

Each anomaly is defined by severity and duration parameters. In this way, different difficulty levels can be generated for the same anomaly type. The injected anomalies are added without overlap and labeled for use during the evaluation stage. In addition, SNMP, ping, and syslog data are generated in a correlated manner rather than independently, so that they represent different reflections of the same event. For example, a device failure is modeled simultaneously through the reset of SNMP counters, ping unavailability, and a syslog error record. To evaluate model performance more realistically, anomalies are generated at three difficulty levels: easy, medium, and hard. At the easy level, large and long-lasting deviations are generated. At the medium level, lower-magnitude anomalies are produced. At the hard level, small, gradual deviations from normal behavior are introduced. This difficulty gradient makes performance differences between models more apparent.

5. Validation of Synthetic Data

The representativeness of the synthetic data with respect to real traffic was validated statistically and functionally. In the statistical validation, structural ratios were first checked; the outgoing/incoming packet ratio was verified to be 1.0, and the SNMP walk ratio was confirmed to remain around 92%. Then, the compatibility of counter distributions with real data was evaluated using the Kolmogorov-Smirnov (KS) test [20]. In the tests conducted for each SNMP counter, the synthetic distributions did not differ significantly from the real distributions. In addition, principal component analysis (PCA) showed that synthetic normal data were concentrated in the same region as real normal data [21]. For functional validation, the TSTR (Train-on-Synthetic, Test-on-Real) method was used. The model was trained only on synthetic data and tested on real laboratory data unseen during training. The ability of the model trained on synthetic data to distinguish limited anomalies in real data from normal traffic indicates that the generated data are also suitable for learning in real environments.

6. System-Wide Preprocessing and Feature Extraction

Since deep learning models require numerical inputs sampled at equal time intervals, SNMP, ping, and syslog data generated at different periods were resampled onto a common one-minute time grid. Text-based syslog records were not used directly; instead, they were converted into numerical indicators, such as the number of messages by severity level within the corresponding time window. In this study, devices are evaluated not individually but through the simultaneous behavior of the entire network. Eight features are extracted from each device, resulting in a $28 \times 8 = 224$-dimensional feature vector at each time step for 28 devices. This approach was preferred because OT/ICS attacks may leave low-magnitude and simultaneous traces across multiple devices. All features were scaled to the 0–1 range. Normalization parameters were computed only from the training set and then applied to the test set using the same values, thereby preventing information leakage.

7. Models Used

In this study, LSTM-AE, TranAD, Anomaly Transformer, and GDN models were compared. All models were trained only on normal data using a semi-supervised approach, and the high reconstruction or prediction error produced for inputs deviating from normal behavior was used as the anomaly score. LSTM-AE was selected as the baseline model, while TranAD was evaluated for its two-stage Transformer architecture, designed to capture small deviations. Anomaly Transformer analyzes contextual inconsistencies using the association discrepancy measure. In contrast, GDN learns relationships between features through a graph structure, making it a strong candidate for multi-device OT/ICS environments.

8. Training, Testing, and Real-Time Threshold Calibration

The models were trained only on normal data, using a 48-hour training set that contained no anomalies. During the test phase, a fully independent dataset containing labeled anomalies was used. To ensure a methodologically fair comparison, all four models were evaluated using the same training set, test sets, and evaluation metrics. Thus, the observed performance differences can be attributed to the models' capabilities rather than to differences in experimental conditions. The trained models were integrated into a real-time monitoring pipeline. At the end of each data collection cycle, a scoring process is triggered; the most recent data are retrieved, processed through the same preprocessing steps, scored for the latest window, and recorded in the database. The system initially operates in calibration mode. In this mode, scores are calculated and stored, but no alarm is generated. This is because generating alarms before determining a meaningful threshold may lead to a high false-positive rate. The threshold value is learned from the system's real normal traffic. During a defined observation period, the distribution of normal scores is analyzed, and the threshold is set at an upper percentile of this distribution, such as 99.5%. The calibration process automatically removes unreliable warm-up scores at the beginning; otherwise, the threshold may be set higher than necessary, causing real anomalies to be missed. Since the threshold is stored in the database rather than hard-coded and can be updated through the interface, the system can be recalibrated without code changes when it is transferred to a different environment. This design choice is also consistent with the ISO/IEC 27001 principles of continuous monitoring and improvement [22].

IV. EXPERIMENTAL RESULTS AND ANALYSIS

1. Evaluation Metrics

ROC-AUC, PR-AUC, and point-adjusted F1 metrics were used to evaluate anomaly detection performance. ROC-AUC measures a model's ability to distinguish between normal and anomalous samples independently of the decision threshold [23]. PR-AUC is particularly important for imbalanced datasets in which anomalies are rare, as it also reflects the tendency of false positives [24], [25]. Point-adjusted F1 is a metric commonly used in

time-series anomaly detection, where an anomaly event is considered detected if any point within the event is correctly identified [26]. To improve the reliability of the results, each experiment was repeated with three different random seeds, and the average performance values were reported.

2. Results by Difficulty Level

The ROC-AUC values for the four models across three difficulty levels, along with their F1 performance at the hard level, are summarized in Table 2. At the easy and medium levels, all models produced high and similar ROC-AUC values; therefore, the main performance differences became evident at the hard level. At the hard level, GDN achieved the highest ROC-AUC value of 0.934, outperforming TranAD (0.833) and Anomaly Transformer (0.835), while LSTM-AE showed the lowest performance with 0.773 (Figure 2). The F1 results align with this trend, indicating that GDN can detect hard anomalies with high precision and recall, achieving an F1 score of 0.979.

Table 2. Performance Metrics By Difficulty Level

Model	**Easy ROC**	**Medium ROC**	**Hard ROC**	**Hard F1**
LSTM-AE	0.972	0.955	0.773	0.697
TranAD	0.998	0.990	0.833	0.955
Anomaly Transformer	0.999	0.991	0.835	0.968
GDN	0.995	0.989	0.934	0.979

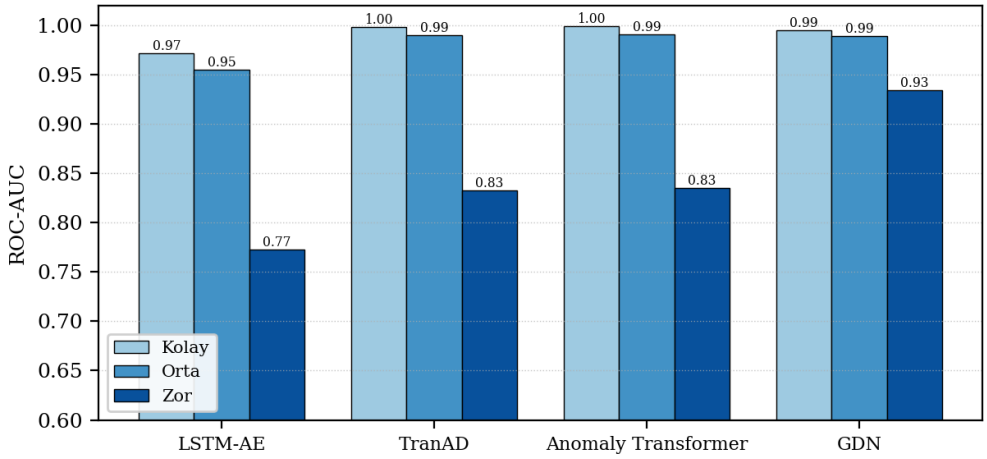

Figure 2. Performance metrics of the models by anomaly difficulty level.

3. Precision, Recall, and Stability Analysis

The practical value of an anomaly detection system depends on its ability to limit false positives without missing real anomalies. In the hard-level PR-AUC results, GDN achieved the most balanced performance with a score of 0.802, while LSTM-AE showed the lowest performance with 0.411. TranAD and Anomaly Transformer

achieved comparable results, with PR-AUC values of 0.697 and 0.707, respectively. In the multi-seed experiments, GDN also maintained high average performance with low standard deviation. These results indicate that GDN is a more stable candidate for deployment across different data periods or different OT/ICS environments.

V. CONCLUSION

This paper presented a behavior-based anomaly detection framework for smart water management SCADA/OT networks using multi-source monitoring data collected from SNMP, syslog, and ping telemetry. To overcome the limited availability of real anomaly data in critical infrastructure environments, a hybrid synthetic data generation approach was developed to preserve the statistical characteristics and structural invariants of normal network traffic while enabling the controlled injection of representative attack and failure scenarios. Four state-of-the-art deep learning models, namely LSTM-AE, TranAD, Anomaly Transformer, and GDN, were evaluated under identical preprocessing and experimental conditions. The experimental results demonstrated that the graph-based GDN model consistently outperformed the other approaches, particularly for hard-to-detect anomalies, achieving an ROC-AUC of **0.934**, an F1-score of **0.979**, and a PR-AUC of **0.802**, indicating its superior capability to capture correlated behavioral deviations across multiple OT devices. Beyond offline model evaluation, the proposed framework integrates multi-source data acquisition, feature extraction, real-time anomaly scoring, adaptive threshold calibration, and explainable alarm visualization into a unified monitoring architecture. These findings demonstrate that combining behavioral analysis with multi-source network telemetry provides an effective and practical solution for improving cyber resilience and operational awareness in smart water management infrastructures. Future work will focus on validating the framework using real-world cyberattack scenarios, incorporating additional OT communication protocols and telemetry sources, and investigating online learning techniques to enable adaptive anomaly detection in continuously evolving operational environments.

ORCID: 0009-0004-7582-2524

Abstract
With the rapid growth of enterprise data, significant challenges have emerged in managing, transforming, and optimizing the datasets collected in an Enterprise Data Warehouse (EDW). Traditional Extract, Transform, and Load (ETL) methods rely extensively on external tools, resulting in operational inefficiencies such as increased data transfer, higher latency, increased operational costs, and underutilization of available resources. This paper proposes a novel PL/SQL-based data transformation and optimization framework that leverages Oracle Database's in-database processing capabilities. The framework integrates advanced PL/SQL operations, such as bulk collection and parallelism, and utilizes various database-level optimization techniques, including index creation and partitioning. The experimental results demonstrate improved efficiency in terms of execution time and fault tolerance.

Keywords: PL/SQL, Data Warehousing, ETL Optimization, Oracle Database, Data Transformation, Performance Tuning, Metadata-Driven Framework

I. INTRODUCTION

In the contemporary IT environment, companies generate vast volumes of data from various sources, including transaction systems, websites, mobile platforms, and external data sources. Effective management and transformation of large volumes of data are essential to ensure successful business intelligence activities. The Enterprise Data Warehouse (EDW) serves as the central repository for data from different sources and as the basis for reporting. As data volumes grow and become increasingly complex, data transformation processes are becoming more difficult. The extraction, transformation, and loading (ETL) process is a major aspect of the data warehousing solution. It involves obtaining unstructured data from various sources, applying transformation rules, and loading the transformed data into the warehouse tables. Contemporary ETL approaches commonly rely on third-party software solutions such as Informatica PowerCenter and Microsoft SQL Server Integration Services. These solutions enable effective integration and data management; however, they are accompanied by several limitations because data must be moved across different platforms. Data migration requires additional resources, including bandwidth and computing power, which reduces efficiency. To resolve this problem, in-database processing has proven highly effective in improving ETL process efficiency. In-database processing involves performing transformations within the database server rather than moving data to another location to apply transformation logic. Oracle DBMS offers one of the most popular procedural languages for SQL processing: PL/SQL. Thus, it becomes possible to apply business rules, perform transformations, and perform batch processing within the database. Several advantages are associated with using PL/SQL code, including opportunities for large-scale data manipulation. For example, it is possible to use BULK COLLECT and FORALL operations to perform transformations faster, since there is no context switching between the SQL and procedural execution engines. There are numerous additional features in PL/SQL, including support for procedures and packages, dynamic SQL, exception handling, and more. However, limited enterprise adoption of PL/SQL is systematic. This paper proposes a novel ETL approach that uses PL/SQL data transformations and optimizations. The system architecture includes components such as a data ingest layer, a data transform layer,

a data optimization layer, and a data storage layer. Advanced PL/SQL techniques and database optimizations are used. Additionally, the system includes components such as error handling, logging, and monitoring. The Novelty of this paper lies in the creation of a comprehensive, reusable, and metadata-driven transformation framework for enterprise data warehouse workloads using PL/SQL bulk processing, set-based transformation, database optimization, logging, and a restartable, fault-tolerant architecture.

In conclusion, this framework contributes the following:

- It presents an ETL/ELT framework driven by metadata based on PL/SQL for enterprise data warehouses.
- It provides integration of staging, validation, transformation, optimization, auditing, logging, and error recovery within Oracle Database.
- It tests the ETL/ELT framework by conducting performance evaluation with EDW benchmarking workload of a banking nature with high transaction rates.
- It compares the proposed ETL/ELT framework with the traditional ETL frameworks in terms of performance measures.

II.LITERATURE REVIEW

The Extract, Transform, Load (ETL) process is an essential part of data warehouse implementation in enterprises, providing mechanisms to integrate data from various sources into a single repository for analysis. As data volumes grow, the importance of effective ETL processes has increased. Data extraction, transformation into more meaningful forms, and loading of transformed data into warehouses are the main functions of the ETL pipeline [1], [2]. Significant changes have occurred in the ETL domain since the initial development of such systems. Earlier versions operated in batch mode and needed considerable human input to function effectively. Contemporary ETL systems offer automated operations, distributed computing, and cloud-based infrastructure. The ELT (Extract, Load, Transform) concept moved the transformation phase into a database environment [3]. Kimball and Caserta stressed the resource-intensive nature of the ETL phase in data warehousing and the need for proper optimization [4]. The same was argued by Vassiliadis et al., who noted the complexity of the process and the necessity of formalized modeling techniques [5]. The topic of ETL optimization has attracted considerable attention, and many methods have been suggested to optimize ETL process performance. For instance, Liu developed techniques such as shared coaching and parallelization, which can greatly reduce execution time and resource utilization for ETL processes [6]. These techniques help avoid unnecessary computations and effectively utilize system resources. Simitsis et al. indicated that techniques such as task scheduling optimization, data partitioning, and pipelining could significantly improve ETL performance in large organizations [7]. Such optimizations play a critical role in handling big data processes in corporate organizations. Push-down optimization can be considered a database-oriented approach in ETL architecture, as ETL logic is executed on the database side rather than by other processing systems. Kodali et al. reported that push-down optimizations significantly reduce data movement and speed up operations in a multi-cloud architecture [8]. Yu et al. demonstrated that moving computation closer to storage systems greatly improves query performance and cost efficiency by a factor of 6.7 [9]. Zhang et al. introduced automated predicate pushdowns, which significantly optimize the query execution process [10]. These findings confirm the efficiency of the database-oriented methodology and are consistent with PL/SQL transformation models. Automation is now an essential aspect of any current ETL system. Automation helps eliminate manual processes and improve performance scalability. Ebadifard et al. [11] highlighted the significance of automation in ETL pipelines for machine learning. Modern ETL solutions feature metadata management and intelligent scheduling, enabling performance optimization and real-time operations. However, existing ETL systems are subject to drawbacks such as long latency caused by data transport, Inability to scale under high load, costly operations and

maintenance, and Inflexibility for advanced transformations. Such problems are associated with the use of external engines rather than native database capabilities [12]. PL/SQL provides a robust mechanism for executing transformations within Oracle databases. As noted by Feuerstein and Pribyl, PL/SQL improves efficiency by reducing context switches between the application and database layers [13]. Harrison underlines the importance of improving performance at the database level in enterprise applications [14]. Recent literature on ETL methodologies, tools, processes, and evaluations further highlights the importance of effective transformations and sound architectural decisions for handling large volumes of data in a data warehouse [15]. At the same time, comprehensive ETL assessment emphasizes scalability and tool choice [16]. Pipeline quality analysis stresses validation and reliability issues [17]. Database benchmarking provides the basis for system performance evaluation [18], and Oracle SQL error management ensures fault tolerance [19]. The database-centered ETL approach using PL/SQL reduces transfer time, speeds up the process, and ensures better data consistency. Despite numerous studies on ETL optimization and automation, a coherent framework that incorporates ETL optimization techniques in PL/SQL environments remains lacking. Current approaches rely on separate ETL tools. This research aims to fill the gap mentioned above by developing a single PL/SQL framework that integrates optimization techniques, such as parallel processing and pushdown execution, into transformation algorithms.

III. FRAMEWORK ARCHITECTURE

The architecture is designed as a multi-layered system that encompasses processes such as data intake, transformation, optimization, and storage. This framework leverages Oracle Database's database functionality to optimize the process while minimizing data transport. Each layer is associated with a specific ETL process.

1. Data Ingestion Layer

The Data Ingestion Layer involves extracting data from sources such as transactional databases, flat files, and other external data stores. It uses software such as SQL*Loader and external tables to rapidly load data into staging areas. The external tables feature enables users to query data files directly without importing them into the database. At this level, preliminary checks are carried out to ensure data integrity. Some checks include null values, data type conflicts, and data format issues. The cleaned data is subsequently loaded into staging tables.

2. Transformation Engine (PL/SQL Core)

The Transformation Engine is the central component of the proposed framework and is implemented in PL/SQL in Oracle Database. The Transformation Layer transforms raw data and applies business logic to produce meaningful, analyzable data. The use of stored procedures and packaged code improves maintainability and promotes code reusability. Techniques such as bulk collect and for all are used to handle high volumes of data by minimizing context switching between the SQL and PL/SQL engines. Also, this layer cleanses, enriches, aggregates, and normalizes data according to the business rules. Complex transformations are performed in the database, including multi-table joins and derived attributes.

3. Optimization Layer

The Optimization Layer is a critical component for enhancing the performance of the transformation process. This layer employs multiple database-level optimization techniques to ensure efficient processing of large-scale datasets. Indexing techniques, including B-tree indexing for high-cardinality columns and Bitmap indexing for low-cardinality columns, are used to improve query performance. Table partitioning is another optimization

technique that divides large tables into smaller, more manageable segments, enabling partition pruning. Parallel execution distributes workloads across multiple CPUs, enabling efficient execution of computationally intensive tasks. Query tuning helps identify and eliminate inefficiencies, including unnecessary full-table scans.

4. Data Storage Layer

The Data Storage Layer stores processed data in the company's enterprise data warehouse. The organization of the data in this layer follows dimensional models such as the star or snowflake schema, which are common approaches for performing analytical processing. Specifically, the layer uses fact tables for quantitative data, such as transactions or measurements, whereas dimension tables hold descriptive information about customers, products, or time periods. The well-structured nature of this layer enables efficient queries and reports that deliver business intelligence. Moreover, performance can be further improved through indexing and aggregation techniques.

In summary, the described approach incorporates all four layers, creating an effective solution that enhances ETL efficiency, minimizes data processing time, and improves scalability through in-database processing.

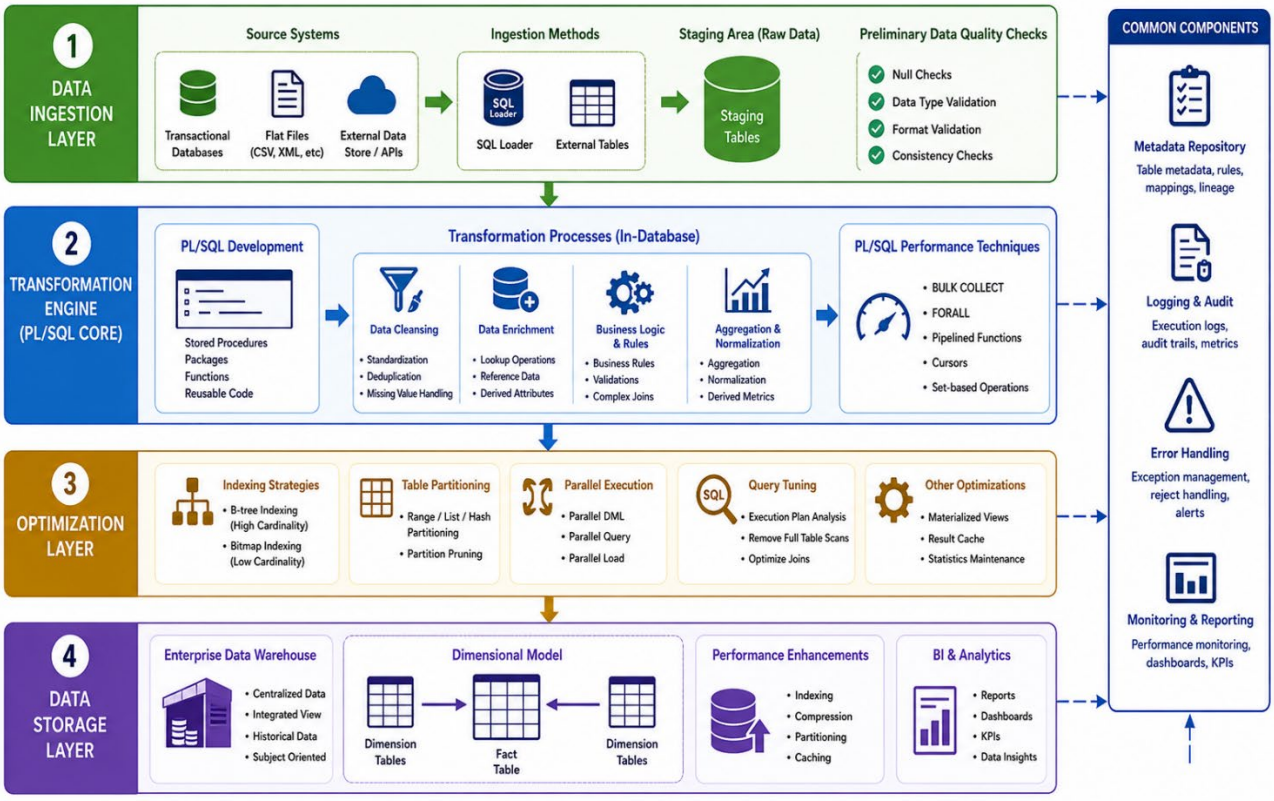

Figure 1. Architecture of a PL/SQL-Based Data Transformation and Optimization Framework for Enterprise Data Warehouses

IV.METHODOLOGY

This study proposes applying an ETL solution based on an in-database technique that leverages PL/SQL capabilities to improve data transformation performance. Data acquisition is the initial stage that includes loading data from diverse sources, such as transactional systems, flat files, and external data storage systems. The SQL*Loader tool and external tables are used to load data into the staging area for preliminary validation, including checking for nulls, data types, and formats.

Subsequently, PL/SQL transformation engines transform the data uploaded to the staging area using stored procedures, functions, and packages that provide data cleaning and validation, data enrichment, and business rule implementation. Techniques such as BULK COLLECT and FORALL are used to process large volumes of data and minimize context switches. Optimization of data transformation processes includes implementing indexing, table partitioning, parallel processing, and execution-plan-based query tuning. The last stage involves loading data into the enterprise data warehouse and dimensional modeling of the data structure (star or snowflake schema). In addition, metadata management systems, logging, and monitoring processes guarantee efficient data quality management. Unlike traditional ETL tools that operate externally, the proposed framework minimizes unnecessary movement of large datasets from the database to external transformation engines. Unlike traditional Oracle ELT scripts, the presented framework is not limited to isolated SQL procedures. Instead, it offers a structured design with metadata-driven rule execution, reusable PL/SQL packages, audit trails, record-rejection capabilities, checkpointing for restart, and database-level optimization.

1. BULK COLLECT with Error Isolation

A critical design consideration for the BPE is the use of the SAVE EXCEPTIONS clause with FORALL DML statements, accompanied by an effective exception handler that can track each row-level error without halting the entire process. In this manner, the throughput is optimized for valid records while maintaining comprehensive traceability for invalid records.

```
PROCEDURE load_staging_bulk(  p_pipeline_id IN NUMBER,  p_batch_size  IN PLS_INTEGER
DEFAULT NULL) IS
  TYPE t_source_tab IS TABLE OF stg_raw_data%ROWTYPE;
  v_source_data  t_source_tab;
  v_batch_size   PLS_INTEGER;
  v_errors       PLS_INTEGER := 0;
  ex_dml_errors  EXCEPTION;
  PRAGMA         EXCEPTION_INIT(ex_dml_errors, -24381);
  CURSOR c_source IS
    SELECT * FROM stg_raw_data
    WHERE  pipeline_id = p_pipeline_id
    AND    status = 'PENDING';
BEGIN
  v_batch_size := NVL(p_batch_size,
    compute_optimal_batch_size('STG_RAW_DATA'));
  OPEN c_source;
  LOOP
    FETCH c_source BULK COLLECT INTO v_source_data
    LIMIT v_batch_size;
    EXIT WHEN v_source_data.COUNT = 0;
    BEGIN
      FORALL i IN 1..v_source_data.COUNT SAVE EXCEPTIONS
        INSERT INTO stg_cleansed_data VALUES v_source_data(i);
    EXCEPTION
```

```
    WHEN ex_dml_errors THEN
     FOR j IN 1..SQL%BULK_EXCEPTIONS.COUNT LOOP
      log_row_error(
       p_pipeline_id, v_source_data(SQL%BULK_EXCEPTIONS(j).ERROR_INDEX),
       SQL%BULK_EXCEPTIONS(j).ERROR_CODE
      );
      v_errors := v_errors + 1;
     END LOOP;
    END;
  END LOOP;
  CLOSE c_source;
END load_staging_bulk;
```

V.IMPLEMENTATION

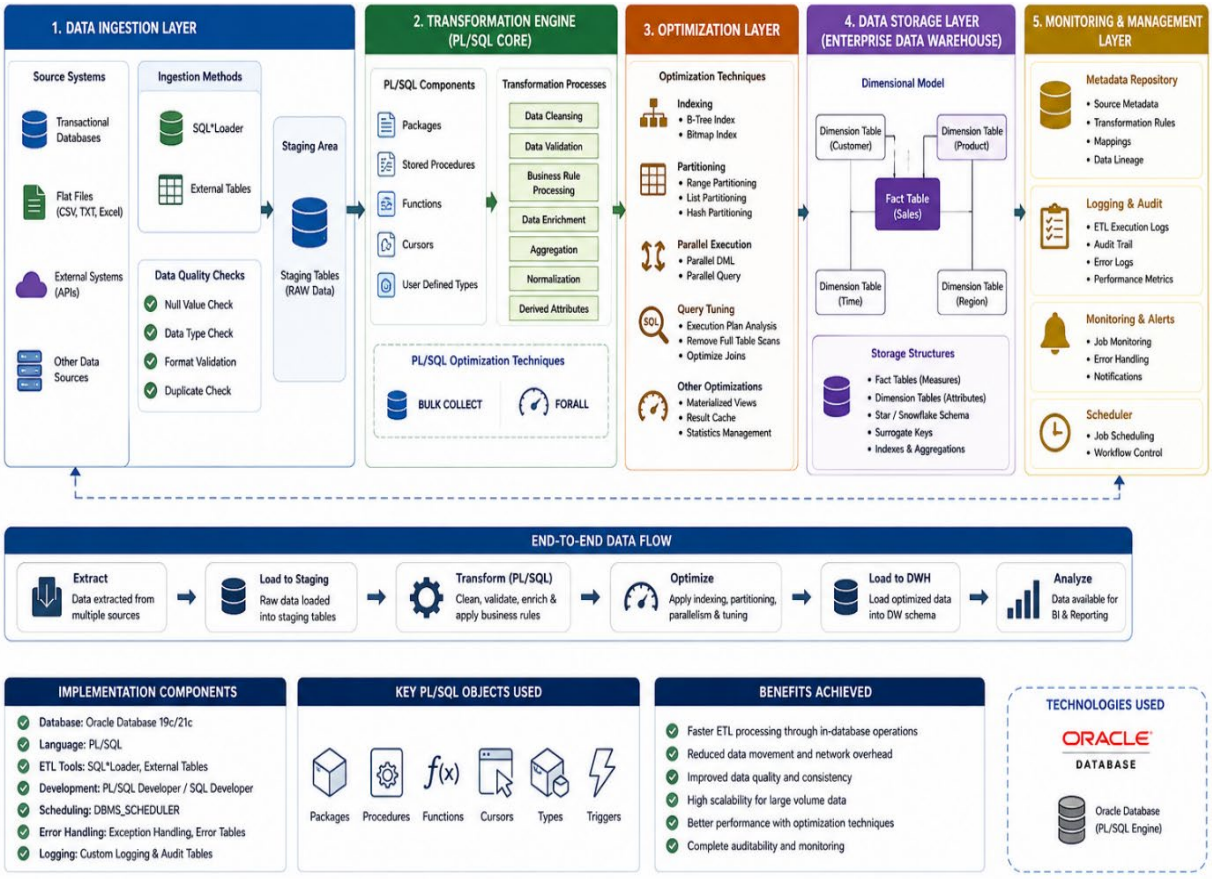

Figure 2. Implementation of a PL/SQL-Based Data Transformation and Optimization Framework for Enterprise Data Warehouses

The PL/SQL-based Data Transformation and Optimization Framework for enterprise data warehouses is implemented in phases using Oracle Database. In the first stage, the data is extracted from several enterprise sources, including transactional databases, flat files, and external systems. Raw data is imported into the staging

tables using Oracle utilities such as SQL*Loader and External Tables. During this stage, data validation checks are performed to identify null records, duplicates, bad data formats, and wrong data types. In the second phase, the data is processed in the staging layer, where it is stored in temporary tables. Temporary tables play a vital role in separating source data from warehouse tables and in allowing for the review of failed or rejected records. Implementation at the Core Level is facilitated by the PL/SQL Transformation Engine that consists of PL/SQL packages, procedures, functions, and cursors. The engine facilitates data cleansing, validation, standardization, enrichment, aggregation, normalization, and business rule enforcement. Techniques such as BULK COLLECT and FORALL facilitate processing voluminous data by reducing context switching between the SQL and PL/SQL engines. The third phase focuses on performance enhancement through indexing, partitioning, parallel processing, and query tuning. For instance, B-tree indexes are implemented on high-cardinality columns, whereas bitmap indexes are deployed on low-cardinality columns. Tables containing millions of records are partitioned to enhance query and transformation performance. Finally, the transformation and optimization processes facilitate loading dimensional models into the data warehouse. In this phase, fact tables will contain measurable business data, while dimensional tables will contain descriptive data. Log files, audit tables, metadata tracking, and error-handling mechanisms will facilitate execution monitoring, failure capture, and record reprocessing.

VI.RESULTS AND EVALUATION

The proposed framework was tested using a real-world banking data warehouse environment, specifically a core banking data warehouse. The data warehouse application is designed to handle large volumes of transaction data, including account, credit card, loan, and ATM transactions.

1. Case Study of Real-Time Banking

The case study involves a large bank that processes 10-15 million transactions daily across various channels, including mobile and internet banking, ATMs, and branch operations. Under the ETL methodology, the data was extracted, transformed using external ETL software, and subsequently loaded into the warehouse. The framework supports real-time banking and other applications where large volumes of data, minimal latency, regulatory requirements, and real-time analysis are key requirements.

2. Experimental Setup

The experiments were performed using Oracle Database 19c (19.11) on a dedicated Exadata X8M infrastructure with identical hardware configurations: 2-node RAC clusters with 48-core Intel Xeon processors, 768 GB of RAM per node, and high-performance NVMe flash storage. The benchmark was designed using a star schema model that included one transactional fact table and several dimension tables for customers, accounts, branches, products, and time. The workload included banking transactions, such as account transfers, card transactions, loan payments, ATM withdrawals, and branch transactions. All experiments were conducted five times, and the average result was calculated. The baseline approaches include an ETL process in an external environment, row-by-row processing using PL/SQL, and set-based transformation of SQL queries. The proposed approach is PL/SQL packages with BULK COLLECT, FORALL, partition pruning, indexing, and parallelization.

3. Results

As shown in the evaluation results, the new framework improves ETL performance compared with the legacy baseline method and the optimized PL/SQL approach. The average ETL execution time decreased from 8.4

hours to 3.1 hours, and the average query response time decreased from 47.2 seconds to 17.4 seconds, resulting in a 63.1% improvement. Peak ETL throughput increased from 285,000 rows per second to 1,840,000 rows per second, which is a 6.5-fold improvement. Concurrently, the data load error rate decreased from 3.8% to 2.0%. Finally, the PGA memory waste decreased from 34.2% to 8.1%. Additionally, the framework improved data quality through integrated error handling, logging, and audit mechanisms.

Metric	Legacy Baseline	Bulk-Optimized PL/SQL	NPDTOF	Improvement vs. Baseline
Avg. ETL Elapsed Time (hours)	8.4	5.9	3.1	63.1% reduction
Avg. Query Response Time (seconds)	47.2	31.6	17.4	63.1% reduction
Peak Throughput (rows/sec)	285,000	890,000	1,840,000	6.5x increase
Data Load Error Rate (%)	3.8%	2.1%	2.0%	47.4% reduction
PGA Memory Waste (%)	34.2%	18.7%	8.1%	76.3% reduction

Figure 3. Performance Comparison Across Evaluation Environments (Averaged)

4. Discussion

The experimental outcomes demonstrate considerable and multifaceted advantages over conventional PL/SQL ETL solutions. It should be noted that the level of improvement achieved – especially 6.5 times faster ETL processes and 63% query time reduction – is not provided by any specific approach; rather, the efficiency of this framework is attributable to the integrated use of bulk processing, flexible memory management, partition-aware processing, and metadata-based approach within the framework of transformations.

Another noteworthy finding is the substantial performance improvement observed in the banking workload. This environment showed the largest query time reduction, at 71%, despite having the lowest data volume among the testing environments. The analysis indicates that the banking data transformation workload involves very complex tasks of lookup, validation, and referencing due to customer profiles, account hierarchy, bank branch maps, product codes, transaction classification, and regulation- and risk-related reference tables. The integration of caching and dimension pre-loading proved particularly effective in reducing redundant lookup operations and queries and enabling fast transformation of account-, transaction-, customer-, and compliance-related data.

VII.LIMITATIONS

The use of Oracle and PL/SQL in the proposed framework results in limited portability, as it cannot be ported to another platform. This method is primarily focused on batch processing; therefore, integrating data in real time or via streams is difficult. The suggested solution requires knowledge of PL/SQL, making its implementation and maintenance technically complex. Even though the proposed framework improves performance when implemented in a single database, it lacks scalability when multiple databases are involved. Using database resources may limit performance if the hardware is underpowered.

VIII.FUTURE WORK

Future research should implement real-time and streaming capabilities, reduce Oracle dependency by ensuring cloud computing and platform independence, and increase scalability by integrating big data platforms such as Spark. Moreover, future research aims to incorporate AI-based optimization, improve data quality and governance, design user-friendly interfaces, and enhance security capabilities.

IX.CONCLUSION

This paper describes a new PL/SQL-based data transformation and optimization framework for enterprise data warehouses, designed to improve ETL efficiency through in-database processing. By leveraging Oracle's capabilities, such as PL/SQL procedures, BULK COLLECT, FORALL, indexing, partitioning, and parallelism, the proposed framework reduces data movement and improves performance. The multi-layered framework, comprising data ingestion, transformation, optimization, and storage layers, ensures systematic and efficient data processing. Experiments conducted in this paper and case studies have shown measurable improvements in processing time, resource utilization, data quality, and fault tolerance. In summary, this study offers effective solutions for high-volume Oracle-based workloads within enterprises. Even though the framework has some limitations regarding its reliance on a particular platform and its real-time capabilities, it provides a robust foundation for efficient ETL processing.

Abstract
Large Language Models (LLMs) have enabled the development of intelligent multi-agent systems capable of planning, collaborating, and making strategic decisions. Recent frameworks have demonstrated the feasibility of employing LLMs as autonomous agents in many domains. However, directly allowing language models to modify persistent environments introduces challenges, including hallucinated actions, invalid state transitions, and inconsistent world representations. These issues become particularly critical in geopolitical simulations, where every decision permanently affects future interactions. This paper presents MACSWC (Multi-Agent Conflict Simulation with World Constraints), a deterministic multi-agent framework designed for safe geopolitical simulation. Inspired by the Second Balkan War, it models sovereign-state agents that make diplomatic, military, and economic decisions using LLMs and operate under a layered validation architecture. Unlike existing systems that directly execute model outputs, MACSWC treats every LLM-generated action as a proposal requiring deterministic validation before execution. The framework consists of Country Agents for strategic reasoning, a Secretary Agent for structural validation, a Board Agent for strategic evaluation, and a centralized World Engine that maintains the authoritative simulation state. This separation between reasoning and execution improves consistency, prevents invalid state transitions, and enables reproducible experimentation across multiple language model providers. The proposed architecture contributes to a reusable framework for trustworthy autonomous simulations and demonstrates how deterministic governance can improve the reliability of LLM-based multi-agent systems.

Keywords: Large Language Models, Multi-Agent Systems, Autonomous Agents, Geopolitical Simulation, Deterministic Validation, AI Governance

I. INTRODUCTION

The rapid development of Large Language Models (LLMs) has transformed artificial intelligence by enabling systems capable of sophisticated reasoning, planning, and natural language understanding. Foundation models such as GPT-4 have demonstrated performance across a wide range of cognitive tasks, encouraging researchers to investigate their use as autonomous decision-making agents rather than conversational assistants alone [1], [2]. One of the fastest-growing research areas is Large Language Model Multi-Agent Systems (LLM-MAS), in which multiple autonomous agents cooperate or compete to solve complex problems. Frameworks such as CAMEL [3], AutoGen [4], MetaGPT [5], and Generative Agents [6] have shown that specialized LLM agents can collaborate effectively through role-based communication, allowing them to complete tasks beyond the capabilities of individual models. More recently, WarAgent demonstrated that autonomous LLM agents could simulate historical geopolitical conflicts through diplomatic negotiation and strategic decision-making [7].

Despite these advances, existing LLM-based systems remain fundamentally probabilistic. Language models may generate hallucinated information, malformed structured outputs, contradictory reasoning, or actions that violate environmental constraints [8]. While such errors may be acceptable in conversational applications, they become

problematic in persistent simulations where every decision modifies a shared world state. A single invalid action may introduce inconsistencies that propagate throughout the remainder of the simulation. Several approaches have attempted to improve reasoning quality through prompt engineering, role specialization, reflection, or self-correction [9-11]. Although these methods reduce reasoning errors, they do not guarantee that the generated actions satisfy the environment's logical or structural requirements. Consequently, the integrity of the simulation often remains dependent on the correctness of language model outputs. This paper introduces MACSWC (Multi-Agent Conflict Simulation with World Constraints), a deterministic framework that separates strategic reasoning from authoritative world-state management. Rather than allowing LLMs to modify the environment directly, MACSWC introduces multiple validation layers that evaluate every proposed action before execution. Country Agents generate strategic proposals, a Secretary Agent validates their correctness, a Board Agent evaluates strategic utility and risk, and a centralized World Engine performs all state modifications. The simulation environment is inspired by the Second Balkan War of 1913 and models interactions among Bulgaria, Serbia, Greece, Romania, and the Ottoman Empire. Although the historical setting provides a realistic geopolitical scenario, the primary contribution of this work is not historical reconstruction but the introduction of deterministic governance for autonomous LLM-based simulations. The contributions of this work are summarized as follows:

- A deterministic architecture that separates LLM reasoning from world-state authority.
- Layered validation pipeline consisting of Country Agents, a Secretary Agent, a Board Agent, and a World Engine.
- Configurable geopolitical simulation supporting diplomatic, military, and economic interactions.
- Model-independent framework compatible with multiple LLM providers.
- Reusable architecture for trustworthy multi-agent simulations.

The remainder of this paper is organized as follows. Section II reviews related research on LLM-based multi-agent systems and AI safety. Section III presents the MACSWC framework. Section IV describes the experimental evaluation, followed by the obtained results and conclusions.

II. RELATED WORK

Recent advances in LLM-based multi-agent systems have demonstrated that language models can cooperate to solve complex reasoning tasks. CAMEL introduced autonomous role-playing agents that collaborate through structured prompting [3], while AutoGen proposed conversational agents capable of iterative problem solving [4]. MetaGPT extended this concept by organizing agents into software engineering roles, demonstrating that role specialization improves task coordination [5]. Similarly, Generative Agents showed that LLMs can maintain memories, plan future activities, and interact realistically within persistent virtual environments [6]. Beyond collaborative reasoning, researchers have investigated the use of LLMs for strategic simulation. WarAgent is among the first large-scale attempts to simulate historical geopolitical conflicts using autonomous country agents [7]. The framework demonstrated that language models can produce coherent diplomatic negotiations and military strategies, enabling the exploration of alternative historical outcomes. However, the simulation's correctness remains strongly dependent on the outputs of the underlying language models. Ensuring the reliable behavior of autonomous language models has therefore become an important research topic. Constitutional AI [9], Reinforcement Learning from Human Feedback (RLHF) [10], ReAct [11], Reflexion [12], and Tree of Thoughts [13] improve reasoning quality through feedback, self-reflection, or structured planning. Although these approaches significantly reduce reasoning errors, they focus primarily on improving the language model itself rather than protecting the environment from incorrect outputs. The key distinction of MACSWC is the introduction of deterministic world-state governance. Rather than assuming that language model outputs are correct, every generated action is treated as a proposal that requires independent validation before execution.

This design separates probabilistic reasoning from authoritative state management, improving reproducibility while preventing hallucinated or logically inconsistent actions from modifying the simulation.

III. MACSWC FRAMEWORK

1. System Architecture

MACSWC is designed around the principle that Large Language Models perform reasoning but never directly modify the simulation state. Instead, every action generated by an LLM is interpreted as a proposal that must pass multiple deterministic validation stages before execution. This separation between reasoning and authority improves reliability while preserving the flexibility of autonomous decision-making. The framework consists of four primary components: Country Agents, a Secretary Agent, a Board Agent, and a centralized World Engine. Together, these components form a layered decision pipeline that validates every action before it affects the simulated environment. During each simulation round, Country Agents receive a structured observation describing the current geopolitical situation. Based on this information, each agent generates one strategic proposal. The proposal is then validated by the Secretary Agent, evaluated by the Board Agent, and, if all validation stages are completed, executed by the World Engine. Fig.1 illustrates the complete architecture.

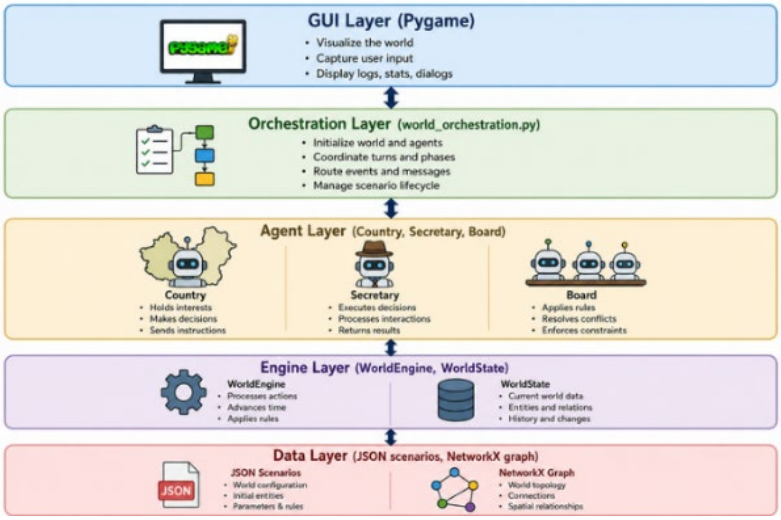

Figure 1. System Architecture.

2. Country Agents

Country Agents represent sovereign states participating in the simulation. Each agent operates independently and receives a structured observation containing diplomatic relations, military status, alliances, economic conditions, recent historical events, and currently available actions. Using this information, the agent selects one diplomatic, military, or economic action for the current simulation round. Supported actions include alliance formation, declarations of war, peace negotiations, sanctions, trade agreements, and diplomatic communication. MACSWC is model-independent and supports multiple LLM providers, including OpenAI, Groq, Hugging

Face, and Ollama. Since every model communicates through the same interface, different LLMs can be evaluated under identical simulation conditions.

3. Secretary Agent

The Secretary Agent performs deterministic validation before strategic evaluation. Its responsibilities include verifying the JSON structure, required parameters, the legality of actions, target countries, and compliance with the registered action set. Invalid proposals are rejected immediately, preventing malformed outputs or hallucinated entities from entering the simulation. This validation layer isolates common LLM failures from the remaining components and ensures that only structurally valid proposals proceed to strategic evaluation.

4. Board Agent

The Board Agent evaluates proposals that satisfy structural validation. The Board Agent estimates the strategic value of each proposal by considering diplomatic relationships, alliance structures, military conflicts, and crisis risk. A simplified utility function is used to determine whether the expected benefit outweighs the potential geopolitical cost:

$$U = W - \alpha R$$

where W denotes the estimated strategic benefit, R represents crisis risk, and α controls the influence of risk on the final utility score. Only proposals exceeding the approval threshold are forwarded to the execution layer.

5. World Engine

The World Engine represents the simulation's authoritative state and is the only component permitted to modify the environment. It maintains all countries, alliances, diplomatic relations, military conflicts, sanctions, treaties, and historical events. Before executing an approved proposal, the World Engine performs a final consistency check to ensure that the resulting state transition remains compatible with the current geopolitical situation. Centralizing all modifications prevents contradictory state transitions and guarantees that every Country Agent observes a consistent representation of the simulated world.

6. Decision Pipeline

Each simulation round follows the same deterministic workflow:

- The World Engine generates structured observations.
- Country Agents generate strategic proposals.
- The Secretary Agent validates structural correctness.
- The Board Agent evaluates strategic utility.
- The World Engine executes approved actions.
- The updated world state becomes the input for the following round.

Sequential execution ensures deterministic behavior while preventing conflicting updates that could occur during simultaneous execution.

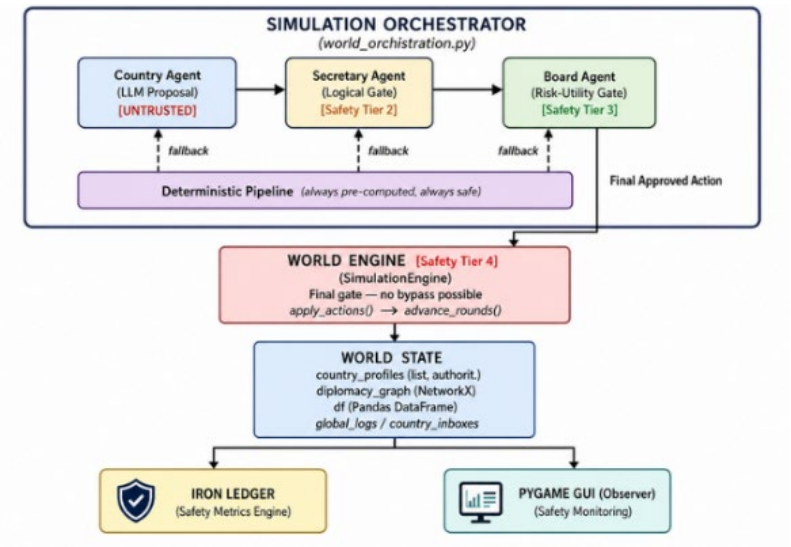

Figure 2. Layered software organization of MACSWC, illustrating the separation between the data, execution, agent, orchestration, and presentation layers to improve modularity and simplify future extension.

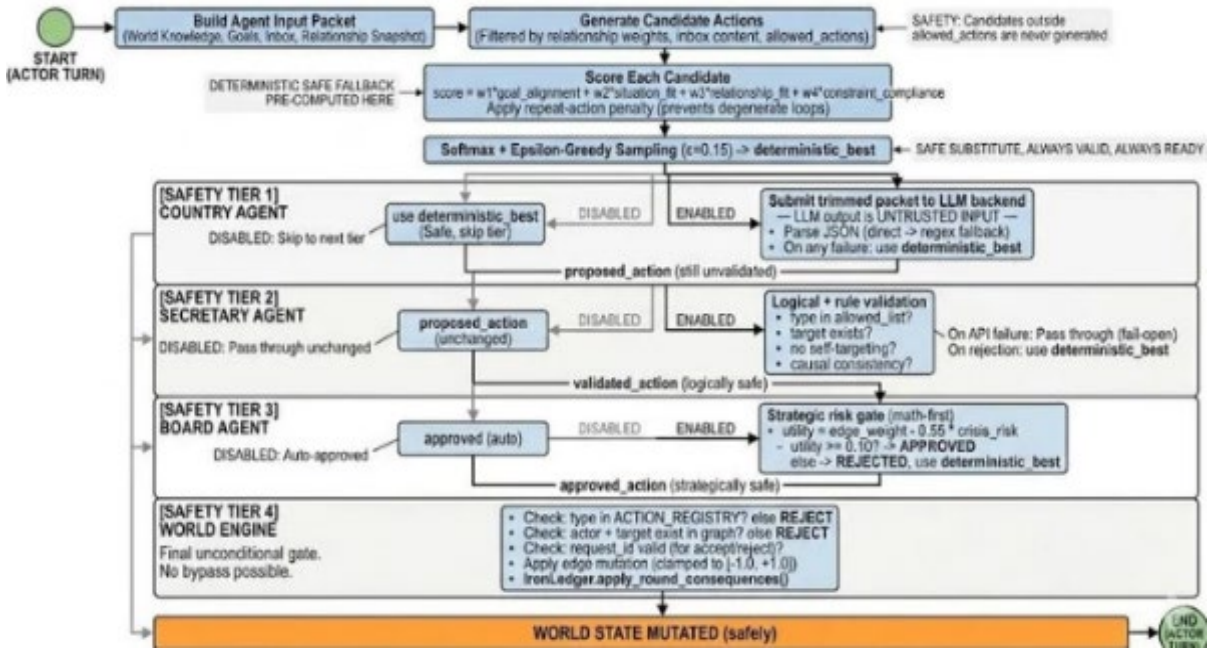

Figure 3. Deterministic decision pipeline illustrating proposal generation, validation, strategic evaluation, and authoritative world-state execution.

IV. EXPERIMENTAL SETUP

The MACSWC framework was implemented in Python 3 using a modular architecture. NetworkX was used to represent diplomatic relationship graphs, while JSON files maintained persistent world-state information. The modular implementation allows individual components to be replaced without modifying the remaining architecture. The evaluation scenario is inspired by the Second Balkan War of 1913 and includes five autonomous Country Agents representing Bulgaria, Serbia, Greece, Romania, and the Ottoman Empire. Each country independently generates strategic actions throughout multiple simulation rounds. The framework supports several LLM providers through a unified interface, including OpenAI GPT models, Groq-hosted models, Hugging Face inference endpoints, and locally deployed Ollama models. Since all models interact with the same deterministic validation pipeline, the architecture remains independent of the underlying reasoning model. The evaluation focuses on architectural reliability rather than prediction accuracy. During execution, the framework records accepted proposals, rejected proposals, alliance formation, military conflicts, diplomatic changes, crisis risk, and simulation stability. These metrics enable reproducible comparison between different simulation runs and language models.

Figure 4. Graphical user interface of MACSWC displaying the geopolitical map, diplomatic relationship graph, country status, and event log during a simulation round.

V. RESULTS AND DISCUSSION

The experimental evaluation demonstrates that deterministic governance substantially improves the reliability of autonomous LLM-based geopolitical simulations. The Secretary Agent successfully intercepted malformed outputs, unsupported actions, missing parameters, and hallucinated entities before they reached the execution layer. Consequently, structural errors generated by language models did not affect the simulation state. The Board Agent provided an additional safety mechanism by rejecting proposals associated with excessive geopolitical risk. Although structurally valid, several actions were prevented from executing because their estimated strategic cost exceeded the predefined approval threshold. This reduced unnecessary escalation while preserving adaptive strategic behavior. The World Engine maintained a consistent and reproducible simulation throughout all experimental rounds. Every accepted proposal satisfied structural, logical, and environmental

constraints before execution, preventing contradictory diplomatic relationships, duplicate alliances, and impossible military operations. Compared with recent LLM-based multi-agent frameworks such as CAMEL [3], AutoGen [4], MetaGPT [5], and WarAgent [7], MACSWC contributes deterministic world-state governance rather than improvements in reasoning capability. While existing systems primarily investigate autonomous collaboration, MACSWC demonstrates that separating reasoning from execution significantly improves simulation consistency without restricting the flexibility of language models. The modular architecture further enables future expansion through additional countries, alternative historical scenarios, richer economic systems, or different language model providers without requiring changes to the validation pipeline. Consequently, MACSWC serves not only as a geopolitical simulator but also as a reusable platform for trustworthy autonomous multi-agent research.

Table 1. Simulation Performance Metrics

Metric	**Value**
Simulation rounds	50
Actions generated	250
Accepted actions	201
Secretary rejections	31
Board rejections	18
World Engine rejections	0

VI. CONCLUSION

This paper presented MACSWC, a deterministic multi-agent framework designed to integrate Large Language Models into persistent geopolitical simulations safely. Unlike conventional LLM-based systems that directly execute model outputs, MACSWC separates strategic reasoning from authoritative execution via a layered architecture comprising Country Agents, a Secretary Agent, a Board Agent, and a centralized World Engine. Experimental evaluation demonstrated that deterministic validation improves simulation reliability by preventing malformed actions, logical inconsistencies, and invalid world-state transitions. The proposed architecture remains compatible with multiple LLM providers while maintaining a consistent and reproducible simulation environment. The principal contribution of MACSWC is the introduction of deterministic world-state governance for autonomous language model agents. By treating every generated action as a proposal that requires independent validation rather than as an executable command, the framework combines the reasoning capabilities of modern LLMs with the reliability of deterministic software systems. Future work will investigate broader geopolitical scenarios, adaptive strategic evaluation, and human-in-the-loop decision support to extend the framework's applicability further.

Abstract
Compressed Internet-of-Things intrusion detectors are usually evaluated by aggregate accuracy, which can mask failures during rare attacks. We audit a compact multilayer perceptron and quantized, pruned, and distilled variants on the full 46-million-flow CICIoT2023 dataset and TON_IoT. Per-class calibration is measured using adaptive expected calibration error and signed confidence gaps; explanation agreement is assessed using KernelSHAP against repeatability and retraining references, as well as through feature-deletion tests. Aggregate accuracy remains high, yet aggressive pruning causes rare-class overconfidence, attribution drift, and zero recall for Web and BruteForce attacks, which it predicts as benign. The attributions remain behaviourally faithful, indicating a change in feature reliance rather than an explainer failure. The pattern transfers across datasets and an independent split. Temperature scaling reduces calibration error but cannot recover lost recall. Compressed detectors should therefore be accepted only after per-class calibration, recall, and explanation-faithfulness checks.

Keywords: class imbalance, long-tail evaluation, intrusion detection, model compression, calibration, explainable AI, trustworthy machine learning.

I. INTRODUCTION

Modern IoT intrusion benchmarks are large and long-tailed. CICIoT2023 contains roughly 46 million flows [1], yet a few classes dominate while security-critical attacks occupy the tail. Aggregate accuracy and weighted F1 are therefore weak acceptance criteria: a detector can score well while failing on rare classes. This work tests whether compression conceals that failure. IoT intrusion detection systems (IDSs) are deployed on gateways with strict memory and compute budgets. Quantization, pruning, and knowledge distillation reduce deployment cost, but compressed models are commonly evaluated only by retained accuracy. Trust also requires calibrated confidence and faithful explanations: alerts should be probabilistically credible and traceable to the computation that produced them. We audit a compact multilayer perceptron (MLP) and five compressed variants on CICIoT2023 and TON_IoT [2]. Per-class calibration is paired with SHAP attribution agreement and deletion tests. Aggressive pruning preserves aggregate accuracy while rare attacks become over-confident, explanations drift, and some attacks are reassigned to benign. Temperature scaling improves calibration but not recall. Our contributions are: (1) a per-class audit that exposes long-tail failures hidden by aggregate metrics; (2) a paired calibration and explanation-faithfulness protocol with bootstrap intervals and repeatability/retraining references; and (3) evidence across two datasets and an independent split, including a benign blind spot, a feature-reliance shift, and a calibration-only remedy.

II. RELATED WORK

1. Lightweight and compressed intrusion detection

Model-compression techniques used for edge deployment include quantization [3], knowledge distillation [4], and pruning [5]. These foundational studies report favorable accuracy–cost trade-offs in general machine-learning settings; evidence specific to compressed IoT intrusion detectors remains limited. Pandey and Ye [6] further show that 8-bit integer (INT8) quantization can turn off backdoor defenses, even while attacks remain effective. We instead examine per-class calibration and explanation faithfulness of the deployed detector.

2. Calibration of neural networks and security models

Neural networks can be overconfident [7], and temperature scaling is a simple post hoc remedy. In imbalanced security data, aggregate calibration can conceal confident errors on rare attacks. We therefore report adaptive expected calibration error and a signed per-class confidence gap.

3. Explanation of faithfulness and stability

SHAP (SHapley Additive exPlanations) [8] is widely used for intrusion-detector interpretation. Security studies evaluate the quality of explanations [9]; Kalakoti et al. [10] compare SHAP, Local Interpretable Model-agnostic Explanations (LIME), Integrated Gradients [11], and DeepLIFT for network intrusion alerts. Interpretations can be fragile [12]. Adversarial behavior can be implemented using the Adversarial Robustness Toolbox (ART) [13], demonstrated with one-pixel perturbations [14], and it affects intrusion detectors [15]; Rajhans and Khawarey [16] directly analyze cybersecurity explanation drift. We study compression, compare against repeatability/retraining references, and verify attribution faithfulness through feature deletion.

III. METHODOLOGY

1. Datasets and labels

CICIoT2023 [1] is the primary benchmark: approximately 46 million flows, 33 attack types mapped to seven groups plus benign, and 46 features. In its test partition, distributed denial-of-service (DDoS) exceeds 5 million flows, whereas Web and BruteForce contain 3,724 and 1,960, respectively. The TON_IoT network subset [2] contains 461,043 flows, a normal class plus nine attacks, and 74 post-processed features. We remove identity-revealing fields, coerce missing markers, one-hot encode low-cardinality categories, use locked stratified splits, fit scaling only on training data, and apply tempered square-root inverse-frequency class weights. No resampling is used, preserving calibration.

2. Model and compression matrix

The anchor is a compact MLP with 128- and 64-unit hidden layers, batch normalization, dropout, and 15,304 parameters. Seed zero is specified as the reference before trust analysis. Quantized variants use TensorFlow Lite (TFLite) dynamic-range INT8 and float16; pruned variants use fixed 50% and 80% magnitude masks with fine-tuning. The distilled student has 3,632 parameters and combines softened teacher logits with hard labels. Quantization and pruning retain the anchor architecture; distillation changes the student architecture and is therefore interpreted as a combined change in architecture and compression. Pruning is evaluated as sparsification and does not reduce dense file size.

3. Calibration measurement

Calibration is measured with adaptive, equal-mass expected calibration error (ECE) at 10, 15, and 20 bins and a signed gap, mean confidence minus accuracy, where positive values indicate over-confidence. Metrics are reported per class, with bootstrap 95% confidence intervals for the signed gaps. Point estimates use all observations. A single temperature is fitted on validation data and evaluated on the locked test set.

4. Explanation of the faithfulness measurement

KernelSHAP is applied via a single probability interface to every model, using 80 seeded instances per class, a fixed k-means background, and 1,500 samples. Attributions target each instance's true class. Agreement is the per-instance Spearman correlation with the anchor, interpreted against a same-model repeatability reference and independently seeded retraining reference. Drift is declared only when its bootstrap interval lies below the retraining reference. Faithfulness is tested by deleting top-ranked features across three maskers and comparing the drop in true-class probability with that from random deletion. Web and BruteForce estimates are interpreted with caution because each uses 80 explained instances, and baseline recall is low.

5. Reproducibility

All splits and stochastic stages use fixed seeds. The scaler is fitted on training data only, the anchor is fixed before the trust analysis, and identical calibration and explanation protocols are applied across variants and datasets. Analysis artifacts and environment specifications are retained to support regeneration of the reported results.

IV. RESULTS

1. Accuracy and aggregate calibration are retained

Table 1 shows that accuracy stays near 0.99 except for INT8 (0.937), including 0.978 under 80% pruning. Macro F1 falls from 0.772 to 0.541, exposing rare-class loss. Only quantization and distillation reduce file size; pruning leaves dense storage unchanged.

Table 1. Compression outcomes: pruning zero weights without reducing the dense file size.

Model	Size (MB)	Macro-F1	Accuracy
Baseline (M0)	0.217	0.772	0.992
50% pruning	0.217*	0.720	0.991
80% pruning	0.217*	0.541	0.978
Distilled student	0.039	0.703	0.990
INT8 quantisation	0.021	0.691	0.937
Float16 quantisation	0.033	0.772	0.992

Aggregate ECE is also reassuring, increasing only from 0.003 to 0.014 under 80% pruning. The per-class results below show why this aggregate is insufficient.

2. Per-class calibration collapses on the rare classes

Table 2 shows the signed confidence gap. Under 80% pruning, Web rises from 0.044 to 0.575, BruteForce from 0.171 to 0.600, Spoofing from 0.007 to 0.412, and Recon from 0.032 to 0.395; DDoS, DoS, and Mirai change little. Figure 1 summarises aggregate ECE and attribution drift across variants relative to the retraining reference.

Table 2. Per-class signed confidence gap with bootstrap 95% confidence intervals (CIs) on CICIoT2023.

Class	Baseline gap [95% CI]	80% pruning gap [95% CI]
Benign	−0.120 [−0.122, −0.118]	−0.333 [−0.335, −0.333]
DDoS	−0.001 [−0.001, 0.000]	−0.010 [−0.010, −0.009]
DoS	0.000 [0.000, 0.001]	−0.041 [−0.042, −0.039]
Mirai	0.000 [−0.001, 0.000]	0.006 [0.005, 0.006]
Recon	0.032 [0.028, 0.035]	0.395 [0.390, 0.398]
Spoofing	0.007 [0.004, 0.010]	0.412 [0.410, 0.415]
Web	0.044 [0.030, 0.058]	0.575 [0.571, 0.578]
BruteForce	0.171 [0.154, 0.187]	0.600 [0.596, 0.604]

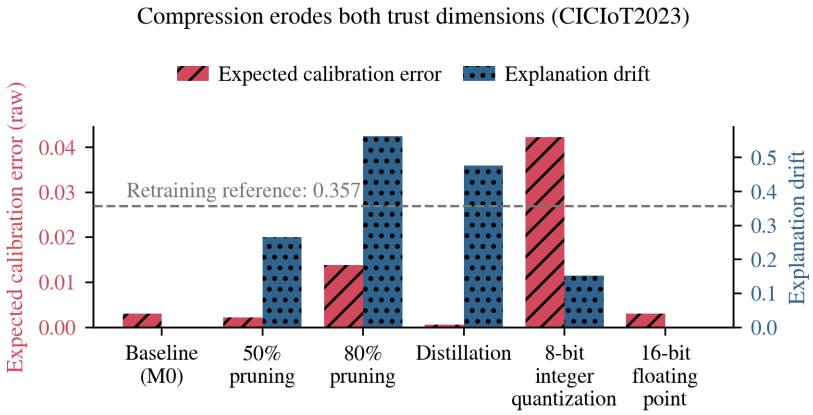

Figure 1. Aggregate expected calibration error and explanation drift by compression variant (CICIoT2023); M0 is the baseline, and the band is the retraining reference.

3. Explanations drift from the baseline but stay behaviourally faithful

Table 3 reports attribution agreement. The same-model repeatability reference is 0.773, and the retraining reference is 0.643. Agreement under 80% pruning (0.437) and distillation (0.524) lies below the retraining

reference, whereas float16 is effectively unchanged (0.999). In Figure 2, deleting top SHAP-ranked features produces a larger true-class probability drop than random deletion for both the anchor and pruned model. Compression changes feature reliance, but the resulting attributions remain behaviourally faithful.

Table 3. Attribution agreement with the baseline on CICIoT2023.

Comparison	Spearman [95% CI]	Below retraining reference
Same-model repeatability	0.773 [0.764, 0.782]	—
Retraining reference	0.643 [0.635, 0.651]	—
50% pruning	0.735 [0.723, 0.745]	No
80% pruning	0.437 [0.418, 0.455]	Yes
Distilled student	0.524 [0.510, 0.538]	Yes
INT8 quantisation	0.847 [0.833, 0.861]	No
Float16 quantisation	0.999 [0.998, 1.000]	No

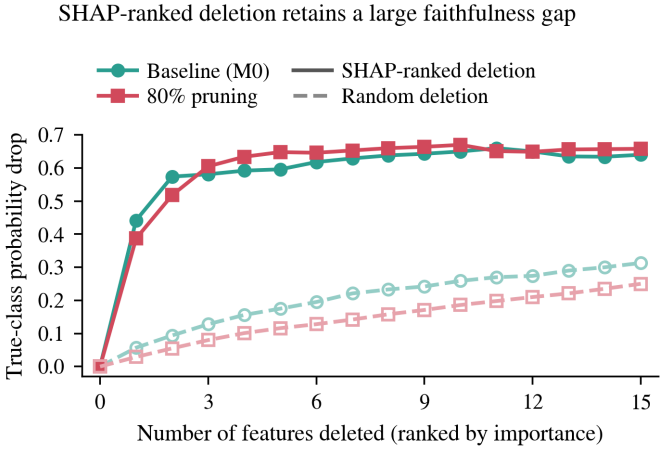

Figure 2. True-class probability drops after deleting SHAP-ranked or random features.

4. Calibration loss and explanation drift co-occur on the rare classes

Rare classes show both the largest confidence gaps and the lowest attribution agreement. Across eight classes, confidence gap and explanation drift correlate (Pearson r = 0.87, p = 0.005); after controlling for class size, the association is weaker (partial r = 0.64, p = 0.122). Within classes, per-instance over-confidence and drift are nearly unrelated (pooled Spearman rho = 0.04). The evidence, therefore, supports class-level co-occurrence through shared difficulty, not a common instance-level mechanism.

5. The benign blind spot

Table 4 and Figure 3 expose the most consequential failure. Baseline recall for Web and BruteForce is already limited (0.428 and 0.335), but 80% pruning reduces both to zero and predicts 95–96% of them as benign.

Spoofing and Recon also lose most recall to benign, while high-volume classes remain stable. Thus, a compressed detector can confidently miss rare attacks even as aggregate accuracy remains 0.978.

Table 4. Rare-class recall under 80% pruning on CICIoT2023.

Class	Baseline recall	80% pruning recall	Mostly predicted as
Web	0.428	0.000	Benign (0.95)
BruteForce	0.335	0.000	Benign (0.96)
Spoofing	0.769	0.147	Benign (0.85)
Recon	0.704	0.232	Benign (0.73)

Aggregate structure masks rare-class recall collapse under 80% pruning (CICIoT2023).

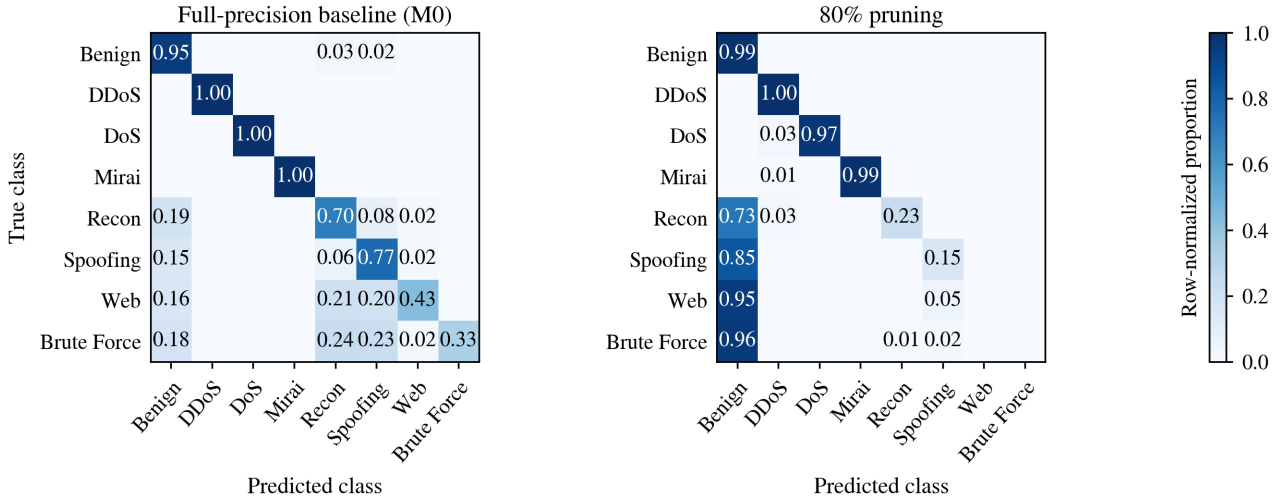

Figure 3. Row-normalized confusion matrices for the baseline and 80% pruning.

6. The pattern transfers to TON_IoT

The pattern transfers to TON_IoT (Figure 4). Aggregate ECE rises from 0.053 to 0.130 under 80% pruning; the largest confidence gap is Ransomware (0.668). Attribution agreement under pruning (0.451) and distillation (0.377) is below the 0.610 retraining reference, with the greatest drift on hard classes such as Injection, DoS, and Man-in-the-Middle. CICIoT2023 shows the same direction: ECE 0.003 to 0.014, worst gap 0.600, and pruning agreement 0.437 below its 0.643 reference.

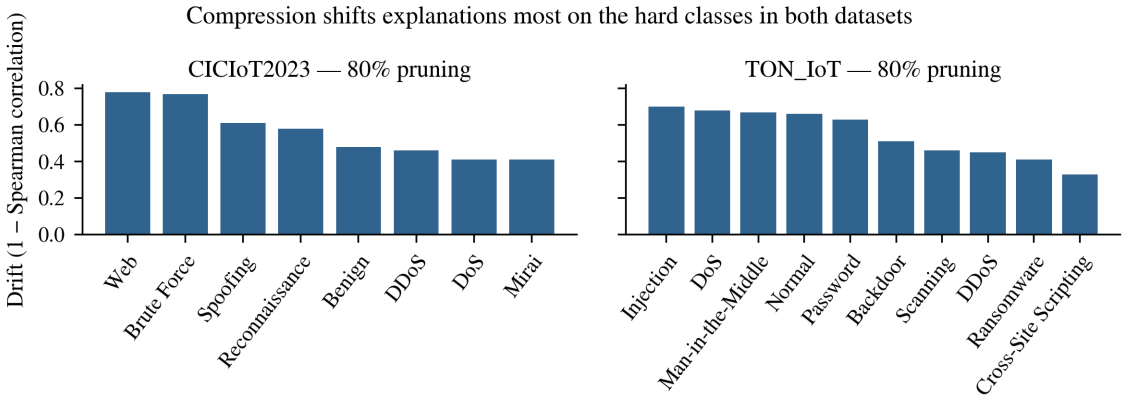

Figure 4. Per-class explanation drift under 80% pruning on CICIoT2023 and TON_IoT.

Dynamic-range INT8 is unstable on TON_IoT's 74-feature space, producing a degenerate fitted temperature; it is excluded from TON_IoT calibration reporting but retained in the attribution analysis. Pruning and distillation drive the cross-dataset conclusion.

7. Robustness and mechanism

An independent stratified split reproduces the pruning gaps (Web 0.585, BruteForce 0.589, Spoofing 0.558, and Recon 0.343), supporting split stability but not temporal generalization. Grouped SHAP importance also shifts modestly from packet-size statistics toward coarse flow-timing features under pruning, offering a candidate explanation for attribution drift.

8. A cheap remedy recovers calibration

Temperature scaling approximately halves CICIoT2023 ECE for 80% pruning (0.014 to 0.007) and INT8 (0.042 to 0.018), as Figure 5 shows. On TON_IoT, it helps every retained variant except distillation (0.063 to 0.084). Rescaling cannot restore rare-class recall because that loss reflects the decision boundary rather than confidence scaling.

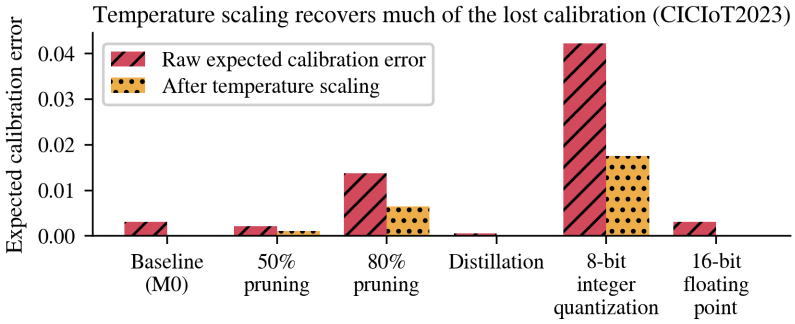

Figure 5. Expected calibration error before and after temperature scaling on CICIoT2023.

V. DISCUSSION

Aggregate accuracy is the most compression-resistant metric and, therefore, a poor proxy for security risk. Aggressive pruning produces over-confident rare-class failures, and shifts feature reliance; in the extreme, attacks are labeled benign and generate no alert. Per-class recall, calibration, and explanation behavior must therefore be reviewed together. Calibration loss and attribution drift co-occur on difficult classes but are not coupled within instances. Deletion tests show that explanations continue to track the compressed model, while the feature-family analysis suggests that pruning moves the model toward coarser timing signals. These findings support an operational association, not a single causal mechanism. Float16 is the safest tested option when trust is the priority: it is about seven times smaller with negligible trust loss. Distillation exhibits significant attribution drift and should be used only when a separately measured deployment benefit justifies its use. INT8 requires per-class calibration checks, and 80% pruning should be avoided where rare-class detection matters. Recommendations are based on file size and trust metrics; latency and energy were not measured.

VI. LIMITATIONS AND FUTURE WORK

The study fixes one MLP family to isolate the effects of quantization and pruning; the distilled student also changes its architecture. Split stability does not establish temporal or subtype-group generalization, and the TON_IoT INT8 calibration result is unstable. Model size is measured, but edge-device latency and energy are not. KernelSHAP uses 80 instances per class, so estimates for rare classes and any proposed feature-shift mechanism require further confirmation. Future work should test convolutional and recurrent detectors, full-integer per-channel quantization, temporal and subtype-grouped splits, larger explanation samples, and on-device latency and energy. A targeted causal study could determine whether calibration loss and attribution drift share a mechanism.

VII. CONCLUSION

Compressed IoT intrusion detectors can retain headline accuracy while becoming overconfident and misclassifying rare attacks as benign. Attribution drift remains behaviourally faithful, showing that compression changes the model's reliance rather than merely breaking the explainer. Temperature scaling reduces much of the confidence error, but not the recall error. Deployment decisions should therefore use per-class recall, calibration, and explanation-faithfulness checks against repeatability and retraining references, rather than aggregate accuracy alone.

Abstract
Cyberattacks are becoming more frequent and technically sophisticated, posing serious risks to organizations across different sectors and regions. In this paper, we conduct an exploratory case study of cybersecurity incident information from 2015 to 2024, using exploratory data analysis, visual analytics, linear trend testing, and statistical testing. The work is built on a publicly available Kaggle dataset containing 3,000 cybersecurity incident records. The study examines temporal patterns, attack types, affected industries, derived severity levels, and temporal changes within the selected dataset. Since the dataset does not include a predefined severity variable, severity levels were derived from financial loss values and grouped into four quartiles: Low, Medium, High, and Critical. Simple linear regression was used to estimate the temporal trend in annual incident counts. At the same time, chi-square tests were applied to examine whether derived severity was associated with attack type and target industry. The results show a weak positive temporal trend, but the linear trend itself does not reach statistical significance. Within the analyzed dataset, sectors such as IT, banking, healthcare, and government appeared to have greater exposure to high-severity records. These findings highlight how useful data-driven visualizations and statistical analytics can be for cybersecurity awareness, risk interpretation, and mitigation planning. However, the conclusions should be interpreted as exploratory and dataset-dependent, rather than as a complete or comprehensive representation of real-world global cybersecurity threat patterns.

Keywords: cybersecurity threats, cyberattack trends, exploratory data analysis, visual analytics, severity analysis, cyber risk assessment, mitigation strategies

I. INTRODUCTION

The increasing dependence of modern society on digital systems has made cybersecurity a major organizational and societal concern. Organizations rely on interconnected networks to store sensitive data, perform financial transfers, and maintain essential services. Digitalization tends to increase efficiency and ease of access, but it also brings vulnerabilities that malicious users can exploit to their advantage [1]. When a cyber incident occurs, it can lead to financial losses, information leaks, service disruptions, and reputational damage [2], especially in critical areas such as finance, healthcare, government, and infrastructure [3]. Data-driven cybersecurity analytics can help uncover temporal patterns, attack categories, sector-specific exposures, and severity levels. Still, the reliability of the results largely depends on how the dataset is constructed, such as its quality and structure. Public datasets may not accurately reflect the distribution of real-world incidents, but they are still commonly used for research, visualization, and methodological demonstration. In this paper, we present an exploratory case study using a publicly available Kaggle cybersecurity dataset covering the period 2015-2024. The study conducts exploratory data analysis, visual analytics, linear trend analysis, severity classification, and chi-square testing to

examine how cybersecurity incidents emerge and evolve within the selected dataset. This study examines temporal trends in cybersecurity incident records, the exposure of different attack types and industry sectors to severe incidents, and the role of visual and statistical analytics in interpreting cybersecurity patterns. It also formulates risk-oriented mitigation recommendations based on patterns in the observed dataset. The novelty of this study lies in combining visual analytics, a derived financial-impact severity classification, linear trend analysis, and chi-square testing within a single exploratory framework for interpreting cybersecurity incidents.

The main contributions of the paper are as follows:

- Exploratory analysis of cybersecurity incident records covering the period from 2015 to 2024.
- A visual and statistical assessment of temporal trends, attack types, sectors, and derived severity levels.
- Chi-square testing, focusing on the association between derived severity level, attack type, and target industry.
- Risk-oriented mitigation recommendations, based on observed data patterns and relevant cybersecurity literature.

II. DATA ANALYSIS AND METHODOLOGY

1. Dataset Description and Preprocessing

This study uses the publicly available Kaggle dataset "Global Cybersecurity Threats 2015–2024" [4], which includes 3,000 cybersecurity incident records spanning 2015 to 2024. The dataset includes fields for country, year, attack type, target industry, financial loss in millions of dollars, number of users affected, attack source, security vulnerability type, defense mechanism, and incident resolution time. The dataset is used as the empirical data source for exploratory analysis and is not treated as independent evidence of the prevalence of real-world global cybersecurity threats. First, the structure of the dataset and variable types are examined. The records are organized by year, attack type, target industry, and country to aid in descriptive and statistical analysis. Annual incident counts and temporal patterns across attack categories were calculated by grouping the records by year and attack category. Since the data set does not include a predefined severity variable, the severity level was derived from the amount of financial loss. The values were divided into four quartile-based groups: Low, Medium, High, and Critical. These categories are intended to reflect the relative financial impact within this specific data set only. Therefore, they should not be interpreted as universal cybersecurity severity thresholds. The processed data were used for descriptive visualization, linear trend analysis, and chi-square testing. The applied statistical procedures follow standard formulations of simple linear regression, chi-square testing, expected-cell calculation, and Cramér's V effect-size estimation. The dataset is publicly available and does not come from an official incident reporting body, so the findings are considered exploratory and dependent on the dataset itself. In addition, the derived severity variable reflects only the financial impact. It does not capture the broader severity of the incident, including factors such as downtime, data sensitivity, affected users, recovery costs, and operational disruption.

2. Exploratory Data Analysis and Visualization

This subsection presents the results of the exploratory data analysis, focusing on temporal evolution, industry-level distributions, attack-type distributions, derived severity patterns, and temporal patterns across attack categories within the analyzed dataset.

3. Exploratory Linear Trend Analysis

To examine the overall time trend in the selected dataset, a simple linear regression was performed to complement the descriptive analysis of the annual cybersecurity incident records. The annual number of incident records was the dependent variable, and the year was the independent variable. The goal of this analysis was not to develop a predictive model, but rather to provide statistical support for the visual interpretation of the temporal pattern presented in Figure 1. Ordinary linear regression was used only as an exploratory summary of the annual count pattern, and the results are interpreted with caution because the analysis is based on only 10 annual observations. Between 2015 and 2024, the annual number of incident records ranged from 263 to 319. The linear regression had a positive slope of approximately 2.56 incident records per year, indicating a modest increasing trend across the dataset.

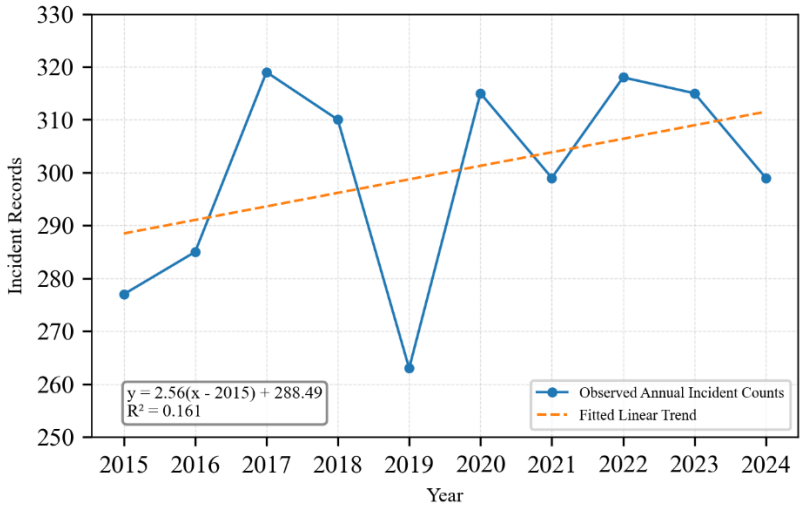

Figure 1. Annual Cybersecurity Incident Records with Exploratory Linear Trend (2015–2024)

Figure 1 presents the observed annual incident counts together with the values predicted by the fitted linear regression model. The observed counts fluctuate considerably, including a noticeable decrease in 2019 and higher values in several subsequent years. The fitted regression slope was 2.56 incident records per year, with a 95% confidence interval of [−2.21, 7.32]. The estimated trend was not statistically significant ($t(8) = 1.237$, $p = 0.251$), and the coefficient of determination was relatively low (büyük harf R kare = 0.161). Thus, this analysis does not provide sufficient statistical support for a consistent increase in annual cybersecurity incident records for the selected dataset. Although the fitted line has a positive slope, the results suggest only a rather weak positive temporal trend. This interpretation is somewhat consistent with the cybersecurity literature describing the persistence and continuous evolution of cyber threats [1], [2]. However, the results should be treated as exploratory and dataset-specific and should not be generalized to real-world global cybersecurity incident trends. Figure 2 presents the normalized percentage distribution of cybersecurity incident records across major industries and derived severity levels for the period 2015–2024. Unlike the raw-count yearly visualization, this figure summarizes the relative severity composition within each industry across the full dataset. The results indicate sector-specific variation in the proportions of Low, Medium, High, and Critical severity categories.

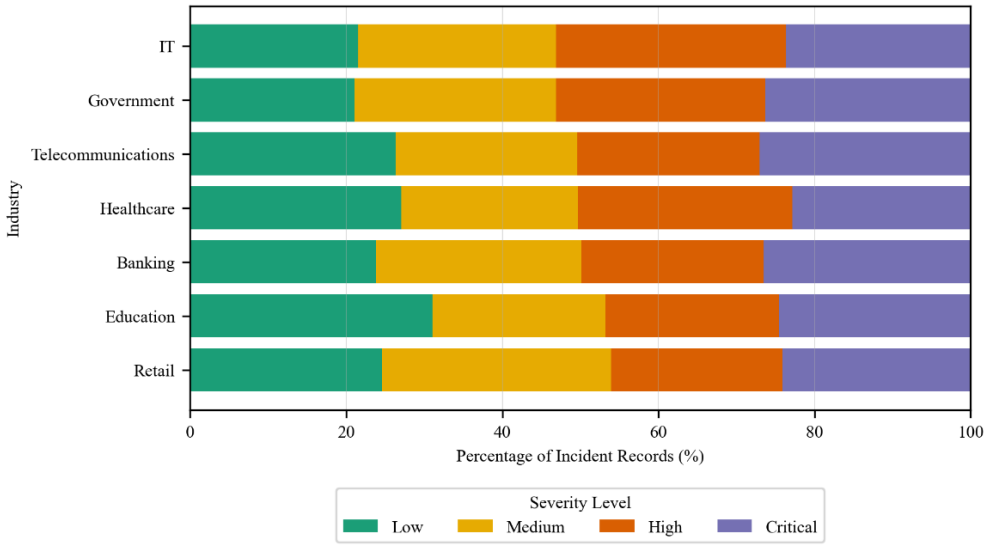

Figure 2. Normalized Distribution of Cybersecurity Incident Records by Industry and Derived Severity Level for the Period 2015–2024

These results suggest that sector-specific cybersecurity risk assessment remains important, especially for industries where cybersecurity incidents may lead to financial, operational, or public-service consequences [3], [5]. However, this interpretation is specific to the analyzed dataset because severity levels are derived from financial loss values.

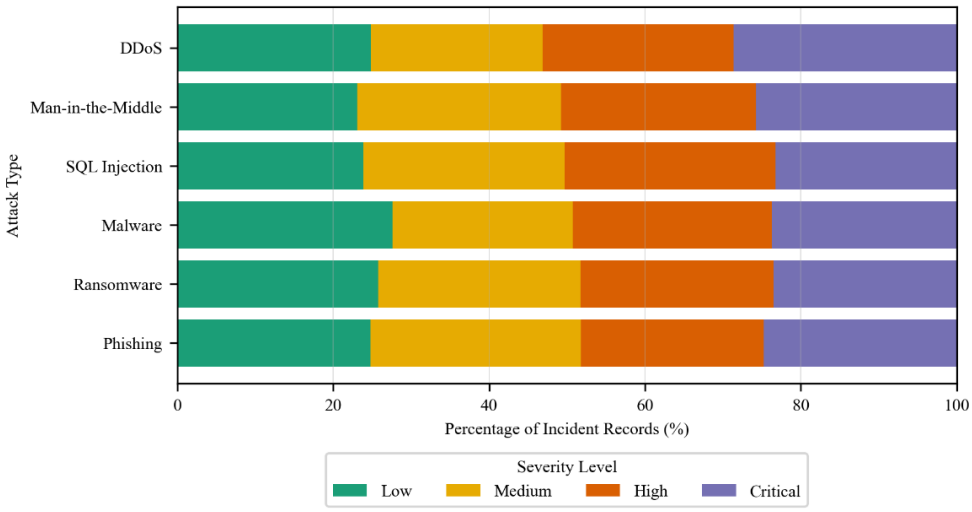

Figure 3. Normalized Distribution of Cybersecurity Incident Records by Attack Type and Derived Severity Level for the Period 2015–2024

Figure 3 presents the normalized percentage distribution of cybersecurity incident records across attack types and derived severity levels for the period 2015–2024. Unlike the raw-count yearly visualization, this figure summarizes the relative severity composition within each attack category across the full dataset. The results

indicate variation in the proportions of Low, Medium, High, and Critical severity categories across different attack types.

These results suggest that interpreting cybersecurity risk should not rely solely on the number of attack records, but also on their derived severity and potential operational impact. However, because financial loss values define severity in this study, these findings should be interpreted in the context of and with the limitations of the selected dataset.

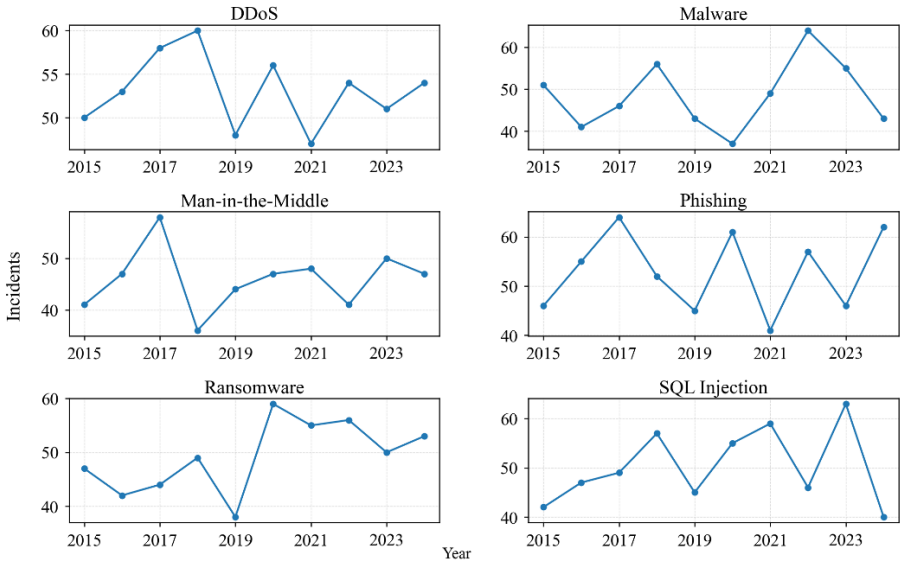

Figure 4. Temporal Evolution of Major Cyberattack Types (2015–2024)

Figure 4 presents the temporal evolution of six major cyberattack types from 2015 to 2024. The attack categories follow different yearly patterns: phishing and malware remain consistently present, while ransomware records have increased after 2020. DDoS and SQL injection show considerable fluctuations, indicating uneven temporal patterns across attack types. These findings support the importance of continuous monitoring and adaptive, multi-layered defense strategies. However, the observed patterns are dataset-specific and should be validated using real-world threat intelligence or official cybersecurity reports.

4. Statistical Analysis of Severity Patterns

To further examine severity patterns within the analyzed dataset, a chi-square test of independence was applied. The aim was to determine whether the derived severity level was statistically associated with attack type and target industry. Since the dataset did not include a predefined severity variable, severity levels were derived from financial loss values and grouped into four quartiles: Low, Medium, High, and Critical. Cross-tabulation was used to compare the distribution of derived severity levels across attack types and target industries. The chi-square test was then applied to determine whether the observed differences were statistically significant. In addition to chi-square values and p-values, degrees of freedom, sample size, Cramér's V, and expected-cell diagnostics were reported to provide a more complete statistical interpretation. The results are summarized in Table 1.

TABLE 1. CHI-SQUARE TEST RESULTS FOR SEVERITY ASSOCIATIONS

Tested relationship	χ^2	df	p-value	Cramér's V	Expected cells	Result
Attack Type vs Severity Level	12.15	15	0.667	0.037	all ≥ 5	Not significant
Target Industry vs Severity Level	30.32	18	0.034	0.058	all ≥ 5	Significant

The results show no statistically significant association between attack type and the derived severity level (χ^2 = 12.15, df = 15, p = 0.667). The corresponding Cramér's V value of 0.037 indicates a very weak association. This suggests that within the analyzed dataset, differences in severity are not strongly associated with attack categories alone. This does not mean that attack type is irrelevant in the actual assessment of cybersecurity risk. The result may be influenced by the dataset's structure, its balance, and the distribution of observations across the selected groups. There is a statistically significant relationship between the target industry and the derived severity level (χ^2 = 30.32, df = 18, p = 0.034). The corresponding Cramér's V value of 0.058 also indicates a weak association, suggesting that the statistical association should be interpreted cautiously. These results indicate that sector context may be relevant to interpreting cybersecurity risk in the analyzed dataset, though this requires validation with larger, more realistic incident datasets.

III. DISCUSSION: CYBERSECURITY INCIDENT INTELLIGENCE

The results presented in Section II suggest that, within the analyzed dataset, cybersecurity incident records remain persistent, diverse, and partly sector-dependent. This discussion interprets the key findings of the analyzed dataset in relation to relevant cybersecurity literature and selected global threat reports. The main goal is to clarify how incident frequency, derived severity levels, sector exposure, and the evolution of attack types can inform the interpretation of cybersecurity risk. However, this section remains quite dataset-specific, as the analysis relies on a publicly available dataset and derives severity levels from financial loss values.

1. Growth Trends, Severity, and Sectoral Risk

Trend analysis suggests that, within the analyzed dataset, cybersecurity incident records remained relatively high throughout the study period. Although the number of records varies from year to year, the overall pattern does not indicate a clear long-term decline. This supports the interpretation of cybersecurity threats as continuous risks rather than isolated events. However, the observed trend should be understood as dataset-specific rather than a complete representation of real-world global cybersecurity activity. Similar concerns regarding the persistence and evolution of cybersecurity threats have been discussed in global cybersecurity perspectives and threat assessment reports [6], [7]. In the dataset examined, distributed denial of service (DDoS) attacks are among the most frequent attack categories and are also associated with several high- or critical-severity levels. Sector analysis suggests that highly digitalized IT environments may be exposed to DDoS-related risks due to their high reliance on online services and digital infrastructure. Organizations that rely heavily on digital services may be more vulnerable to volumetric attacks and service disruption. Severity-based analysis shows that, within the examined dataset, IT, banking, healthcare, and government are among the sectors with higher proportions of high-severity records. Because these sectors often handle sensitive data, conduct financial operations, and support essential public services, cybersecurity incidents may have substantial consequences. The IT sector is particularly important because cybersecurity incidents affecting IT providers may have cascading effects on other organizations through supply chains and interconnected systems. Previous research on critical infrastructure also highlights the importance of adaptive and intelligent cybersecurity mechanisms [8]. From a temporal perspective, records for different attack types follow different patterns over time. Within the dataset, ransomware records increase after 2020, consistent with the broader

literature on ransomware evolution and financially motivated cybercrime [9], [10]. However, the observed trend alone is insufficient to establish a causal relationship. SQL injection and Man-in-the-Middle incident records exhibit more variable temporal patterns and may be associated with software misuse and the exploitation of network vulnerabilities. These results reinforce the need for continuous monitoring, secure software engineering, timely patch management, and adaptive detection-oriented security strategies [5], [11]. According to the findings, even in a research dataset, the interpretation of cybersecurity risk should not rely solely on incident frequency. The derived severity level, the affected sector, the geographical context, and the growth patterns of attacks allow for a more complete risk-oriented interpretation. This supports the use of data-driven cybersecurity analytics as a decision-support approach within modern risk management frameworks [5], [12]. At the same time, the results highlight the need for validation using larger, more realistic, and independently verified cybersecurity incident datasets.

IV. RISK-ORIENTED MITIGATION RECOMMENDATIONS BASED ON OBSERVED DATASET PATTERNS

Based on observed data patterns, derived severity levels, and sector-specific exposures, this section presents risk-oriented mitigation recommendations informed by the existing cybersecurity literature. These recommendations were not experimentally evaluated in this study; rather, they were derived from research findings and established cybersecurity practices. Therefore, they should be interpreted as practical recommendations rather than mitigation strategies validated by the data set. For DDoS-related risks, organizations should consider traffic filtering, cloud-based mitigation, load balancing, and network redundancy to maintain service availability [1], [13]. Phishing mitigation should combine technical filtering measures, email authentication practices, URL reputation analysis, and continuous user awareness training [2], [14]. Ransomware protection should include strict access control, offline or immutable backups, endpoint detection and response, and network segmentation as part of broader cybersecurity risk management and resilience planning [1], [5], [10]. SQL injection risks should be addressed through secure software development practices, including parameterized queries, input validation, application security testing, vulnerability scanning, and timely patch management [15]. For Man-in-the-Middle risks, organizations should enforce HTTPS and TLS, use end-to-end encryption where appropriate, and strengthen monitoring for unauthorized access points as part of broader cybersecurity risk management practices [5], [16]. Since the IT, banking, healthcare, and government sectors showed higher proportions of high-severity records in the analyzed dataset, these sectors should prioritize sector-specific risk assessment, supply chain security checks, and multi-layered cybersecurity controls [5], [6], [8].

V. CONCLUSION AND FUTURE WORK

This paper presented an exploratory analysis of a publicly available cybersecurity incident dataset spanning 2015 to 2024. The analysis used exploratory data analysis, visualization, derived severity classification, and statistical testing to examine temporal patterns, attack categories, affected sectors, and severity-related associations within the selected dataset. The exploratory linear trend analysis identified a weak positive trend, but it was not statistically significant. In the analyzed dataset, attack categories such as DDoS, phishing, malware, and ransomware appear as persistent, evolving incident records. Within the examined dataset, the sectors with higher proportions of high-severity records included IT, banking, healthcare, and government. This may be related to their dependence on digital services, sensitive data, and critical operations. However, these findings should be interpreted as dataset-specific and should not be treated as a complete representation of real-world global cybersecurity threat trends. The findings suggest that cybersecurity risk interpretation should not rely only on incident frequency. Derived severity levels, sector exposures, geographic distributions, and

temporal patterns across attack categories should also be considered. The chi-square analysis showed that, within the analyzed dataset, the target industry is significantly associated with the derived severity level, whereas attack type alone is not statistically significant. This underscores the importance of sector-specific risk assessment and calls for validation against larger, more realistic incident datasets. This study has several limitations. First, the analysis is based on a publicly available Kaggle dataset, which may not fully represent real-world cybersecurity incident distributions. Second, the severity classification was derived solely from financial loss values and does not capture other important factors, such as downtime, data sensitivity, affected users, recovery costs, or operational disruption. Third, the quartile-based severity classification is relative to the selected dataset and may lead to threshold-dependent interpretations. A full sensitivity analysis using alternative severity thresholds is left for future work due to space limitations and the exploratory scope of this conference paper. Finally, the proposed mitigation recommendations were not experimentally tested but were derived from observed patterns in the dataset and supported by existing literature. Future work should validate the findings using larger and more realistic incident datasets, official cybersecurity reports, real-time threat intelligence feeds, and sector-specific incident records [17]. Future studies should also examine the sensitivity of the severity classification by applying alternative thresholds, such as fixed financial-loss intervals, domain-informed thresholds, or composite severity scores that combine financial loss, affected users, and incident resolution time. In addition, predictive analytics and machine learning models could be explored to support more advanced cyber risk assessment.

Abstract
As more care is being transferred from hospitals to homes, solutions are needed to enable the care recipient's independence at home. Smart home technologies enable remote control of home devices, such as lamps and fans, via various units, including mobile phones. Depending on the degree of functional impairment the care recipient has, requirements are placed on the usability of such units. For example, reduced mobility can be compensated for with voice control. This contribution aims to study the usability of a headset for people with severe functional impairments. The contribution describes the implementation of the headsets, how they are controlled by neural activity and/or minor muscle movements, and how combinations of these, in turn, are used to control home devices.

Keywords: Brain Computer Interface, Ambient Assisted Living, Multimodal Human-Computer Interaction, Smart Home

I. INTRODUCTION

Increasingly, advanced healthcare is being delivered directly from traditional hospital settings into patients' homes [1]. In a Swedish context, this has been observed for several years [2], with reasons including a general desire to see development towards home healthcare [3]. Meanwhile, statistics show that the number of care beds in Swedish hospitals is decreasing [4]. In this context, digitalization is highlighted as a key concept for enhancing healthcare efficiency and freeing up resources [5]. Here, Telemedicine refers to IT-based systems that connect patients to medical expertise remotely [6]. In [7], it is claimed that home telemedicine shortens hospital stays, generally lowers costs, and enables faster recovery without increasing the risk of relapse. Moreover, [8] shows that Telemedicine at home increases patients' and relatives' sense of control, security, and quality of life. Furthermore, by combining telemedicine with smart home solutions – so-called Ambient Assisted Living (AAL) – patients can not only be medically monitored but also remotely control their physical home environment, such as lighting and ventilation, for safer and more independent living [9], [10]. Here [9] describes how integrating IoT (Internet of Things) with automation (controlling lighting, temperature, and fans) creates an environment in which the elderly and sick can maintain their independence despite disabilities. In this context, [11] addresses assistive IoT-based Smart Home technologies for young people with functional disabilities. That work describes a system that is under ongoing experimentation and is briefly outlined in Figure 1.

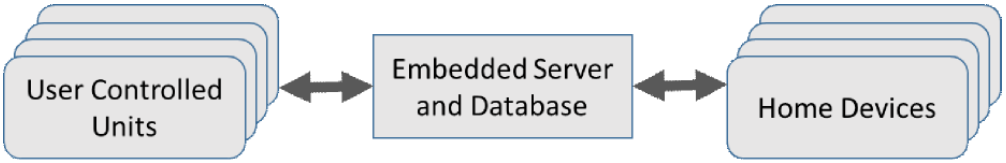

Figure 1. An overview of a Smart Home system. Users control Home Devices (lamps, fans, …) through units, such as smartphones and web interfaces. An embedded server and a database act as a mediator between units and devices [11]

To support the diverse needs of people with functional disabilities, it is especially essential to highlight user-controlled units and customize them. Thus, experiments have been performed using, for instance, cameras and accelerometers to capture gestures in the air, AI for context awareness, and speech-to-command translation. This contribution will focus on headsets (see Figure 2) as user-controlled units for communicating with Smart Home Devices. The headset captures both facial and head muscle activity (EMG) and also reads EEG activity, which is then converted into commands to control the Smart Home system.

Figure 2. OpenBCI headset, obtained from [12].

II. RELATED WORK

1. Inclusion and Sustainable Development

The principle of 'leaving no one behind' [13] is a cornerstone of the United Nations Agenda 2030. It emphasizes the need to ensure participation and quality of life for all citizens, including persons with disabilities. Several Sustainable Development Goals (SDGs) explicitly address issues related to disability, inclusion, and equal opportunities. In the context of assistive technologies and smart home environments, SDG 3 (Good Health and Well-being) and SDG 10 (Reduced Inequalities) are particularly relevant, as they promote independent living, participation in society, and equal access to supportive technologies [14]. The Convention on the Rights of Persons with Disabilities (CRPD) [15] further emphasizes the importance of enabling people with disabilities to make independent life choices and participate fully in society. To achieve these goals, research and development of accessible assistive technologies are highlighted as essential. Similarly, the World Health Organization (WHO) has stressed that access to assistive technology [16] should be regarded not only as a means of improving quality of life but also as a fundamental human right. Within this context, smart home technologies can play an important role by increasing autonomy and reducing barriers in everyday life. By providing accessible

mechanisms for environmental control, such technologies may contribute to both individual well-being and broader societal inclusion, thereby supporting the ambitions of Agenda 2030, the CRPD, and WHO initiatives on assistive technology.

2. Smart Home Technologies for People with Disabilities

AAL has become an important research area for supporting independent living through IoT-enabled smart home technologies. Recent reviews show that sensor-based monitoring, activity recognition, and health-related applications dominate the field. However, many existing solutions focus primarily on observation and monitoring rather than providing accessible mechanisms for active interaction and environmental control. Furthermore, challenges related to usability, user acceptance, and real-world deployment remain open research issues [17],[18]. Existing Ambient Assisted Living systems often rely on IoT-enabled sensing and monitoring technologies. However, recent reviews highlight persistent trade-offs between usability, privacy, cost, and system reliability. These challenges are particularly important when designing smart home solutions for individuals with severe disabilities, where accessible interaction mechanisms are essential for independent living [17],[18]. Still, while much of the AAL literature focuses on supporting aging populations, fewer studies investigate accessible smart-home interaction for users with severe physical disabilities [18] more generally. Thus, the diversity of such physical disabilities necessitates experimentation with customized, appropriate user interaction interfaces.

3. Accessible Interaction Modalities

While many smart-home solutions focus on automation and monitoring, accessible interaction technologies are needed to keep the user actively involved in controlling the environment. Different disabilities require different interaction mechanisms, motivating the need for adaptable and multimodal smart-home interfaces. Here, concepts such as Universal Design [19] and Inclusive Design [20] especially address structures and solutions to include people regardless of their abilities. Thus, accessible smart-home environments should support multiple interaction modalities rather than relying on a single interface paradigm.

Figure 1 outlines the context of the experiments on Smart Home techniques for disabled people, performed at the Computer Science department at the authors' home university. On one hand, devices of a Smart Home to interact with include lamps, fans, pull-downs, and sensors for temperature, smoke detection, and motion. On the other hand, available tools for user interaction include web-based user interfaces, smartphone apps, and speech-based controls, as shown in Figure 3 and further discussed in [11]. Thus, the architecture of Fig 3 supports the Universal Design principle of flexibility in use by providing multiple interaction mechanisms adapted to different functional abilities.

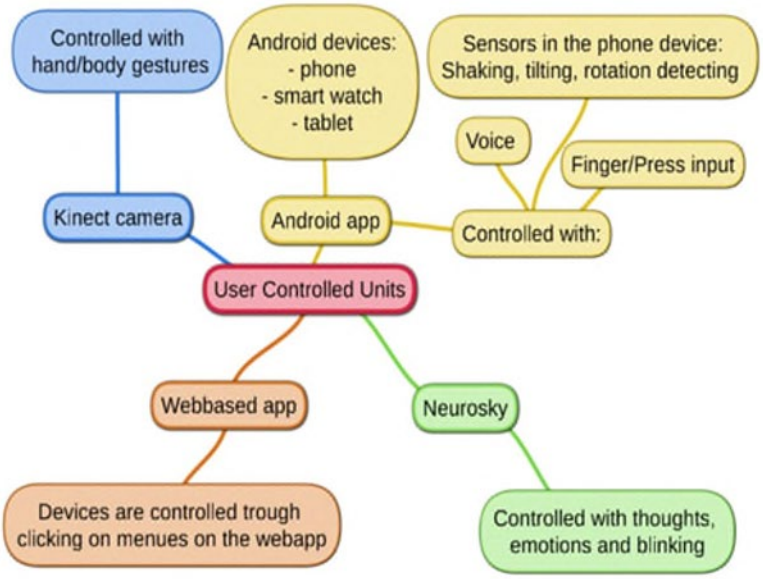

Figure 1. An overview of the Smart Home system's Users' controller units [11]

The concept of Ability-Based Design [21] is based on adapting technology to the user's abilities rather than requiring the user to adapt to the technology. Here, the term Ability-Based Design corresponds to criticism towards the previous focus on disabilities rather than abilities. This, in the context of Figure 3, would instead emphasize abilities such as: if the user can talk, then use voice-based interfaces; if the user can move their body, then use Kinect cameras [22]. If the user can use a mobile phone, use Smartphone apps; if the user can only blink, use a NeuroSky [23]. To further motivate, Figure 3 illustrates, at a conceptual level, that Multimodal Human-Computer Interaction (MHCI) emphasizes the central argument that different users need different interaction channels and that combinations of multiple modalities often provide better accessibility than a single channel [24]. Figure 3 clearly outlines several interaction options, and this contribution aims to advance interaction with Smart home devices via headsets, as discussed in the forthcoming sections. The article [25] summarizes a comparison of design possibilities for different steps in data processing, expecting that many of the current challenges will be resolved 'soon'. In our contribution, we present projects both with and without data processing. Headset manufacturers also offer APIs where signal processing and filtering have already been applied, providing users with preprocessed data. Even if modifications are possible, prepared APIs are easy to use when project time is limited, such as student projects. Instead, we focus on designing feasible command solutions suitable for AAL applications.

III. MATERIAL AND METHODS

1. Single vs Multiple Channel EEG Recording

The EEG signals obtained are weak and therefore need to be amplified to get clearer signals. This is done by placing one or more electrodes on the head or earlobes as reference points and calculating the difference between them (see Figure 2). This means that only a few electrodes are enough for measurements. But to obtain a more accurate measurement, it is desirable to use more electrodes.

Today, several headsets are available, each with a different number of electrodes for recording. In the authors' home Computer Science department, NeuroSky [26] and OpenBCI [12] with 16 electrodes were used for experimental purposes, by both students and teachers. NeuroSky works on 3,3 V (volts) and uses dry sensor technology; that is, no gel is needed to receive a signal. As presented in Figure 4, one electrode is recording activity on the forehead. This headset uses a sampling frequency of 512 Hz. One more sensor is placed on the earlobe as a reference point, and another on the ground. NeuroSky offers the possibility to read raw data and experiment with it. But it also offers a program that can translate a signal into 8 different EEG frequency bands, which can be used in further work.

Figure 4. NeuroSky MindWave headset obtained from [26]

The gel-based OpenBCI headset shown in Figure 6 enables the acquisition of 16-channel EEG data rather than 1-channel data. The Cyton board is connected to the cap and communicates via a dongle through USB or Bluetooth. Sampling frequency is 250 Hz.

2. Projects performed

The following are the four kinds of projects performed at the Computer Science department:

a) Mental exercise as a command: While stimulus can come from the outside, it can also come from the inside, for instance, through mental stimulation. Different mental exercises were designed and implemented to identify thoughts that produce the strongest effects, for future use as a command. Here [27], we used a NeuroSky headset with one electrode placed on the forehead. EEG activity in the frontal brain is associated with focused concentration, whereas relaxation (lacking concentration) is associated with lower frontal activity. Studies were conducted to identify mental exercises that put the user in the best possible state of focus. The sampling frequency was set to 512 Hz because the NeuroSky uses that frequency. Each exercise lasted 20 seconds, and each recording was repeated 5 times. 7 volunteers participated in the experiment. For more technical details, please refer to [27].

Tasks with open eyes:
“Up”- Imagine raising a window blind with your mind and watching more of the window appear.
“Down” - Imagine lowering a window blind with your mind and watching the window gradually disappear.
“Balloon” - Imagine a white balloon drifting in the wind and focus on its movement and color.
“Rectangle” - Think of one blue square. Concentrate on the blue color and follow the thick black contour line.

Tasks with closed eyes:
“Eyes Closed” - Think of whatever with eyes closed.

"Relax" - Close your eyes and relax in your muscles.
"Count Back" - Calculate backward. Start from 100.

"Point" - With closed eyes, imagine that you have a black dot between your ears in your head. Concentrate on that dot.

b) Focus, relax, and blink as a command combination: Focused and relaxed modes are again used by students [28] for command creation, combined with different numbers of blinks. Here, the NeuroSky was used with a single-electrode signal to measure its activity and control sensors on the miniature house developed by the Computer Science department (see Figure 5).

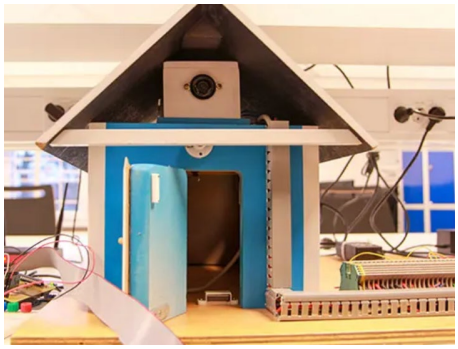

Figure 5. Miniature Smart house with varying sensors

c) Head movement combined with jaw muscle activity: Students continued to work on exploring how the creation of commands is achieved by using jaw muscle activity, EMG (electromyography- muscle response value), in combination with head movements, to construct commands. Here, the OpenBCI headset with several electrodes is used, but not all 16.

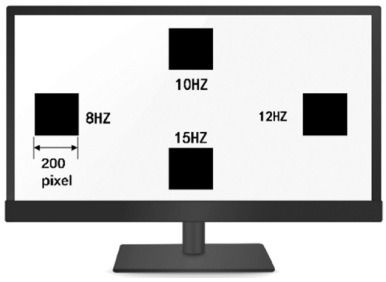

Figure 6: The image shows 4 frequencies used for the stimulus. The image is obtained from [29]

d) Using different frequencies to form a user command: Other work concerns flashing boxes at different frequencies (see Figure 6), which has been suggested for use in combination with AR (augmented reality) for future command creation. This idea is based on the content from the article [29]. Similar research has been applied to the design of BCIs for individuals who exclusively communicate with their eyes, such as when driving a wheelchair. The article [29] lies behind the motivation for this research, which showed that SSVEP (Steady State Visual Evoked Potentials) with the CCA-CWT-SVT (Canonical Correlation Analysis – Continuous

Wavelet Transformation- Super Vector Machine) algorithm achieved 91.76% accuracy in recognizing different frequencies in EEG signals.

The 4 squares with different frequencies were flashing on a screen in front of a person. Because the eyes are involved, the visual cortex is mapped to the back of the brain (occipital lobe). The electrode positions are T5, O1, O2, T6, P3, and P4 to catch the signals from this brain area. When a person looks at a flashing square with a specific frequency, for example, 15Hz, the EEG signal will show a huge spike at 15Hz. Experiments using AR (augmented reality) were added to the knowledge gained from [29] to investigate how AR can reduce the need to carry a monitor.

IV. RESULT

Define abbreviations and acronyms the first time they are used in the text, even after they have been defined in the abstract. Abbreviations such as IEEE, SI, MKS, CGS, sc, dc, and rms do not have to be defined. Do not use abbreviations in the title or headings unless they are unavoidable.

a) The results of the experiment with mental exercises showed several things:

- Closed eyes reduce visual artifacts and give stronger results.
- Closed eyes, combined with thinking of having a point between the ears in the middle of the head, give the strongest visual effect in the spectrogram.

Finally, if combining the thought of imagining the point with counting backward, with closed eyes, the classification achieves 97% accuracy with the Nearest Neighbor classifier and the strongest visual Power Spectral Density (PSD) effect (see Figure 7).

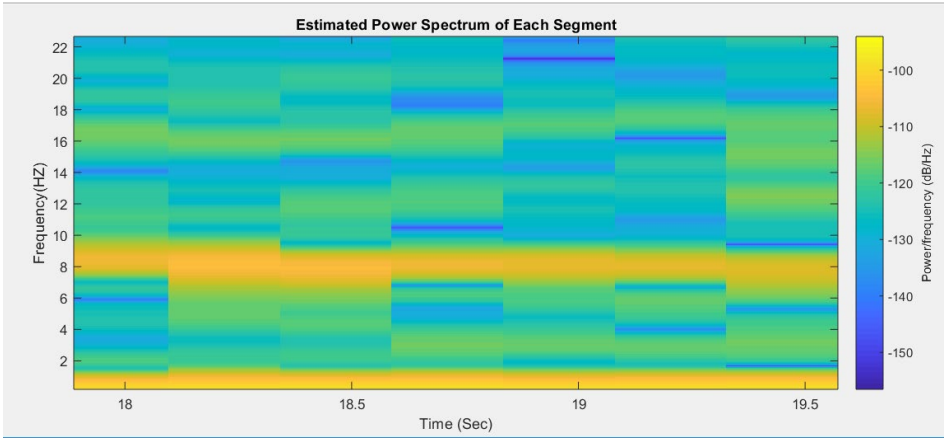

Figure 7. The mental exercise "Point" produces the strongest visual PSD effect in the spectrogram. Vertical axis: Frequency (Hz), horizontal axis: Time (Sec), bar to the right: Power/Frequency (dB/Hz)

b) The results of the experiment, focusing, relaxing, and blinking, showed that the commands are successfully used to move the mouse inside a menu represented by several boxes. You need to relax and concentrate to move

the mouse above the box, and when you are above the box, you need to blink 2 times to open it. If it fails, you will need to blink 2 times to restart (see Figure 8).

c) The result of the experiment with jaw muscles shows that muscle activity is recognized as stronger activity, which makes EMG a great combination. Also, it is important to note that the head cap is used to measure activity from the head, not from any other body part. This can be of interest to individuals, depending on their head muscle activity, because of their impairment.

d) The result of the experiment with frequencies and AR shows that the performance of AR's processors is important and that the accuracy of AR implementation depends on the implementation of AR factors. However, more work is required in this area to understand how different design factors affect accuracy.

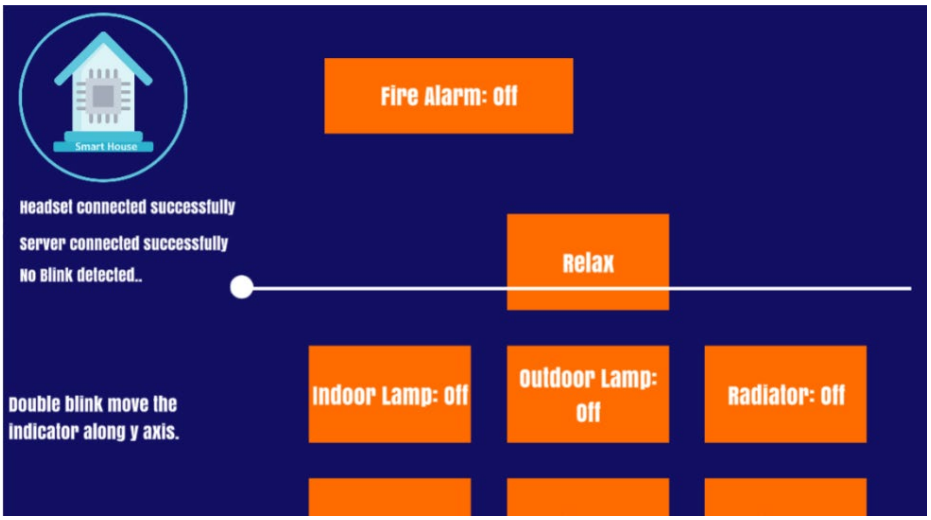

Figure 8. Smart home webpage, picture obtained from [28]

The result overview is presented in Table 1, indicating that all 4 projects show promising results and are potential candidates for AAL solution constructions.

Table 1. Result overview

Project	BCI equipment	Number of electrodes	Combinations	Raw Data Preprocessing	Applicable as an AAL solution
a)	Neurosky	one	Mental exercises	yes	yes
b)	Neurosky	one	Focus/relax + blink	no	yes
c)	OpenBCI	16	Focus+ jaw muscle	no	yes
d)	OpenBCI	16	AG + SSVEP	yes	pending

V. DISCUSSIONS

The findings indicate that both headsets have considerable potential as BCI platforms for developing command architectures that promote user independence, according to AAL and MHCI, where the user's mental health is indirectly ensured. The experimental data is not shared online due to ethical concerns. Since the studies are in an experimental phase, the headsets have not been tested by target users to confirm the results. Future work would involve continuing the work on command combination design and allowing the target user to test the prototype. The data in use is certainly of significant importance. For experimental reasons, synthetic data may be used. Moreover, involving human data raises significant ethical considerations. Furthermore, AI models and algorithms will be studied to improve the experimental results.

VI. CONCLUSIONS

The results of this study showed that brain wave activity, which was our focus from the start of the investigation, can be used to create commands that control a smart home, thereby achieving user independence. Surprisingly, small head muscles, which gave a high response in activity, are also great for designing commands. Small head muscles are also successfully combined with brain waves to increase the number of commands.

ACKNOWLEDGEMENT

The authors would like to acknowledge the valuable contributions of the students involved in projects and thesis work.

Abstract
This paper presents a topological investigation of Sierpinski triangular networks, a classical fractal structure and a special type of graph, through their network representation, as a recursively generated figure that replicates its own structure at each iteration. The Sierpinski triangle exhibits a high level of both geometric and mathematical regularity. The study focuses on how the numbers of vertices and edges vary with the iteration level, deriving specific formulas for vertices of degrees 2 and 4. Additionally, a comprehensive set of topological graph indices, including Zagreb, Randic, Bell, Sigma, and others, is calculated and analyzed. The quantitative results obtained demonstrate that Sierpinski triangle networks are not only theoretically significant but also applicable in fields such as chemistry, communication systems, and network science. The exponential growth behavior observed with scaling aligns with the nature of complex systems, enhancing the utility of this structure in modeling large, self-similar networks. By combining fractal geometry and graph theory, this study aims to offer a fresh perspective on the analytical potential of Sierpinski-type networks.

Keywords: Sierpinski network, Sierpinski triangle, Sierpinski graph, topological graph index, modeling

I. INTRODUCTION

Fractal geometry was developed to model intricate patterns commonly found in nature, patterns that cannot be effectively explained by classical geometry. Among these, the Sierpinski triangle stands out due to its structural simplicity and strong self-similar properties. Introduced by the Polish mathematician Wacław Sierpiński, [1] this figure evolves recursively, with each iteration comprising three scaled-down replicas of the original triangle. In this paper, the Sierpinski triangle is examined using graph theory, focusing on how its iterative structure influences the distribution of vertices and edges. By categorizing vertices according to their degree, recursive and explicit-form expressions are derived for both degree 2 and degree 4 vertices. Similarly, the number and types of edges are analyzed based on the degree combinations of their connecting vertices, yielding general formulas applicable at any iteration level. Beyond these structural metrics, the study explores a variety of topological indices widely used in chemical graph theory and network analysis. Indices such as the Zagreb, Randic, Bell, and Sigma indices are computed to assess the complexity, connectivity, and irregularity of the Sierpinski triangle networks. These metrics are instrumental in evaluating molecular structures, optimizing sensor networks, and designing robust communication topologies [2]. This introductory section sets the stage

for a comprehensive analysis, wherein both theoretical derivations and applied interpretations are presented, accompanied by tabulated data illustrating the evolving behavior of the Sierpinski network across iterations.

Sierpinski triangle networks are fractal structures built according to a specific pattern. They are one of the main examples in real analysis where the notion of measure is studied. The numbers of vertices and edges in these networks vary with the construction stage k. With this notation, we will denote the Sierpinski triangle at the k-th stage by S_k. See Figure 1.

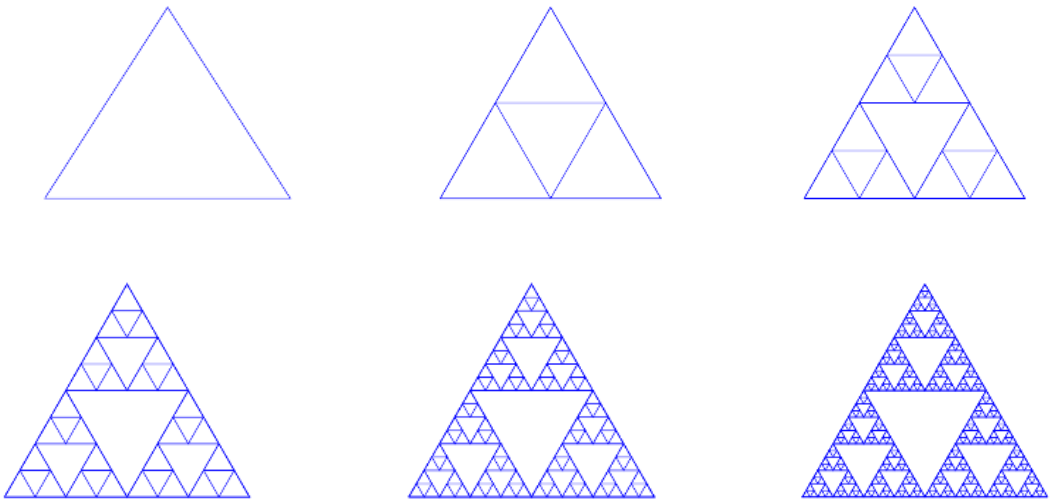

Figure 1. Sierpinski triangle networks S_k for k = 1, 2, …, 6

One of the most important reasons graphs have become one of the most popular subjects in Mathematics is that one can model almost all real-life situations with a graph and study it using mathematical tools and methods to obtain outcomes about the situation under consideration. Several important problems, such as the Traveling Salesman Problem and the Shortest Route Problem, are examples. The main tools for studying a graph model are matrices, polynomials, eigenvalues, certain parameters, and mathematical formulae called topological graph indices. When the application area is chemistry or related fields, these indices are mostly called molecular descriptors, and the study belongs to QSAR or QSPR. The definitions of various topological indices used as graph invariants, which are going to be compared in this work, are as follows:

In 1972, Gutman and Trinajstic [3] introduced the first and second Zagreb indices defined as

$$M_1(G) = \sum_{v \in V(G)} d_v^2$$

$$M_2(G) = \sum_{uv \in E(G)} dudv,$$

respectively. Here, d_i is the degree of the i-th vertex, and n is the total number of vertices. uv represents an edge connecting vertices u and v, and E is the edge set of the graph. These two indices have been studied widely for many years. For the historical background and mathematical properties of the Zagreb indices, we refer the reader to [4-8]. Another Zagreb-type index, called the forgotten index, is defined as the sum of the cubes of the degrees of all vertices in the graph, [9]:

$$F(G) = \sum_{v \in V(G)} d_v^3.$$

The hyper Zagreb index is defined as the sum of the squares of the sums of the degrees of vertices over the edges of the graph, [10], that is, as

$$HM(G) = \sum_{uv \in E(G)} (du + dv)^2.$$

It is used to characterize properties such as branching structure, molecular size, and shape. It is one of the irregularity indices that help determine the symmetrical structure of the graph under consideration. It is defined as the sum of the squares of the differences of the degrees of the vertices over all edges of the graph, [11], [12]:

$$\sigma(G) = \sum_{uv \in E(G)} (du - dv)^2.$$

The inverse sum index is defined in [13] by

$$ISI(G) = \sum_{uv \in E(G)} \frac{dudv}{du + dv}$$

and the Bell index is defined in [14] as another irregularity measure by

$$B(G) = \sum_{v \in V(G)} \left(d_v - \frac{2\mathrm{m}}{\mathrm{n}} \right)^2$$

The total irregularity index is similarly defined in [15] as yet another irregularity index by

$$Irr_t(G) = \sum_{v \in V(G)} \left| d_v - \frac{2\mathrm{m}}{\mathrm{n}} \right|.$$

The harmonic index is defined in [16] by

$$H(G) = \sum_{uv \in E(G)} \frac{2}{d_u + d_v}$$

One of the famous degree-based topological graph indices is the atom-bond connectivity index, which has molecular applications in terms of atoms and chemical bonds between them. It is defined in [17] by

$$ABC(G) = \sum_{uv \in E(G)} \sqrt{\frac{d_u + d_v - 2}{d_u d_v}}$$

The geometric-arithmetic index is defined in [18] by

$$GA(G) = \sum_{uv \in E(G)} \frac{2\sqrt{d_u d_v}}{d_u + d_v}$$

The augmented Zagreb index, which is another member of the Zagreb indices family, is defined in [19] by

$$AZ(G) = \sum_{uv \in E(G)} \left(\frac{d_u d_v}{d_u + d_v - 2}\right)^3$$

Another popular irregularity index is the Albertson index, defined in [20] by

$$Alb(G) = \sum_{uv \in E(G)} |du - dv|.$$

One of the most well-known topological graph indices is the Randic index, defined in [21] by

$$R(G) = \sum_{uv \in E(G)} \frac{1}{\sqrt{d_u d_v}}$$

The reciprocal Randic index is defined similarly to the Randic index and has some advantages in chemical calculations, see [22]:

$$RR(G) = \sum_{uv \in E(G)} \sqrt{d_u d_v}$$

1. Combinatorics of Sierpinski graphs

Up to this point, we have recalled the topological graph indices to be studied here. As seen, all the indices we are going to utilize are vertex-degree-based. Some of them are defined only in terms of each vertex degree such as the first Zagreb index, forgotten index, Bell index and total irregularity index while the others are defined

by means of the vertex degrees of end vertices of all the edges. Therefore, we next obtain the number of vertices and edges of Sk by means of vertex and edge partitions. Note that there are vertices of degree 2 and 4 only in Sk. As an immediate result, all the possible edges are of type (2,2), (2,4), or (4,4).

Observation 2.1. For k > 1, the partition of the vertices in the network Sk is as follows:

Vertex degree du	**The number of vertices of degree du**
2	3
4	$\frac{3^k-3}{2}$
Total number of vertices in S_k	$\frac{3^k+3}{2}$

The formula for the number of vertices of degree 2 is clear, as there is exactly one such vertex at each corner of the outside triangle. For the number of vertices of degree 4, the formula is obtained by the definition as a geometric series: $\sum_{i=1}^{k-1} 3^i$ and its sum is equal to $\frac{3}{2}\left(3^{k-1}-1\right)$ which can be rearranged as $\frac{3^k-3}{2}$. The total number of vertices can easily be formulized as a result of the above results.

Observation 2.2. For k > 1, the partition of the edges in the network S_k is as follows:

Vertex degrees (du,dv)	**The number of edges with end vertex degrees du and dv**
(2,2)	3 for k = 1 0 for k > 1
(2,4)	0 for k = 1 6 for k > 1
(4,4)	0 for k = 1 3^k-6 for k > 1
Total number of edges in S_k	3^k

2. Topological indices of Sierpinski triangle networks

Now, we give the results for chosen topological indices of Sierpinski triangle networks:

Theorem 3.1. The Zagreb indices of the Sierpinski triangle network S_k are

$$M_1(S_k) = 8 \cdot 3^k - 12 \quad (1)$$

$$M_2(S_k) = 16 \cdot 3^k - 48 \quad (2)$$

$$M_2(S_1) = 12 \quad (3)$$

$$F(S_k) = 32 \cdot 3^k - 72 \quad (4)$$

$$HM(S_1) = 48(5)$$

$$HM(S_k) = 64 \cdot 3^k - 168. \quad (5)$$

Proof. *Let us calculate the first Zagreb index for S_k ($k > 1$). By the vertex partition, there are three vertices of degree 2. So their contribution is 3 × 22 = 66. There are $\frac{3^k-3}{2}$ vertices of degree 4. Hence, their contribution is $\frac{3^k-3}{2} \cdot 16 = 8 \cdot 3^k - 24$. Thus, the first Zagreb index of S_k is*

$$M_1(S_k) = 12 + 8 \cdot 3^k - 24 = 8 \cdot 3^k - 12.$$

For $k = 1$, S_1 has 3 vertices of degree 2. So, $M_1(S_1) = 3 \cdot 2^2 = 12$, satisfying the rule.

Now we calculate $M_2(S_k)$. For $k = 1$, S_1 is a triangle with 3 edges, and all vertices have degree 2. Hence $M_2(S_1) = 3 \cdot (2 \cdot 2) = 12$. Let us calculate the second Zagreb index for S_k when $k > 1$. There are six edges between vertices of degree 2 and degree 4 connecting the three outer degree 2 vertices to the inner structure. Their contribution is $6 \cdot (2 \cdot 4) = 48$. Finally, the number of edges between two vertices of degree 4 is $3^k - 6$. Their contribution is $(3^k - 6) \cdot (4 \cdot 4) = 16(3^k - 6)$. Note that for $k > 1$, there are no edges directly connecting with two degree 2 vertices. Thus, for $k > 1$, the second Zagreb index is

$$M_2(S_k) = 48 + 16(3^k - 6) = 16 \cdot 3^k - 48.$$

Let us next calculate the forgotten index for S_k, $k > 1$. There are three vertices of degree 2 giving a contribution of $3 \cdot 2^3 = 24$. There are $\frac{3^k-3}{2}$ vertices of degree 4 with a contribution of $\frac{3^k-3}{2} \cdot 4^3 = 32 \cdot 3^k - 96$. Thus, the forgotten index is

$$F(S_k) = 24 + 32(3^k - 3) = 32 \cdot 3^k - 72.$$

For $k = 1$, S_1 only has three vertices of degree 2. So $F(S_1) = 3 \cdot 2^3 = 24$, satisfying the general rule.

Finally, we calculate the hyper Zagreb index of Sierpinski triangle networks starting with the particular case of S_1. As there is only one type of edge, that is, the ones of type (2,2), we have HM(S1) = 3(2 + 2) ^2 = 3(16) = 48. Secondly, for $k > 1$, we have six edges between vertices of degrees 2 and 4, giving a contribution of 6(2 + 4) ^2 = 6(36) = 216. Also there are $3^k - 6$ *edges between two vertices of degree 4 giving the second contribution of $(3^k - 6)(4 + 4)^2 = 64 \cdot 3^k - 384$. So, for $k > 1$, we find*

$$HM(S_k) = 216 + 64 \cdot 3^k - 384 = 64 \cdot 3^k - 168.$$

Theorem 3.2. The eleven degree-based topological graph indices of Sierpinski triangle networks are

$$
\begin{aligned}
&ISI(S_k) = 2\cdot 3^k - 4 && \text{for } k > 1,\\
&ISI(S_1) = 3 && \text{for } k = 1,\\
&\sigma(S_k) = 24 && \text{for } k > 1,\\
&\sigma(S_1) = 0 && \text{for } k = 1,\\
&B(S_k) = \tfrac{12(3^k-3)}{3^k+3} && \text{for } k > 1,\\
&B(S_1) = 0 && \text{for } k = 1,\\
&Irr_t(S_k) = \tfrac{12(3^k-3)}{3^k+3} && \text{for } k > 1,\\
&Irr_t(S_1) = 0 && \text{for } k = 1,\\
&H(S_k) = \tfrac{3^k+2}{4} && \text{for } k > 1,\\
&H(S_1) = \tfrac{3}{2} && \text{for } k = 1,\\
&ABC(S_k) = 3\sqrt{2}\tfrac{\sqrt{6}(3^k-6)}{4} && \text{for } k > 1,\\
&ABC(S_1) = \tfrac{3\sqrt{2}}{2} && \text{for } k = 1,\\
&GA(S_k) = 4\sqrt{2} - 6 + 3^k && \text{for } k > 1,\\
&GA(S_1) = 3 && \text{for } k = 1,\\
&AZ(S_k) = \tfrac{512\cdot 3^k-1776}{27} && \text{for } k > 1,\\
&AZ(S_1) = 24 && \text{for } k = 1,\\
&Alb(S_k) = 12 && \text{for } k > 1,\\
&Alb(S_1) = 0 && \text{for } k = 1,\\
&R(S_k) = \tfrac{6\sqrt{2}-6+3^k}{4} && \text{for } k > 1,\\
&R(S_1) = \tfrac{3}{2} && \text{for } k = 1,\\
&RR(S_k) = 12\sqrt{2} - 24 + 4\cdot 3^k && \text{for } k > 1,\\
&RR(S_1) = 6 && \text{for } k = 1.
\end{aligned}
$$

Proof. *By their definitions, all these degree based topological graph indices are calculated by means of vertex and edge partitions of S_k:*

$$ISI(S_1) = \sum_{uv\in E(S_1)} \frac{d_u d_v}{d_u + d_v} = 3\cdot\frac{2\cdot 2}{2+2} = 3\cdot\frac{4}{4} = 3$$

for k = 1. For k > 1, the contribution from 6 edges between vertices of degree 2 and 4 is $\mathbf{6}\cdot\frac{\mathbf{2\cdot 4}}{\mathbf{2+4}} = 8$ *and the contribution from* $\mathbf{3^k}-6$ *edges between vertices of degree 4 is* $(\mathbf{3^k}\text{-}6)\frac{\mathbf{4.4}}{\mathbf{4+4}} = 2(\mathbf{3^k}\text{-}6)$. *Therefore*

$$ISI(S_k) = 8 + 2(3^k - 6) = 2\cdot 3^k - 4.$$

For k=1, all three edges connect vertices of degree 2. So $\sigma(S_1) = 3 \cdot (2-2)^2 = 0$. *For k > 1, the contribution of six edges between vertices of degree 2 and 4 is* $6 \cdot (2-4)^2 = 24$ *and the contribution from* $3^k - 6$ *edges between vertices of degree 4 is* $(3^k - 6) \cdot (4-4)^2 = 0$. *So, for* $k > 1$;

$$\sigma(S_k) = 24.$$

Let us next calculate the Bell index for S_k. *For* $k = 1$, $m = 3$ *and* $n = 3$. *So* $\frac{2m}{n} = 2$. $B(S_1) = \sum_{v \in V(G)} (d_v - 2)^2 = 3(2-2)^2 = 0$. *For* $k > 1$, $m = 3^k$, $n = 3 + \frac{3}{2}(3^{k-1} - 1) = \frac{3^k+3}{2}$. *So* $\frac{2m}{n} = \frac{4 \cdot 3^k}{3^k+3}$. *There are three vertices of degree 2, and* $\frac{3}{2}(3^{k-1} - 1)$ *vertices of degree 4. Hence*

$$B(S_k) = 3\left(2 - \frac{4 \cdot 3^k}{3^k+3}\right)^2 + \frac{3}{2}(3^{k-1} - 1)\left(4 - \frac{4 \cdot 3^k}{3^k+3}\right)^2 = \frac{12(3^k-3)}{3^k+3}.$$

For the irregularity index, we can use the $\frac{2m}{n}$ *found earlier in the Bell index calculation. For* $k = 1$, $\frac{2m}{n} = 2$ *giving that*

$$Irr_t(S_1) = \sum_{u \in V(S_1)} |d_u - 2| = 3|2-2| = 0.$$

For k > 1, $\frac{2m}{n} = \frac{4 \cdot 3^k}{3^k+3}$ *and hence*

$$Irr_t(S_k) = \sum_{v \in V(S_k)} \left| d_u - \frac{4 \cdot 3^k}{3^k+3} \right| = 3\left| \frac{6 - 2 \cdot 3^k}{3^k+3} \right| + \frac{3^k-3}{2} \left| \frac{12}{3^k+3} \right|.$$

Since k > 1, $3^k > 3$ *so* $6 - 2.3^k < 0$ *and* $3^k + 3 > 0$ *giving that*

$$Irr_t(S_k) = \frac{12(3^k-3)}{3^k+3}.$$

Let us next calculate the Harmonic index for S_k. *For* $k = 1$

$$H(S_1) = \sum_{uv \in E(S_1)} \frac{2}{d_u + d_v} = 3.\frac{2}{2+2} = \frac{3}{2}.$$

For $k > 1$, the contribution of six edges between vertices of degree 2 and 4 is $6 \cdot \frac{2}{6} = 2$ and the contribution from $3^k - 6$ edges between vertices of degree 4 is $\left(3^k - 6\right) \cdot \frac{2}{8} = \frac{3k-6}{4}$ so

$$H(S_k) = 2 + \frac{3k-6}{4} = \frac{3^k + 2}{4}$$

Let us calculate atom-bond connectivity index for S_k. For $k = 1$, we have

$$ABC(S_1) = \sum_{uv \in E(S_1)} \sqrt{\frac{d_u + d_v - 2}{d_u d_v}} = 3\sqrt{\frac{2+2-2}{2.2}} = \frac{3\sqrt{2}}{2}.$$

For $k > 1$, the contribution of six edges between vertices of degree 2 and 4 is $6 \cdot \sqrt{\frac{2+4-2}{2.4}} = 3\sqrt{2}$ and the contribution from $3^k - 6$ edges between vertices of degree 4 is $\left(3^k - 6\right) \cdot \sqrt{\frac{4+4-2}{4.4}} = \left(3^k - 6\right)\frac{\sqrt{6}}{4}$. Hence

$$ABC(S_k) = 3\sqrt{2} + \frac{\sqrt{6}(3k-6)}{4}.$$

Let us calculate geometric-arithmetic index for S_k. For $k = 1$, we have

$$GA(S_1) = \sum_{uv \in E(S_1)} \frac{2\sqrt{d_u d_v}}{d_u + d_v} = 3\frac{2\sqrt{2.2}}{2+2} = 3.$$

For $k > 1$, the contribution of six edges between vertices of degree 2 and 4 is $6 \cdot \frac{2\sqrt{2.4}}{2+4} = 4\sqrt{2}$

and the contribution from $3^k - 6$ edges between vertices of degree 4 is $\left(3^k - 6\right) \cdot \frac{2\sqrt{4.4}}{4+4} = 3^k - 6$ giving

$$GA(S_k) = 4\sqrt{2} + 3^k - 6.$$

Let us calculate augmented Zagreb index for S_k. For $k = 1$, we write

$$AZ(S_1) = \sum_{uv \in E(S_1)} \left(\frac{d_u d_v}{d_u + d_v - 2}\right)^3 = 3\left(\frac{2.2}{2}\right)^3 = 24.$$

For $k > 1$ *, the contribution of six edges between vertices of degree 2 and 4 is* $6 \cdot \left(\frac{2.4}{4}\right)^3 = 48$

and the contribution of $3^k - 6$ *edges between vertices of degree 4 is* $\left(3^k - 6\right) \cdot \left(\frac{4.4}{6}\right)^3 = \frac{512}{27}\left(3^k - 6\right)$ *giving that*

$$AZ(S_k) = \sum_{uv \in E(S_1)} \left(\frac{d_u d_v}{d_u + d_v - 2}\right)^3 = 48 + \frac{512}{27}\left(3^k - 6\right) = \frac{512.3^k - 1776}{27}.$$

Let us calculate Albertson index for S_k*. For* $k = 1$*, we have*

$$Alb(S_1) = \sum_{uv \in E(S_1)} |d_u - d_v| = 3|2 - 2| = 0.$$

For $k > 1$ *, the contribution of six edges between vertices of degree 2 and 4 is* $6 \cdot |2 - 4| = 12$ *and the contribution from* $3^k - 6$ *edges between vertices of degree 4 is* $\left(3^k - 6\right) \cdot |4 - 4| = 0$ *giving that*

$$Alb(S_k) = 12.$$

Let us calculate the Randic index for S_k*. For* $k = 1$*, we get*

$$R(S_1) = \sum_{uv \in E(S_1)} \frac{1}{\sqrt{d_u d_v}} = 3.\frac{1}{\sqrt{2.2}} = \frac{3}{2}.$$

For $k > 1$ *, the contribution of six edges between vertices of degree 2 and 4 is* $6 \cdot \frac{1}{\sqrt{2.4}} = \frac{3\sqrt{2}}{2}$ *and the contribution from* $3^k - 6$ *edges between vertices of degree 4 is* $\left(3^k - 6\right) \cdot \frac{1}{\sqrt{4.4}} = \frac{3^k - 6}{4}$ *finally giving that*

$$R(S_k) = \frac{3\sqrt{2}}{2} + \frac{3^k - 6}{4} = \frac{6\sqrt{2} + 3^k - 6}{4}.$$

Let us calculate the reciprocal Randic index for S_k*. For* $k = 1$*, we have*

$$RR(S_1) = \sum_{uv \in E(S_1)} \sqrt{d_u d_v} = 3.\sqrt{2.2} = 6.$$

For $k > 1$, the contribution of six edges between vertices of degree 2 and 4 is $6 \cdot \sqrt{2.4} = 12\sqrt{2}$ and the contribution of $3^k - 6$ edges between vertices of degree 4 is $\left(3^k - 6\right) \cdot \sqrt{4.4} = 4.3^k - 24$ giving us

$$RR(S_k) = 12\sqrt{2} + 4.3^k - 24.$$

II. CONCLUSION

Networks are special graphs that interconnect people or things within a group. In this paper, 15 vertex degree based topological indices of Sierpinski triangle networks have been calculated and their general formulae are presented. These indices are important metrics for understanding the topological properties of the networks. Also, they can be used to estimate many physicochemical properties of molecular structures modeled as graphs using regression. Also, their potential applications span all fields of science, including pharmacology, industrial engineering, city planning, and neuroscience, which are not the main focus of this computational work.

Abstract
Heritage buildings are valuable cultural assets that serve as important links to historical traditions. In Malaysia, these buildings are more than just landmarks as they define the nation's identity and play a key role in attracting tourists. However, many heritage structures face rapid deterioration due to environmental exposure, reactive maintenance practices, and a lack of modern monitoring systems. Therefore, this project proposes HeritageCare, an AI-driven system designed to support the monitoring and maintenance management of heritage buildings. The system integrates DHT22 and DS18B20 sensors to continuously collect real-time humidity and temperature data. The collected environmental data are used for real-time monitoring through the system dashboard and as input for the Long Short-Term Memory (LSTM) model to predict future maintenance dates based on environmental conditions. The model achieved 96.96% accuracy, 71.49% precision, 83.37% recall, and 75.74% F1-score. This enables a shift from reactive repairs to proactive preservation by supporting timely maintenance planning. Additionally, the platform incorporates LiDAR-based 3D modeling to ensure that restoration work preserves the original architectural design with high accuracy. The proposed system assists heritage authorities in improving maintenance planning, reducing deterioration risks, and enhancing decision-making, while also increasing public awareness and support for heritage conservation.

Keywords: Predictive Maintenance, LSTM, LiDAR 3D Modeling, Building Preservation

I. INTRODUCTION

Heritage buildings are valuable cultural assets that preserve a nation's historical identity and architectural heritage. In Malaysia, heritage sites such as George Town and Melaka contribute significantly to cultural tourism and education. However, these buildings are highly susceptible to deterioration from humidity, thermal stress, rainfall, air pollutants, wind, vibration, and human activities [1]. This study focuses solely on temperature and humidity, as they can be continuously monitored with low-cost IoT sensors to support predictive maintenance. The primary challenge in preserving these assets is the continued reliance on reactive maintenance practices, in which interventions are carried out only after visible structural damage has occurred [2]. This situation is further complicated by the limited adoption of predictive technologies in the local heritage sector, leaving authorities dependent on manual inspections that often miss early-stage risks [3], [4]. Furthermore, restoration activities often rely on two-dimensional documentation, which lacks the accuracy required to preserve complex architectural details [5], [6].

To address these challenges, this paper proposes HeritageCare, an AI-enabled heritage management platform that integrates IoT-based environmental monitoring, LSTM-based predictive maintenance, and LiDAR-based 3D modeling. Temperature and humidity data collected by DHT22 and DS18B20 sensors are monitored in real time via the system dashboard and used as inputs to predict optimal maintenance dates. Meanwhile, LiDAR-generated 3D models support accurate restoration planning by providing detailed geometric references, ensuring repair work remains consistent with the original structure. The proposed system enables data-driven heritage

conservation by facilitating early detection of deterioration, improving maintenance planning, and enhancing restoration accuracy.

II. BACKGROUND AND RELATED WORK

1. Machine Learning in Predictive Maintenance

To achieve accurate scheduling, the system uses the Long Short-Term Memory (LSTM) algorithm, a specialized type of recurrent neural network (RNN) designed for sequential data. Traditional RNNs often struggle with the "vanishing gradient" problem, which prevents them from learning long-term dependencies [7]. LSTM addresses this by using a unique cell state and a series of gates that control the flow of information over time. This makes it highly effective for learning from time-series inputs, such as sensor-captured humidity and temperature readings [8]. This capability is important for HeritageCare because the deterioration of heritage buildings is a slow process, with damage accumulating over months due to continuous exposure to weather and moisture. Unlike standard models that only look at immediate data, LSTM can remember these long-term seasonal trends and link them to current sensor readings. This allows the system to predict the "Days Remaining until Maintenance," thereby generating the predictive maintenance date and optimal timing for interventions.

2. DHT22 and DS18B20 Sensor

Humidity and temperature were selected as the primary monitoring parameters because they are the main environmental factors contributing to the deterioration of heritage buildings in tropical climates [1]. High humidity promotes moisture accumulation, leading to mold growth and wood decay, while temperature fluctuations cause thermal expansion and contraction that can produce cracks in masonry structures [9, 10]. In the proposed work, the system integrates the DHT22 and DS18B20 digital sensors with an ESP8266 microcontroller. The DHT22 is utilized for ambient monitoring, offering a 0-100% relative humidity range and ±2% accuracy [11]. Complementing this, the DS18B20 is used for temperature monitoring, measuring values from -55°C to +125°C with ±0.5°C accuracy between -10°C and +85°C [12]. Furthermore, waterproof versions of the DS18B20 provide the robustness required for monitoring temperatures within internal masonry and foundations.

3. LiDAR 3D Modeling

Unlike traditional documentation methods that rely on 2D photography or hand-drawn sketches, a 3D model captures a building's spatial depth and geometric complexity [13]. Repairs based on 2D documentation often face challenges due to reduced spatial context, because a single 2D view from limited angles cannot fully represent the building's spatial layout. In contrast, a 3D digital record provides a more accurate architectural reference for restoration. LiDAR operates by emitting laser pulses and measuring the time it takes for them to reflect off surfaces. This helps to create a dense collection of data points known as a "point cloud" [14]. This point cloud is then processed into a textured mesh, forming a realistic 3D replica. This approach is important for modeling heritage sites where complex decorative elements, detailed carvings, and irregular structural changes are difficult to document accurately using traditional 2D methods [6].

III. METHOD

1. Preliminary Study

A structured questionnaire was conducted over one week from 11 July to 18 July 2025. The survey was implemented using Google Forms. In total, 100 completed responses were received. The questionnaire was divided into four sections and contained 21 questions designed to capture user requirements comprehensively. Section A focused on gathering basic demographic information, and Section B explored "Awareness of Heritage Preservation" to assess how well people understand the importance of conserving heritage sites, the risks they face, and the benefits of protecting them. It also measured public concern about key issues such as environmental damage, physical deterioration, and insufficient maintenance. Section C examined public acceptance of modern conservation technologies. Finally, Section D focused on practical requirements such as language, device types, and design elements to ensure an accessible user experience.

2. Proposed System Architecture

Figure 1 shows the architecture diagram of the HeritageCare system. The system follows a web architecture in which the frontend and backend are decoupled and communicate via a REST API. The infrastructure is hosted across a dedicated web server and a database server to ensure scalability and security. Both the administrative tasks and public exploration features use the same centralized database for consistent data storage and retrieval.

3. Web and Server Architecture

The HeritageCare system adopts a three-tier architecture consisting of a React-based frontend, a Django backend, and a PostgreSQL database. Nginx serves the frontend, while RESTful APIs facilitate communication between the client and server. The backend manages user authentication and maintenance scheduling, whereas PostgreSQL stores heritage and maintenance. TCP-based communication ensures reliable data exchange between the application and database servers [15].

4. Sensor Integration

HeritageCare integrates DHT22 and DS18B20 sensors to monitor temperature and humidity at heritage sites in real time. Sensor readings are transmitted to an IoT gateway via the MQTT protocol, a lightweight messaging standard suitable for resource-constrained networks [16]. The gateway preprocesses and normalizes the data before forwarding it to the backend server for real-time alerts and LSTM-based predictive maintenance analysis.

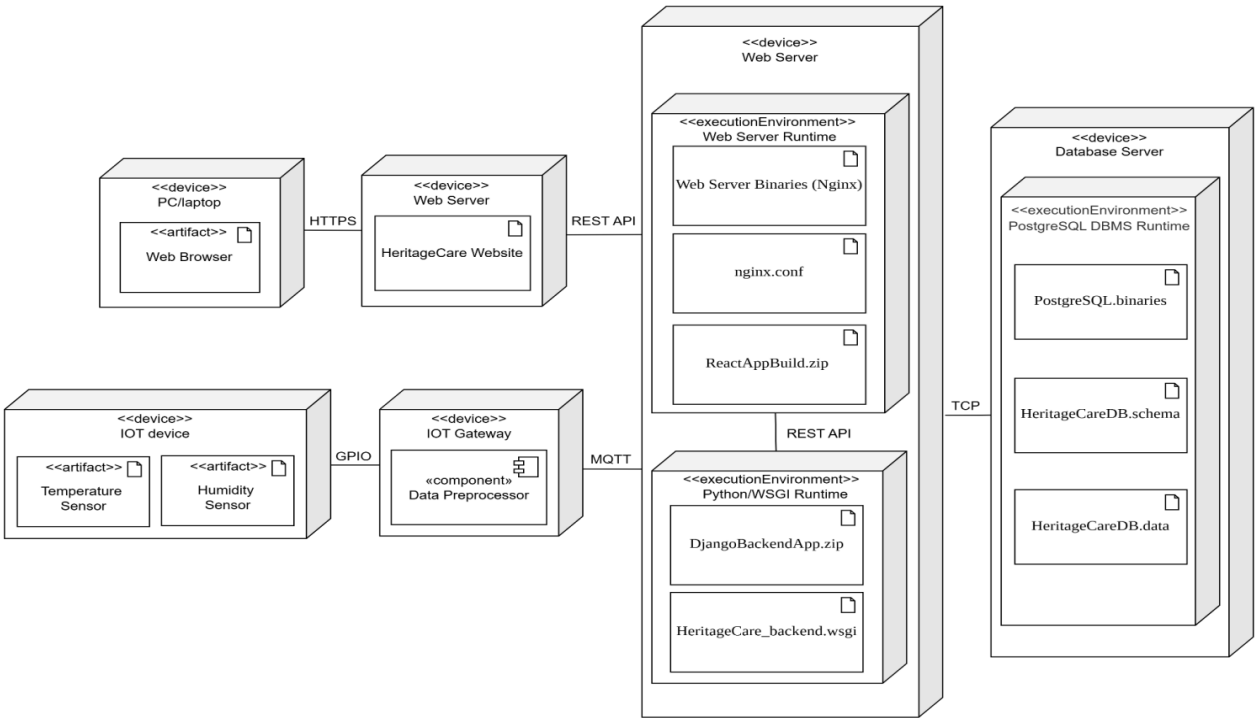

Figure 1. Architecture diagram of HeritageCare

5. System Implementation
6. Implementation of Predictive Maintenance

The predictive maintenance models were developed using an open-access environmental monitoring dataset from Zenodo [17], comprising 34,928 records with timestamps, building and weather temperature, building and weather humidity, mold risk, and thermal stress risk. The dataset was divided into 80% for training and 20% for testing. Missing values were handled using linear interpolation, while Min-Max scaling was applied to normalize the continuous features.

Three deep learning models, namely Long Short-Term Memory (LSTM), Gated Recurrent Unit (GRU), and One-Dimensional Convolutional Neural Network (1D-CNN), were trained to predict mold and thermal stress risks using timestamp, temperature, and humidity as input features. Model performance was evaluated using accuracy, precision, recall, and F1-score, as shown in Table 1.

Although the GRU model achieved slightly higher accuracy and F1-score, the LSTM model was selected for deployment because it provided better recall and precision. In predictive maintenance for heritage buildings, minimizing false negatives is critical, as undetected deterioration can lead to irreversible structural damage and significantly higher restoration costs. The selected LSTM model predicts mold and thermal stress risks, which are combined with the building material type to determine maintenance priority, recommend appropriate maintenance intervals, and estimate the next maintenance date.

Table 1. Performance Comparison of the Model

Final Deep Learning Comparison Matrix

Algorithm Model Architecture	Accuracy	Precision	Recall	F1-Score
LSTM (Proposed)	96.96%	**71.49%**	**83.37%**	75.74%
GRU (RNN Baseline)	**97.73%**	70.35%	76.00%	**79.41%**
1D-CNN (CNN Baseline)	94.93%	61.07%	58.29%	59.57%

7. IoT Monitoring and LiDAR Visualization

The HeritageCare system integrates IoT-based environmental monitoring and LiDAR-based 3D visualization to support proactive heritage conservation. An ESP8266 microcontroller connected to DHT22 and DS18B20 sensors collects real-time humidity and temperature data from heritage sites. It transmits the readings to the Django backend, where the collected data are processed for environmental risk assessment and maintenance date prediction using an LSTM model. Data validation and error-handling mechanisms are implemented to enhance the reliability and consistency of sensor readings. The implementation of LiDAR 3D modeling begins with capturing the heritage site using a LiDAR scanner to generate a precise point cloud representation of the structure. The captured spatial data is processed and converted into a web-compatible 3D model, with mesh optimization applied to improve model loading efficiency while preserving important architectural details. The completed model is integrated into the system via an interactive interface, allowing users to explore, zoom in on, and inspect the heritage structure from different angles.

8. System Testing

HeritageCare was evaluated using black-box and white-box testing. Black-box testing verified system functionality, including user input validation, maintenance workflow transitions, sensor monitoring, and alert generation, while white-box testing validated the Django backend and predictive maintenance logic. As shown in Tables 2 and 3, all functional requirements were satisfied, and the predictive maintenance module correctly generated maintenance schedules based on environmental conditions, building material type, and maintenance history.

Table 2. DHT22 and DS18B20 Sensors Functional Testing Results

No	Test Condition	Expected Result	Actual Result	Status
DHT22 Sensor Testing				
1	Normal room environment	Humidity is in the normal range, and the dashboard shows "Normal".	55.4% detected, dashboard shows "Normal"	Pass
2	High humidity simulation (Water sprayed near the sensor)	Humidity above 70% triggers "Abnormal" alert.	89.2% detected, "Abnormal" alert triggered	Pass
3	Boundary threshold test (30% < Humidity < 70%)	Humidity near threshold, maintain "Normal" status.	Temperature repeatedly changed between 29.9°C and 30.1°C, causing continuous status changes	Fail
4	Dry threshold test (Hairdryer used near the sensor)	Humidity below 30% triggers "Abnormal" alert.	25.3% detected, "Abnormal" alert triggered	Pass
5	Sensor disconnected from microcontroller	Detect failure, log "Sensor Error".	NaN detected, backend logged "Sensor Error"	Pass

DS18B20 Sensor Testing				
1	Normal surface temperature condition	Temperature normal, dashboard shows "Normal".	27.2°C detected, dashboard shows "Normal".	Pass
2	High temperature simulation (Hairdryer applied near the sensor)	A temperature above 40°C triggers an "Abnormal" alert.	41°C detected, "Abnormal" alert triggered	Pass
3	Boundary threshold test (20°C < Temp < 40°C)	Temperature near threshold, maintain "Normal".	39.8°C detected, dashboard shows "Normal"	Pass
4	Low temperature condition (Dipped into ice water)	A temperature below 20°C triggers an "Abnormal" alert.	19.5°C detected, "Abnormal" alert triggered	Pass
5	Sensor disconnected from microcontroller	Detect failure, log "Sensor Error".	NaN detected, backend logged "Sensor Error"	Pass

Table 3. Predictive Maintenance Testing

Environmental Condition	**Last Maintenance**	**Expected Result**	**Actual Result**	**Status**
Timber				
High Humidity + Low Thermal Stress	15 Mar 2024	Generate an earlier maintenance date due to high humidity risk	14 Apr 2024 (30 days). Reason: High humidity detected	Pass
High Thermal Stress + Low Humidity	15 Mar 2024	Generate an earlier maintenance date due to high thermal stress risk	29 Apr 2024 (45 days). Reason: High thermal stress detected	Pass
High Humidity + High Thermal Stress	15 Mar 2024	Generate the earliest maintenance date due to combined mold and thermal stress risks	29 Mar 2024 (14 days). Reason: High humidity and high thermal stress detected	Pass
Low Humidity + Low Thermal Stress	15 Mar 2024	Generate a routine maintenance date due to low environmental risk conditions.	11 Sep 2024 (180 days). Reason: Low humidity and low thermal stress detected	Pass
Masonry				
High Humidity + Low Thermal Stress	10 Jan 2024	Generate an earlier maintenance date due to high humidity risk	09 Apr 2024 (90 days). Reason: High humidity detected	Pass
High Thermal Stress + Low Humidity	10 Jan 2024	Generate an earlier maintenance date due to high thermal stress risk	09 May 2024 (120 days). Reason: High thermal stress detected	Pass
High Humidity + High Thermal Stress	10 Jan 2024	Generate the earliest maintenance date due to combined mold and thermal stress risks	10 Mar 2024 (60 days). Reason: High humidity and high thermal stress detected	Pass
Low Humidity + Low Thermal Stress	10 Jan 2024	Generate a routine maintenance date due to low environmental risk conditions.	08 Jul 2024 (180 days). Reason: Low humidity and low thermal stress detected	Pass

Brickwork				
High Humidity + Low Thermal Stress	20 Feb 2024	Generate an earlier maintenance date due to high humidity risk	20 Apr 2024 (60 days). Reason: High humidity detected	Pass
High Thermal Stress + Low Humidity	20 Feb 2024	Generate an earlier maintenance date due to high thermal stress risk	05 May 2024 (75 days). Reason: High thermal stress detected	Pass
High Humidity + High Thermal Stress	20 Feb 2024	Generate the earliest maintenance date due to combined mold and thermal stress risks	05 Apr 2024 (45 days). Reason: High humidity and high thermal stress detected	Pass
Low Humidity + Low Thermal Stress	20 Feb 2024	Generate a routine maintenance date due to low environmental risk conditions	18 Aug 2024 (180 days). Reason: Low humidity and low thermal stress detected	Pass
Metal				
High Humidity + Low Thermal Stress	05 Apr 2024	Generate an earlier maintenance date due to high humidity risk	20 May 2024 (45 days). Reason: High humidity detected	Pass
High Thermal Stress + Low Humidity	05 Apr 2024	Generate an earlier maintenance date due to high thermal stress risk	20 Apr 2024 (15 days). Reason: High thermal stress detected	Pass
High Humidity + High Thermal Stress	05 Apr 2024	Generate the earliest maintenance date due to combined corrosion and thermal stress risks	12 Apr 2024 (7 days). Reason: High humidity and high thermal stress detected	Pass
Low Humidity + Low Thermal Stress	05 Apr 2024	Generate a routine maintenance date due to low environmental risk conditions	02 Oct 2024 (180 days). Reason: Low humidity and low thermal stress detected	Pass
Concrete				
High Humidity + Low Thermal Stress	01 Dec 2023	Generate an earlier maintenance date due to high humidity risk	30 Mar 2024 (120 days). Reason: High humidity detected	Pass
High Thermal Stress + Low Humidity	01 Dec 2023	Generate an earlier maintenance date due to high thermal stress risk	30 Mar 2024 (120 days). Reason: High thermal stress detected	Pass
High Humidity + High Thermal Stress	01 Dec 2023	Generate the earliest maintenance date due to combined mold and thermal stress risks	30 Jan 2024 (60 days). Reason: High humidity and high thermal stress detected	Pass
Low Humidity + Low Thermal Stress	01 Dec 2023	Generate a routine maintenance date due to low environmental risk conditions.	29 May 2024 (180 days). Reason: Low humidity and low thermal stress detected	Pass

IV. RESULT AND DISCUSSION

1. User Acceptance Test

User Acceptance Testing (UAT) was conducted to evaluate the usability and functionality of the HeritageCare system. A total of 50 participants completed a structured questionnaire assessing the system interface, real-time environmental monitoring, predictive maintenance scheduling, and LiDAR 3D modeling using a five-point Likert scale. The evaluation results are summarised in Tables 4-6. Overall, the results indicate a high level of user acceptance. Participants rated the system positively for usability, visual consistency, and functional effectiveness. Among all features, the predictive maintenance schedule was identified as the most valuable by 50% of participants.

Table 4. UAT Response Grouping

Question	Usability	Information Quality	System Completeness	Decision Support	User Engagement
Q1. Dashboard is intuitive and easy to navigate	✓		✓		
Q2. Consistent visual style and layout	✓	✓			
Q3. Environmental visualizations are clear and easy to interpret	✓	✓	✓	✓	
Q4. Abnormal threshold notifications are effective	✓	✓	✓	✓	
Q5. Predicted maintenance schedule assists planning		✓	✓	✓	
Q6. Prediction logically aligns with environmental trends		✓	✓	✓	
Q7. 3D viewer responsiveness and control	✓		✓		✓
Q8. 3D model detail is sufficient for inspection	✓	✓	✓	✓	✓

Table 5. UAT Mean, Standard Deviation, and Percentage Scores

Indicator	Questions	Mean	Standard Deviation	Percentage
Usability	Q1, Q2, Q3, Q4, Q7, Q8	4.483	0.654	89.66%
Information Quality	Q2, Q3, Q4, Q5, Q6, Q8	4.443	0.665	88.87%
System Completeness	Q1, Q3, Q4, Q5, Q6, Q7, Q8	4.450	0.67	89.00%

Decision Support	Q3, Q4, Q5, Q6, Q8	4.444	0.67	88.88%
User Engagement	Q7, Q8	4.520	0.674	90.40%

Table 6. Interpretation of UAT Result

Indicator	Interpretation
Usability (M = 4.483, SD = 0.654)	Respondents generally agreed that the system is intuitive and easy to use. The low SD indicates good agreement among respondents.
Information Quality (M = 4.443, SD = 0.665)	The system provides clear, understandable, and useful information, with respondents showing consistent opinions.
System Completeness (M = 4.450, SD = 0.670)	Users perceived the integrated functions as comprehensive and effective in supporting heritage preservation tasks.
Decision Support (M = 4.444, SD = 0.670)	The predictive maintenance and monitoring features were rated highly, indicating that they effectively assist users in making preservation decisions.
User Engagement (M = 4.520, SD = 0.674)	This indicator achieved the highest mean score, suggesting that the interactive 3D viewer successfully encourages user participation and engagement.

2. Discussion

The User Acceptance Testing (UAT) results show that HeritageCare effectively achieves its main objectives of supporting heritage site preservation and increasing community engagement. However, user feedback and observations during system implementation identified several limitations that can be addressed in future improvements. The first limitation is that the LSTM model's performance may decrease when learning from very long sequences, as important information from earlier time steps can gradually be forgotten. As a future improvement, a Transformer-based architecture can be incorporated to better capture long-term dependencies by allowing the model to focus on the most relevant information across the entire sequence [18]. This may improve prediction accuracy and enhance the reliability of maintenance scheduling.

System testing shows that while the DHT22 and DS18B20 sensors are effective for monitoring temperature and humidity, they cannot detect other deterioration factors, such as structural shifting, rainfall, air pollutants, wind, and human activities. Future enhancements could integrate additional sensors, such as accelerometers for vibration monitoring, rain gauges for rainfall measurement, anemometers for wind monitoring, and air quality sensors for pollutant detection. These data can be incorporated as additional input features for the predictive maintenance model to provide a more comprehensive assessment of deterioration factors, thereby improving prediction accuracy and maintenance planning. In addition, the LiDAR 3D modeling process currently requires users to scan the site with a LiDAR-enabled device and manually upload the data. To improve efficiency, future versions of the system could install fixed LiDAR scanners at heritage sites to perform automated and regular 3D scans of buildings.

V. CONCLUSION

HeritageCare demonstrates a digital approach to heritage preservation by integrating environmental sensors, machine learning, and LiDAR 3D modeling into a single platform. Instead of relying on reactive maintenance, the system enables users to monitor real-time environmental conditions, view interactive 3D models of heritage structures, and utilize predictive maintenance schedules to support planning. The LSTM-based maintenance prediction model achieved 96.96% accuracy, 71.49% precision, 83.37% recall, and 75.74% F1-score, demonstrating its capability to support maintenance risk prediction. Furthermore, User Acceptance Testing involving 50 participants showed strong user acceptance, with high scores in usability (89.66%), information quality (88.87%), system completeness (89.00%), decision support (88.88%), and user engagement (90.40%). Overall, the results indicate that HeritageCare provides an effective and user-friendly platform for supporting heritage site monitoring, maintenance planning, and preservation activities, demonstrating the potential of digital technologies to enhance sustainable heritage conservation practices.

Abstract
This paper presents AurIA, a domain-restricted intelligent administrative support assistant developed by the Dirección de Sistemas de Información (DSI) of the Universidad Autónoma de Tamaulipas (UAT). AurIA combines a curated institutional knowledge layer with controlled access to authorized operational data through Microsoft Copilot Studio, Microsoft Power Automate, institutional REST APIs, and Microsoft SQL Server databases. The proposed three-tier architecture separates the generative artificial intelligence (AI) interface, the orchestration middleware, and the institutional data layer so that the assistant does not directly query backend databases. The knowledge layer is derived from selected current official sources and AurIA-specific information artifacts, structured according to project-defined metadata rules. A controlled internal technical evaluation comprising 205 functional and adversarial events achieved a 100% response rate, a 96.10% coherence rate, a 96.10% global effectiveness rate, and a mean response latency of 5.83 seconds. The results provide an initial technical-readiness baseline for further user-centered and longitudinal evaluation of domain-restricted generative AI assistants in university administrative environments.

Keywords: Generative AI, Microsoft Copilot Studio, conversational AI, university administrative systems, REST APIs, knowledge grounding, AI governance

I. INTRODUCTION

Digital transformation in higher education increasingly depends on institutions' ability to modernize administrative services while preserving the continuity of legacy information systems that support financial, human resources, payroll, and academic operations. Universities commonly operate heterogeneous portfolios of applications developed across multiple technological generations. Although these systems remain essential to institutional operations, users often must navigate multiple platforms, consult procedural documentation, interpret administrative requirements, and retrieve information from specialized systems. The *Universidad*

Autónoma de Tamaulipas (UAT) is a public university in northeastern Mexico with approximately 40,000 students per semester, nearly 3,000 faculty members, and administrative operations distributed across secretariats, central offices, schools, and faculties. The *Dirección de Sistemas de Información* (DSI), part of the Secretaría de Finanzas, develops, maintains, and supports institutional information systems for financial transactions, payroll processes, human resources administration, budget workflows, and related services. These systems support approximately 300 direct administrative users while indirectly affecting a broader population of up to 46,000 university stakeholders. These figures are based on internal institutional records available to the project team at the time of this study. Providing support for this environment involves more than making documentation available. Administrative information is distributed across relatively static institutional knowledge, such as organizational documents, governmental accounting regulations, system manuals, procedures, and frequently asked questions, and dynamic operational information stored in institutional systems, such as transaction status, authorization queues, balances, and other data whose availability depends on the user's role and organizational context. Based on internal DSI operational records, approximately 100 support requests are received per day through Microsoft Teams, telephone calls, and Outlook email during business hours. Many of these requests concern system navigation, procedural requirements, recurrent institutional information, and status inquiries. Traditional documentation repositories and knowledge portals can address part of the demand for support by centralizing manuals, regulations, and procedural information. However, they still require users to locate the appropriate source and interpret its contents. They cannot, by themselves, resolve requests that depend on current transactional data or user-specific authorization. Consequently, the problem addressed in this study is not simply the absence of documentation but the need for a unified, controlled mechanism for accessing both institutional knowledge and authorized operational information. To address this problem, the DSI developed AurIA, a domain-restricted intelligent administrative support assistant based on Microsoft Copilot Studio and deployed within the Microsoft cloud ecosystem. AurIA combines a curated institutional knowledge layer with controlled access to real-time information through institutional REST APIs. The knowledge layer is not limited to the direct ingestion of existing manuals; it is constructed from selected current official organizational and governmental accounting sources and complemented by AurIA-specific frequently asked questions and consolidated information artifacts structured according to the project's defined formats and metadata rules. This process improves the organization and retrieval of institutional knowledge while preserving the need for source validity and periodic content maintenance. For requests involving operational data, AurIA does not access institutional databases directly. Microsoft Power Automate acts as an orchestration layer between the conversational assistant and domain-specific REST APIs. These APIs remain responsible for applying business rules, validating user context, enforcing authorization, and returning only information within the user's permitted scope. AurIA therefore acts as a conversational access layer that combines knowledge retrieval and controlled transactional data access without transferring data-access authority to the generative AI component. The contributions of this paper are threefold. First, it presents a three-tier architecture that integrates a generative conversational interface, an orchestration middleware layer, and institutional administrative services while preventing direct AI access to backend databases. Second, it describes a knowledge-and-access model that combines curated institutional content with dynamic, permission-aware information retrieved via controlled APIs. Third, it reports a controlled internal technical evaluation comprising 205 functional and adversarial events and provides quantitative results for responsiveness, coherence, effectiveness, and response latency. The remainder of this paper is organized as follows. Section II reviews related work on conversational AI in higher education, knowledge-grounded generative systems, administrative support, and AI governance. Section III describes the AurIA architecture and institutional knowledge model. Section IV presents the administrative support capabilities included in the current scope. Section V discusses security and AI-governance considerations. Section VI describes the evaluation methodology. Section VII presents and discusses the results. Section VIII outlines limitations and future work, including user-centered and longitudinal evaluation. Section IX concludes the paper.

II. RELATED WORK

Conversational agents in higher education have been studied for information retrieval, student support, administrative assistance, and learning-related services. Pérez, Daradoumis, and Puig reported growing research interest in educational chatbots and identified diverse goals and evaluation approaches [1]. More recent reviews of generative AI chatbots in higher education describe a rapidly evolving field in which institutional adoption is accompanied by concerns about reliability, governance, and empirical validation [2]. A review focused specifically on university support chatbots shows that non-instructional use cases commonly include frequently asked questions, admissions, enrollment, and other administrative interactions [3]. Recent implementations provide closer comparisons for AurIA. Ilagan and Ilagan developed a large language model (LLM)-based virtual university support agent grounded in student handbook documents to address policy questions from students, faculty, and staff [4]. Gevher, Öncü, and Erdoğdu evaluated generative AI for large-scale learner-support inquiries and compared responses across frequently asked questions and previously unresolved cases [5]. López-Galisteo reported a 2026 university administrative case in which structured generative AI knowledge repositories and an internal assistant were evaluated against real administrative inquiries and longitudinal email-volume data [6]. These studies reinforce the relevance of knowledge-grounded conversational support and illustrate the importance of explicit evaluation criteria and institutional governance. Intelligent assistants in higher education have also been proposed as reusable architectures for accessing institution-specific information. Sajja et al. presented a platform-independent assistant architecture designed to answer domain-specific questions and reduce recurring communication barriers [7]. Although much of this literature is student-facing, it provides useful architectural and evaluation precedents for institutional assistants. Knowledge-grounded generation is particularly relevant when generated responses must remain tied to authoritative sources. Lewis et al. introduced Retrieval-Augmented Generation (RAG), which combines generation with retrieved external knowledge [8], and Siriwardhana et al. showed that retrieval-augmented systems can be adapted to specialized domains [9]. More recently, Susilo et al. reported a RAG-based university virtual assistant grounded in academic manuals and evaluated through accuracy, response time, and user satisfaction [10]. AurIA does not implement a custom RAG pipeline; instead, it uses Copilot Studio knowledge sources populated through a curated institutional preparation process. The underlying design principle is similar: generated responses to procedural questions should be grounded in a bounded, authoritative knowledge layer rather than open-domain information. Security and governance become more important when conversational systems are connected to operational administrative data. The National Institute of Standards and Technology (NIST) Artificial Intelligence Risk Management Framework (AI RMF) organizes AI risk activities around the GOVERN, MAP, MEASURE, and MANAGE functions [11]. Microsoft documentation describes additional Copilot Studio controls for security, governance, data loss prevention, and knowledge source configuration [12], [13]. In this paper, Microsoft documentation is used only to describe platform-specific implementation capabilities; the research motivation and positioning are supported primarily by peer-reviewed literature. The literature, therefore, supports the use of conversational AI for university information services and the value of knowledge grounding. Still, empirical evidence remains comparatively limited for administrative assistants who combine curated institutional knowledge with permission-aware access to live transactional data through controlled enterprise APIs. AurIA addresses this practical gap by documenting an end-to-end administrative architecture, an explicit knowledge-preparation process, API-mediated authorization, and a controlled functional and adversarial technical evaluation.

III. SYSTEM ARCHITECTURE

1. Tier 1 Generative Artificial Intelligence and Interaction Layer

The top tier includes Microsoft Copilot Studio, which provides a conversational interface, topic configuration, knowledge source management, and analytics capabilities. Users interact with AurIA via natural-language prompts about UAT administrative procedures and systems. The assistant is configured to respond to questions within its institutional scope and to decline requests unrelated to its purpose. This scope control is essential because an administrative copilot should not behave as an unrestricted general-purpose assistant. AurIA uses two categories of information. Static knowledge is derived from selected current official sources, including organizational documents, governmental accounting materials, system manuals, procedural guidance, and administrative regulations. The DSI team complements these sources with AurIA-specific frequently asked questions (FAQs) and consolidated information artifacts, and applies project-defined formats and metadata rules before publishing them as knowledge sources. This curation step is intended to improve consistency and retrieval, but it does not make obsolete or inaccurate content reliable; source ownership, review, and updating remain necessary governance responsibilities. Dynamic knowledge is retrieved at query time through domain APIs when a user requests current operational data.

2. Tier 2 Integration and Orchestration Layer

The middleware tier is implemented using Microsoft Power Automate. It receives structured requests from the Copilot agent, validates the request context, and invokes the appropriate institutional service. Rather than exposing backend services directly to the conversational layer, the middleware provides a controlled point for routing and transformation. Service communication uses HTTPS and JSON payloads. Standardized request and response formats allow additional administrative domains to be integrated without changing the assistant's high-level interaction model.

3. Tier 3 Data Layer

The data layer includes UAT domain-specific REST APIs and their underlying SQL Server databases. Existing systems, such as financial, payroll, and human-resources platforms, expose controlled service endpoints that return JSON-encoded responses. The APIs are responsible for enforcing business rules, applying user-specific access restrictions, and limiting returned data to the user's authorized scope. In this model, the AI assistant does not directly query databases; it consumes only controlled service responses produced by institutional APIs. The architecture, therefore, combines curated static knowledge, dynamic data retrieval, and security-mediated service integration. Figure 1 summarizes the general design.

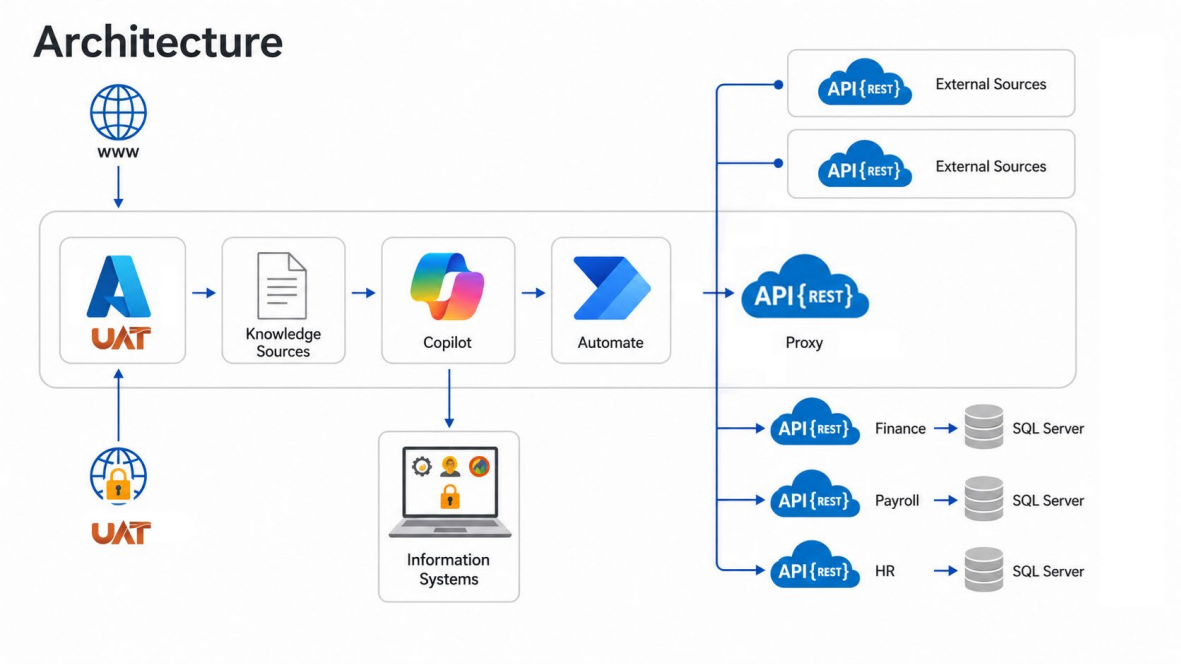

Figure 1. AurIA's three-tier architecture integrates Copilot Studio, Power Automate, REST APIs, and SQL Server data sources.

IV. ADMINISTRATIVE SUPPORT CAPABILITIES

The scope evaluated in this study centers on four administrative-support capabilities: conversational procedural assistance, authorized administrative-data retrieval, institutional information retrieval, and escalation to human support. Operational analytics are used to identify frequent topics, unresolved categories, response times, and escalation patterns. Managerial summaries and action-oriented workflows have been technically tested, and a use case is under development. Still, they are not yet deployed in the production environment and are therefore treated as future extensions rather than as evaluated core capabilities.

1. Conversational Assistance and Query Resolution

The assistant allows users to ask questions in plain Spanish about system operation, procedures, and administrative data. For procedural questions, AurIA retrieves information from the institutional knowledge layer and generates step-by-step explanations. For data-driven requests, it invokes the relevant API through Power Automate and presents the returned information in natural language. This approach reduces the need for users to know which system module, document, or menu contains the information they need. Routine inquiries include how to complete a financial form, how to verify the status of a pending authorization, where to find a payroll-related option, or which documentation applies to a specific administrative process. The present study evaluates whether AurIA can resolve representative scenarios of this type; actual reduction in DSI workload remains a hypothesis to be measured after broader deployment.

2. Authorized Administrative Data Retrieval

A representative use case involves a staff member requesting a payroll advance balance, travel credit status, reimbursement status, or the status of pending authorizations. AurIA authenticates the request context, invokes the corresponding domain API, and returns a structured response. The backend API remains responsible for enforcing user-level authorization. For example, a payroll user can access only information associated with the user's authorized institutional role, while a financial administrator can access only data permitted by the assigned organizational scope.

3. Institutional Information and Procedural Guidance

Many support requests involve static information such as institutional contacts, office locations, procedural requirements, regulations, or system navigation instructions. These requests do not require database access and can be resolved from the curated knowledge layer. The conversational interface adds contextual retrieval and synthesis to the underlying documentation, while the validity of each answer still depends on the quality and currency of the approved source material.

4. Escalation and Operational Analytics

When a query exceeds AurIA's configured resolution capacity, the assistant can initiate an escalation to human support while preserving relevant conversation context. Operational analytics can then be used to identify frequent query topics, response times, unresolved categories, and escalation patterns. Recurring unresolved questions can inform new FAQs, metadata adjustments, or updates to existing knowledge artifacts, creating a feedback loop between support activity and knowledge-base maintenance.

V. SECURITY AND Artificial Intelligence GOVERNANCE

Security is a foundational requirement for AurIA because the assistant interacts with institutional financial and administrative systems. The design combines institutional controls, API-level authentication, role-based authorization, curated knowledge governance, and cloud platform capabilities. The objective is to improve service access without expanding the information that a user is already authorized to view through institutional systems.

1. Institutional Access Controls

AurIA follows a defense-in-depth model organized around six institutional access layers. First, the user must connect from an authorized institutional network or an approved virtual private network (VPN). Second, access may be restricted by a registered device. Third, the user must authenticate with institutional credentials. Fourth, the user must have permission to use AurIA. Fifth, API responses are restricted according to the user's role and organizational unit. Sixth, confidential information requires additional authorization. These controls are intended to maintain the principle of least privilege across all interactions.

2. Service Authentication and Data Access

REST API endpoints are protected by API-key authentication and are not exposed as unrestricted public services. Requests without valid credentials are rejected before reaching backend systems. At the domain level, APIs validate the user context and return only data that corresponds to the user's permissions. Authorization is

therefore not delegated solely to the AI layer: AurIA acts as a conversational interface and orchestration client, while institutional APIs remain the authoritative enforcement points for operational data access.

3. Cloud Controls and Scope Containment

AurIA uses Microsoft Azure and Copilot Studio capabilities that support enterprise security and governance, including HTTPS communication, identity-aware access, data loss prevention, knowledge source governance, and platform-level content filtering [12], [13]. The assistant is configured as domain-restricted and is expected to decline unrelated requests, including open-domain topics, programming assistance, or sensitive subjects that fall outside its operational purpose. Scope containment is implemented through topic configuration, prompt design, bounded knowledge sources, and platform controls.

4. Alignment with the NIST Artificial Intelligence Risk Management Framework

The project does not claim formal compliance with the NIST AI RMF; however, its current design can be mapped to selected functions of the framework [11]. GOVERN is reflected in controlled knowledge-source selection, metadata rules, access responsibilities, and institutional ownership of backend services. MAP is addressed by defining the administrative domain, user roles, data sources, and out-of-scope behaviors. MEASURE is represented by the controlled functional and adversarial evaluation described in Section VI. MANAGE is supported through least-privilege API enforcement, scope containment, human escalation, knowledge maintenance, and remediation of non-conforming test cases. A formal AI-risk assessment remains future work.

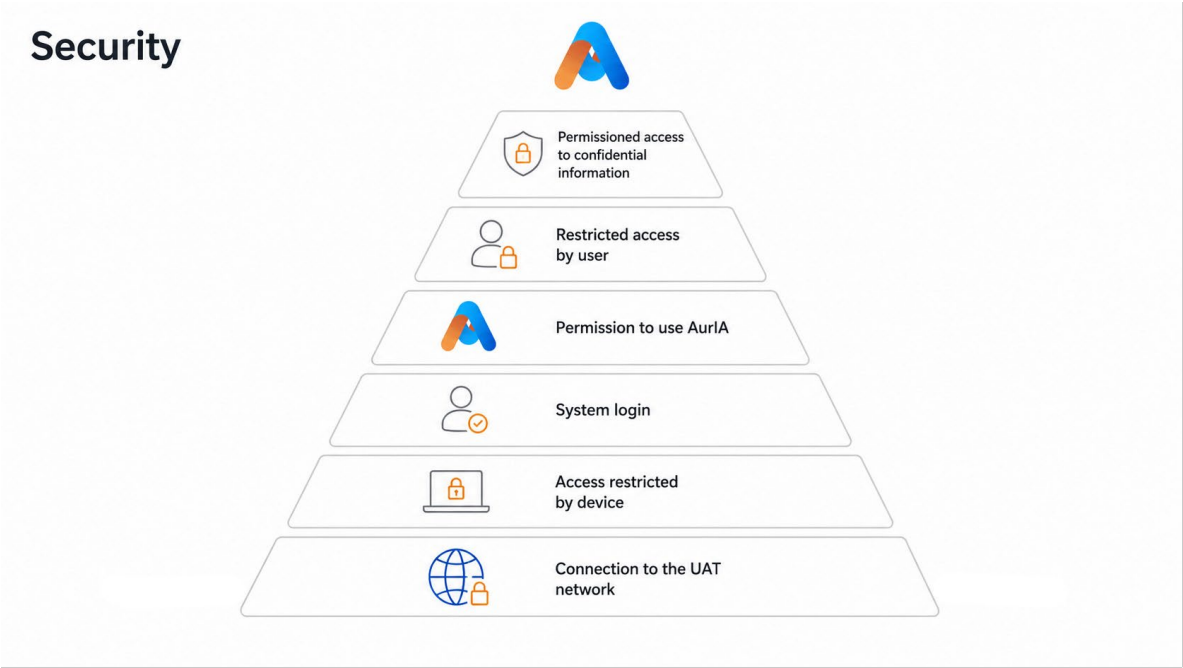

Figure 2. Institutional access-control model for AurIA, from network connectivity to permission for confidential information.

VI. EVALUATION METHODOLOGY

Before full institutional deployment, AurIA was evaluated through a controlled internal technical-readiness test designed and executed by the DSI team. The evaluation included 205 events covering representative operational queries and adversarial probes. No administrative end users participated in this evaluation. Its purpose was to determine whether the assistant could reliably produce responses, maintain coherence, fulfill user intent within its domain, and decline inappropriate requests. The test was not designed to measure usability, satisfaction, adoption, or organizational workload reduction.

1. Test Set Composition

The 205 events were constructed from representative support scenarios and risk-oriented probes. Functional events included system navigation questions, procedural guidance requests, institutional contact inquiries, and administrative data retrieval scenarios. These categories correspond to the recurring support needs described in Section I. Adversarial events included out-of-scope topic questions, code-generation requests, and sensitive-subject prompts selected to test whether the assistant maintained its intended operational scope.

2. Evaluators and Scoring Criteria

Members of the DSI development and testing team, familiar with the institutional systems and the expected behavior of AurIA, performed the evaluation. Each event was assessed using three binary criteria. Responsiveness was scored as pass when the assistant produced an output. Coherence was scored as pass when the response was grammatically understandable, internally consistent, and contextually appropriate. Effectiveness was scored as a pass when the response either correctly fulfilled the user's request within the assistant's domain or appropriately declined the request in adversarial cases. Because the evaluators were members of the development organization, the results should be interpreted as internal technical validation rather than independent user evaluation. Latency was measured as the observed round-trip time from user submission to assistant response. For requests requiring live data, this interval includes conversational processing, middleware routing, domain API invocation, SQL Server query execution, and response generation. The reported latency, therefore, represents pilot-stage performance in a controlled institutional environment rather than a guaranteed production service level.

3. Reproducibility and Interpretation

The evaluation procedure was intentionally simple so that the same events can be rerun after changes to knowledge sources, metadata, topic configuration, or API integrations. Binary scoring supports repeatable operational regression testing, but it does not capture partial correctness or user experience. Subsequent phases should add independent or end-user evaluators, inter-rater agreement, usability and satisfaction measures, task-completion metrics, and comparison with human-support baselines.

VII. RESULTS AND DISCUSSION

Table 1 summarizes the controlled technical evaluation. AurIA produced a response in all 205 events, corresponding to a response rate of 100%. Coherence and global effectiveness were both 96.10%, equivalent to 197 successful events out of 205. Eight events were classified as non-conforming and were documented for subsequent analysis and remediation through knowledge updates and topic refinement.

Table 1. AurIA controlled technical evaluation results (N = 205 events)

Total evaluation events	205
Response rate	100.00%
Coherence rate	96.10% (197 / 205)
Global effectiveness rate	96.10% (197 / 205)
Failure rate	3.90% (8 / 205)
Mean response latency	5.83 seconds
Median response latency	6.00 seconds

[a] Adversarial categories: out-of-scope topics; code-generation requests; sensitive-subject queries.

The mean response latency was 5.83 seconds, with a median of 6.00 seconds. This result demonstrates a near-immediate system response under the tested conditions. Still, it should not be treated as a direct comparison with email or telephone support, as human support channels include queueing, prioritization, availability, and issue complexity effects that were not measured in the pilot. The adversarial portion of the test indicates that AurIA maintained its configured scope during the evaluated events. Out-of-scope topics were declined or redirected, code-generation requests were not fulfilled, and sensitive-subject prompts triggered refusal behavior. Within this controlled sample, no unsafe or unrelated answer was observed for the adversarial categories. Broader red-team testing remains necessary before making stronger claims about robustness against prompt injection, social engineering, or previously unseen adversarial strategies. With respect to the research question, the pilot provides evidence that the proposed combination of curated institutional knowledge, controlled API-mediated data access, and domain restrictions can produce coherent and effective responses for representative support scenarios under internal technical testing. The 96.10% effectiveness rate is therefore an internal readiness baseline, not evidence that AurIA outperforms other university assistants or that it has already improved institutional service outcomes. The results are consistent with recent higher-education studies showing that bounded, institution-specific generative assistants can perform well when responses are grounded in curated administrative or academic knowledge [4-6], [10]. AurIA extends this pattern by adding permission-aware access to live administrative data through institutional APIs. At the same time, the eight non-conforming cases reinforce the importance of knowledge coverage, source maintenance, and regression testing after content or configuration changes.

VIII. LIMITATIONS AND FUTURE WORK

This study has several limitations. First, the evaluation sample was controlled and was executed only by DSI personnel. Although 205 events provide an initial technical-readiness baseline, they do not capture the full diversity of real-world behavior across administrative units and do not constitute a user study. Future evaluation should involve administrative personnel and measure usefulness, clarity, ease of use, satisfaction, task completion, and trust, preferably with independent assessment or inter-rater agreement where practical. A second limitation concerns organizational impact. The paper reports approximately 100 daily support requests as motivation, but the current evaluation does not demonstrate that AurIA reduces this volume, saves staff time, or improves service quality. A longitudinal deployment study should measure resolution rate, escalation frequency, support-request volume, response time, adoption, and workload before and after operational use. Recent administrative GenAI studies provide useful methodological precedents for this type of evaluation [6]. A third limitation concerns knowledge maintenance. AurIA depends on selected current official sources, AurIA-specific FAQs, consolidated information artifacts, and metadata rules. Curating these materials improves retrieval structure but does not eliminate the risk of obsolete or incorrect source information. The project, therefore, requires content ownership, review schedules, version control, update procedures, and feedback mechanisms for reporting incorrect or incomplete answers. A fourth limitation concerns compliance and security validation. This paper describes implemented and intended controls and maps them to selected NIST AI RMF functions. Still, it does not constitute a formal security audit, privacy impact assessment, or

certification of compliance. Future work should include penetration testing, prompt-injection testing, access-control verification, audit-log review, privacy analysis, and formal documentation of AI-governance responsibilities. Functional expansion will proceed only after the core support scope is validated. Managerial report summaries and controlled, action-oriented workflows have been technically tested, and one use case is under development. Still, they are not yet deployed in the production environment and were not included in the results reported here. Future studies should evaluate these capabilities separately because they involve different user roles, decision contexts, and risk levels. Additional domain APIs and knowledge sources may then be integrated using the same architecture.

IX. CONCLUSION

This paper presented AurIA, a Microsoft Copilot Studio-based assistant developed by the DSI at the Universidad Autónoma de Tamaulipas to support university administration. The proposed architecture combines a conversational AI layer, a curated institutional knowledge layer, Power Automate orchestration, and controlled REST APIs backed by SQL Server databases. The design distinguishes static institutional knowledge from dynamic operational data and keeps authorization and business-rule enforcement in institutional services rather than in the generative AI component. A controlled internal technical evaluation of 205 functional and adversarial events produced a 100% response rate, a 96.10% coherence rate, a 96.10% global effectiveness rate, and a mean latency of 5.83 seconds. These findings establish an initial technical-readiness baseline and support continued evaluation of the architecture. Still, they do not yet demonstrate user satisfaction, adoption, workload reduction, or long-term institutional impact. AurIA therefore demonstrates the technical feasibility of combining a domain-restricted generative assistant with curated institutional knowledge and permission-aware access to live administrative data through controlled APIs. The next stage of the project is user-centered and longitudinal evaluation, along with stronger security testing and formalized AI governance processes.

Abstract
Web-published museum inventories increasingly expose structured collection metadata, yet cross-institutional discovery, transparent object-to-object linking, and governed relationship management remain limited. This study presents MuseDSL, an explainable and federated framework for curator-governed museum object linking that complements existing metadata standards rather than replacing them. MuseDSL combines a federated interaction layer for decentralized discovery and metadata exchange; a domain-specific language for expressing curatorial matching rules; an agent-oriented workflow for discovery, semantic normalization, rule evaluation, and explanation generation; and a human-in-the-loop mechanism for curator validation of uncertain matches. The prototype was evaluated in a federated pilot that involved five museum inventory nodes, API-based cross-node querying, and an external mineralogical authority. The evaluation inventory contained 1,000 museum records, comprising 644 minerals, 137 rocks, 162 fossils, 39 biological specimens, and 18 other objects, from which a task pool of 100 source objects was drawn. Mineral records were submitted to Mindat for name normalization, classification checks, and evidence enrichment, resulting in a matching rate above 90% after normalization. The system also generated rule-activation traces, field-level similarity decompositions, composite scores, and decision states for candidate relationships. The results provide initial evidence that museum interoperability can be operationalized as a rule-governed, explainable, and curator-supervised interaction process without centralized metadata aggregation. MuseDSL therefore offers a practical foundation for scalable, accountable, and semantically controlled object linking across distributed museum inventories.

Keywords: museum interoperability, domain-specific language, federated systems, explainable artificial intelligence, human-in-the-loop, cultural heritage informatics

I. INTRODUCTION

Museums and cultural heritage institutions increasingly publish collection records through institutional web portals, national catalogs, and international aggregation services. This transition has improved public access to collections and created new opportunities for research, education, and digital interpretation. Nevertheless, publishing records does not automatically make distributed museum inventories interoperable with respect to object relationships. Two institutions may independently hold objects that are taxonomically related, materially similar, historically connected, or relevant to the same scientific question. At the same time, their online systems remain unable to discover or explain such relationships automatically [1], [2].

Current interoperability approaches provide strong foundations for data representation and exchange. CIDOC CRM supports semantic modeling of cultural heritage information [3], LIDO structures object metadata for publication and aggregation [4], IIIF standardizes the delivery of high-resolution digital images [5], and OAI-PMH supports repository-level metadata harvesting [6], [7]. Web-oriented vocabularies and structured data approaches further improve machine readability and discoverability [8]. These contributions are essential, but they primarily address description, publication, harvesting, or aggregation. They do not fully specify how autonomous museum systems should discover related objects, evaluate candidate links, explain why a link is proposed, and allow experts to govern that link over time. This gap is particularly important for natural history and scientific collections. When a fossil, mineral, rock, biological specimen, or archaeological object is registered in one museum, related or comparable objects may already be held by other institutions. A curator may therefore ask a practical question: which museums hold objects that belong to the same taxonomic group, geological period, material class, provenance context, or scientifically relevant neighborhood as this new record? A useful computational system should not only return candidate objects; it should also expose the evidence behind each suggestion and preserve the authority of museum professionals to validate or reject the relationship. This paper presents MuseDSL, a federated and explainable framework for cross-institutional linking of museum objects. MuseDSL combines a lightweight Museum Interoperability Protocol, a domain-specific language for curatorial matching rules, task-oriented software agents, a shared operational representation named M-CORE, and a human-in-the-loop governance process. The framework does not require participating museums to move their complete inventories into a central repository. Instead, each institution remains an autonomous node that can expose selected metadata, receive federated queries, return candidate objects, and participate in the controlled formation of relationships. This conference version focuses on the architecture, rule model, operational workflow, and initial federated pilot. The extended journal version is intended to include broader baseline comparisons, ablation experiments, threshold sensitivity studies, and larger-scale curator-centered evaluation. The present contribution is therefore positioned as a concise but complete description of the core framework and its initial empirical feasibility.

II. RELATED WORK AND RESEARCH GAP

Semantic interoperability in cultural heritage has traditionally been approached through conceptual models, metadata schemas, and repository protocols. CIDOC CRM provides a shared ontological framework for representing events, actors, places, objects, and provenance relations [3]. LIDO provides a practical XML-based schema for exchanging descriptive museum records [4]. IIIF supports interoperable access to visual resources [5], whereas OAI-PMH enables low-barrier metadata harvesting across distributed repositories [6], [7]. These mechanisms address important parts of the interoperability problem, but they do not define a complete operational process for accountable object-to-object linking between autonomous institutions. Linked data and structured web publication improve the exposure of cultural heritage resources to external systems and search engines [8]. However, publishing semantically enriched records is different from governing a proposed relationship. A relationship such as the same specimen type, a close taxonomic match, a related geological context, or a provenance association carries interpretive meaning. It may need to be reviewed, revised, accepted, or withdrawn. This requirement introduces a governance layer that is not normally central to harvesting or aggregation protocols. Agent-based architectures are suitable for separating discovery, transformation, matching, and coordination tasks in distributed environments [1]. In MuseDSL, the term agent is used in a software architectural sense: specialized modules perform defined tasks rather than claiming emergent autonomous intelligence. Explainable AI research also motivates the requirement that automated decisions should be inspectable, especially when they support expert judgment [9]. Domain-specific languages offer a complementary mechanism by expressing expert rules in a form that can be inspected and executed by software [10]. Within the cultural heritage domain itself, agent-oriented and ontology-driven systems have so

far been applied mainly to visitor interaction and content exploration, for example, ontology-based chatbots for experiential learning [11] and conversational agents for navigating European aggregated collections [12], rather than to the governance of links between institutional records. Earlier work on semantic bridges between museums, libraries, and archives likewise emphasized shared conceptual models rather than an operational linking process [13]. MuseDSL integrates these ideas into a single framework: federated discovery, domain rules, explainable evidence, and curator-governed relationship lifecycle management.

Table 1. Positioning of MuseDSL relative to common interoperability approaches

Approach	Main purpose	Federated discovery	Object linking	Explanation	Human review
CIDOC CRM	Semantic modelling	No	Conceptual	Limited	Conceptual
LIDO	Metadata exchange	No	No	No	No
IIIF	Image interoperability	No	No	No	No
OAI-PMH	Metadata harvesting	Limited	No	No	No
MuseDSL	Governed object linking	Yes	Yes	Yes	Yes

III. MUSEDSL FRAMEWORK ARCHITECTURE

The proposed framework models each participating museum as an autonomous digital node.

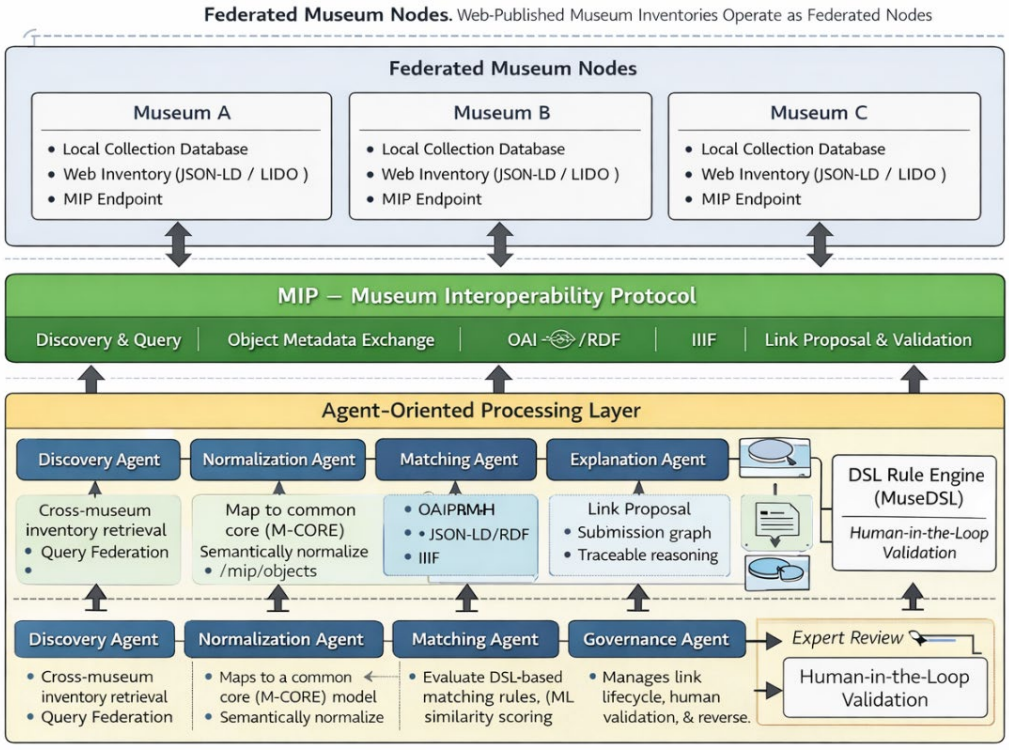

Figure 1. Layered architecture of the MuseDSL federated museum interoperability framework.

A node retains authority over its local collection database and determines which fields or records are exposed for interoperable access. The framework introduces a semantic interaction layer above existing publication standards rather than replacing them. Its architecture contains three principal layers: museum nodes, a federated interaction layer, and an agent-oriented processing layer.

1. Museum Nodes and Institutional Sovereignty

Each node represents a museum or collection system that publishes selected structured metadata through a web-accessible endpoint. The architecture allows institutions to retain local ownership and avoids mandatory replication of complete inventories into a central database. A museum can participate using JSON-LD, LIDO-derived metadata, or another structured representation, provided that the exposed fields can be mapped to the operational representation used by the matching workflow. This separation between local storage and interoperable interaction is important for institutional autonomy, access control, and gradual adoption.

2. Museum Interoperability Protocol

The Museum Interoperability Protocol (MIP) defines the logical interactions required by the framework. In the current prototype, MIP is implemented as lightweight API-based operations rather than as a final internet standard. Its core capabilities are node discovery, query forwarding, candidate metadata retrieval, link proposal, validation state exchange, and relationship lifecycle management. A source node can submit a query object to participating nodes, receive candidate records, and later send a proposed relationship for review without copying the complete remote inventory.

3. M-CORE and Agent-Oriented Processing

Heterogeneous candidate records are mapped into M-CORE, a shared internal representation that contains the fields required by the matching process. Depending on the collection type, these fields may include title, category, subtype, material, provenance, locality, taxonomic descriptors, geological age, and auxiliary metadata. The goal is operational normalization rather than universal ontology replacement, and mapping is performed only for the fields needed by the active MuseDSL rule.

The processing layer separates four responsibilities. The Discovery Agent retrieves candidates from federated nodes and external authorities. The Normalization Agent harmonizes values and maps records into M-CORE. The Matching Agent executes MuseDSL rules and calculates evidence scores. The explanation and governance functions produce traceable decision artifacts and route uncertain cases to curators. This modular separation improves maintainability and makes it possible to inspect which component produced each transformation or decision.

4. MuseDSL Rule Model

MuseDSL expresses curatorial matching logic as explicit, reusable rules. A rule specifies the scope of the comparison, the metadata fields to be compared, field-specific similarity functions, evidence weights, optional conditions, decision thresholds, and the relationship type that may be proposed. For example, a mineral rule can prioritize the normalized mineral name and the chemical formula, whereas a fossil rule can emphasize taxonomic name, subtype, geological age, and locality. This design makes the assumptions of the matching

process visible to domain experts and allows rules to evolve independently of the general software infrastructure.

$$S(q, c) = \sum w_i s_i, \qquad \sum w_i = 1 \tag{1}$$

In (1), q is the query object, c is a candidate object, s_i is a field-level similarity contribution, and w_i is the corresponding rule weight. The system converts the composite score into one of three states: ACCEPT, REVIEW, or REJECT. The REVIEW state forms a deliberate governance band for cases that are plausible but not strong enough for automatic acceptance.

IV. METHODOLOGY AND OPERATIONAL WORKFLOW

1. Research Design

The study follows a design-science-oriented approach in which the research artifact is developed to address a practical interoperability problem and is then evaluated through operational use. The objective is not to claim that a single similarity function solves all museum entity resolution problems. Instead, the study evaluates whether federated discovery, explicit domain rules, explanation generation, and curator-controlled validation can be integrated into a coherent workflow across heterogeneous web-published inventories.

2. Sequential Workflow

A query begins when an object is registered or selected within a participating museum. The Discovery Agent sends selected metadata to the federated search layer. Other nodes return candidate records and, where relevant, query an external authority source as well. The Normalization Agent maps the records into M-CORE, resolves common lexical variation, and prepares the fields required by the active rules. The Matching Agent then evaluates the candidates with MuseDSL. For each candidate, the system stores the activated rules, field-level similarity values, composite score, proposed relationship type, and decision state. ACCEPT candidates can be presented as high-confidence proposals, REVIEW candidates are routed to a curator, and REJECT candidates remain unlinked.

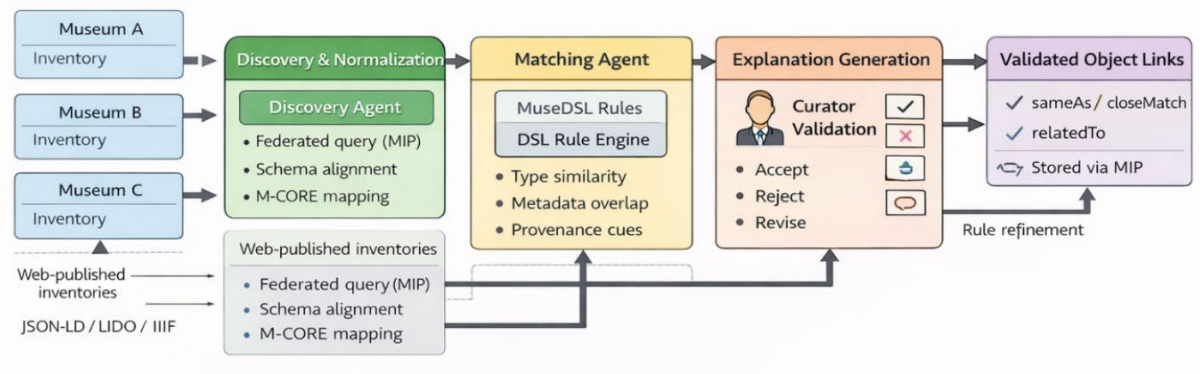

Figure 2. Operational workflow from federated discovery to curator-validated object links.

3. Explainability and Governance

An explanation artifact represents every candidate relationship. At minimum, the artifact contains the active MuseDSL rule, the compared fields, the field-level similarity values, the composite score, the decision state,

and the proposed link type. This trace allows a curator to understand not only what the system recommends but also why the recommendation was generated. The governance model treats a relationship as a lifecycle object rather than a one-time classification, so a proposed link can be reviewed, accepted, rejected, revised, or later withdrawn as museum knowledge changes.

4. External Authority Enrichment

The pilot uses Mindat as an auxiliary mineralogical authority source [14]. Mineral records can be submitted for name normalization, classification checking, synonym handling, and evidence enrichment. External authority evidence does not automatically determine the final cross-museum relationship; it is one source of evidence within the explanation chain. This distinction preserves the separation between external scientific references and institutional curatorial responsibility.

V. PROTOTYPE EVALUATION

1. Federated Pilot Environment

The prototype was evaluated in a web-based, federated pilot involving five museum inventory nodes, anonymized as Nodes A-E. Each node exposed selected metadata through API-based interfaces. No central index or pre-aggregated repository was created for the evaluation. A query object originating from one node could be sent to the other nodes, candidate metadata could be retrieved on demand, and the returned records could be evaluated through the common MuseDSL pipeline. The evaluation was designed around five practical questions: whether candidate objects could be discovered across nodes; whether collection-specific MuseDSL rules could be executed on heterogeneous records; whether an external authority could improve mineral name normalization; whether an auditable explanation could accompany every proposal; and whether uncertain results could be routed to human review rather than being forced into a binary decision.

2. Inventory and Task Pool

The evaluation inventory contained 1,000 web-published museum records distributed across five collection categories. The dataset is dominated by geological and natural history objects, making it suitable for testing rules that depend on mineral, rock, fossil, and biological descriptors. A batch of 100 source objects was used as an agent task pool. For each source object, the Discovery Agent queried the connected nodes, retrieved candidates, invoked authority matching for mineral-related records where applicable, and passed the results through normalization, matching, explanation, and decision routing.

Table 2. Distribution of object categories in the evaluation inventory

Category	Records	Percentage
Minerals	644	64.4%
Rocks	137	13.7%
Fossils	162	16.2%

Category	Records	Percentage
Biological specimens	39	3.9%
Other objects	18	1.8%
Total	1,000	100.0%

3. Federated Discovery and Rule Execution

The pilot confirmed the operational feasibility of the federated workflow. Candidate records could be retrieved from participating nodes without constructing a centralized collection database, and then normalized and evaluated using collection-specific rule families. Category gating prevented obviously incompatible categories from entering the same rule path, while M-CORE mapping enabled the comparison of differently structured fields through a shared operational representation. The architecture, therefore, supported interoperability as an interaction process rather than as a prior homogenization of global schemas. The strongest practical value of the rule approach was transparency. A curator can inspect whether a candidate was supported by name normalization, category compatibility, material similarity, taxonomic correspondence, geological age, locality, or another rule-defined feature. In contrast to a single opaque similarity score, the explanation artifact makes the computational path available for review. It enables revision of the rule when domain experts disagree with its behavior.

4. Mindat Authority Matching

Minerals formed the largest category, with 644 records. These records were submitted to the external authority matching process for name normalization and evidence enrichment. After normalization, the authority-matching rate exceeded 90% for the mineral subset, indicating that the majority of local mineral labels could be associated with recognized external entries. Unmatched or weakly matched records could, in turn, be treated as candidates for curator inspection. Possible causes of non-matches include spelling variants, synonyms, incomplete labels, local terminology, and records that require more detailed scientific review.

The authority result should not be interpreted as a final accuracy score for cross-museum object linking. It measures the success of associating local mineral labels with an external mineralogical authority after normalization. The broader object linking task also depends on the semantic relationship being sought and on additional evidence fields. Nevertheless, the result demonstrates the value of integrating external scientific authorities into an explainable rule-based workflow.

5. Explainability and Human Review

For the evaluated candidate relationships, the prototype generated rule-activation traces, field-level similarity decompositions, composite scores, proposed relationship types, and decision states. Cases that did not clearly satisfy the acceptance or rejection conditions could be routed to REVIEW. The review state is a central design feature because it prevents the system from presenting every computationally plausible link as an institutional fact. It also allows the framework to capture curator feedback and, in future implementations, to support controlled rule refinement. The current conference evaluation establishes feasibility rather than exhaustive comparative superiority. Large-scale baseline comparisons, ablation studies, threshold sensitivity analyses,

inter-rater agreement studies, and curator workload measurements are intentionally reserved for the expanded journal evaluation. This separation keeps the conference paper focused on the core artifact and the verified pilot observations, while leaving sufficient methodological space for a substantially extended archival publication.

VI. DISCUSSION

1. From Data Exchange to Governed Semantic Interaction

The main conceptual contribution of MuseDSL is to reposition museum interoperability as a process of forming governed relationships. Existing standards answer important questions about how cultural heritage information should be represented, exchanged, harvested, or displayed. MuseDSL addresses a different operational question: once several institutions expose compatible metadata, how can a new or existing object actively discover related objects, how can the evidence for a candidate relationship be expressed, and how can museum professionals remain responsible for the final decision? This distinction explains why the proposed framework is complementary rather than competitive. A museum node can continue to use CIDOC CRM, LIDO, IIIF, OAI-PMH, JSON-LD, or institution-specific databases. MuseDSL operates above these technologies as a rule-governed interaction layer. Its value depends on the availability of structured metadata, but it does not prescribe a single storage system or require participating museums to surrender control over their records.

2. Why a Domain-Specific Language Matters

Museum object linking is knowledge-intensive. The evidence that matters for two mineral records differs from that for two fossils or two archaeological artifacts. A general-purpose similarity function can be useful for retrieval, but it obscures domain assumptions when all fields are collapsed into a single implementation. MuseDSL exposes those assumptions as rules that can be read, reviewed, versioned, and adapted by domain communities. This is particularly important when different institutions use different acceptance thresholds or prioritize different evidence fields. The rule language also creates a practical bridge between software engineering and curatorial knowledge. Developers can implement reusable matching operators, while curators can reason about rule scope, field relevance, evidence weights, and relationship types. The resulting explanation trace provides a shared object for technical debugging and scholarly review.

3. Limitations

The pilot has several limitations. First, five nodes are sufficient to demonstrate distributed operation but not to establish national or international scalability; larger networks may introduce latency, availability, rate-limiting, duplicate-record, and multilingual metadata challenges. Second, the inventory is dominated by geological and natural history collections, so the current rule set cannot be assumed to apply directly to art-historical, ethnographic, archival, or archaeological domains. Third, the reported Mindat matching rate reflects the authority association after normalization and should not be conflated with end-to-end object link precision or recall. Fourth, the present conference paper does not report a complete quantitative comparison against alternative entity resolution models. These limitations define the next stage of evaluation. The extended study will compare title-only, multi-field lexical, authority-assisted, and full MuseDSL configurations; perform ablation studies of category gating, semantic normalization, authority enrichment, rule weighting, and the review band; examine threshold sensitivity; and evaluate the usefulness of explanations and museum

professionals' trust in them. Scalability tests will also measure response time, failure rate, throughput, candidate volume, and curator review workload under larger federated conditions.

VII. IMPLEMENTATION DETAILS AND REPRESENTATIVE RULE BEHAVIOUR

1. Federated Query and Relationship Lifecycle

A MuseDSL interaction begins with a source object that belongs to an initiating museum node. The source can be either a newly registered record or an existing object selected for cross-collection exploration. The initiating node prepares a compact query package that contains only the fields required by the active rule profile. This minimizes unnecessary data transfer and allows each institution to retain local control over fields irrelevant to the matching task. The query package identifies the source node, the object identifier, the requested collection scope, the active rule family, and the selected descriptive metadata. Participating nodes respond with candidate records rather than complete inventory exports. The Discovery Agent collects these responses and records the originating node for each candidate. This provenance information is preserved throughout the pipeline, because a relationship proposal is not merely a link between two metadata strings; it is a relationship between institutional records governed by different authorities. After normalization and matching, a proposal can be returned to the relevant target node, along with its evidence artifact and proposed relationship type. The lifecycle of a relationship is modeled through explicit states. A candidate may first exist as discovered and then become proposed after rule evaluation. High-confidence proposals enter the ACCEPT recommendation state; uncertain proposals enter REVIEW; and incompatible candidates are marked REJECT. A curator can validate, reject, or revise a proposal. A validated link can later be re-examined when new evidence appears, when an object record changes, or when a rule profile is updated. This lifecycle orientation is important because museum knowledge is not static: taxonomic classifications, provenance interpretations, object names, and institutional policies may all change over time.

2. Normalization and Field-Specific Similarity

MuseDSL separates normalization from matching. This design prevents every rule from re-implementing the same cleaning operations and makes the transformation process easier to inspect. Common normalization operations include case folding, whitespace trimming, removal or harmonization of diacritics, controlled synonym mapping, multilingual label alignment, and conversion of selected local fields into M-CORE. Domain-specific operations can also be attached to a field. For minerals, these operations may include mapping mineral names to synonyms and authority lookups. For fossils and biological specimens, taxonomic name normalization and rank-aware comparison may be used. For rocks, controlled vocabularies can represent rock class, texture, and genesis. Field-specific similarity is necessary because museum metadata fields have different semantics. A title may be compared using token overlap or normalized label equivalence, whereas a category field may require exact compatibility. Geological age can be compared using period mapping, locality using gazetteer-aware fuzzy matching, and numerical descriptors using tolerance functions. MuseDSL therefore treats similarity operators as reusable functions selected by rules rather than hard-coded into a single global scoring model. The composite score summarises the active evidence but does not replace the explanation. If a candidate achieves a score of 0.88, a curator should still be able to see whether that value was produced by strong taxonomic agreement, a shared material, a matching geological period, or several weaker signals. For this reason, the system stores the field-level contributions alongside the total. Optional fields are also distinguished from mandatory constraints: a missing locality, for example, should not necessarily invalidate a mineral species match, whereas a category mismatch may be sufficient to prevent a rule from executing at all.

3. Representative MuseDSL Rule Families

The prototype currently contains representative rule families for minerals, rocks, fossils, and biological specimens. The mineral rule family places high importance on the normalized mineral label and can use chemical formula, mineral group, and hardness as supporting evidence when those fields are available. The rock rule family emphasizes rock type and rock class, with texture and genesis as additional evidence. The fossil and biological rule family uses category compatibility, taxonomic name, specimen subtype, geological age, and locality. These examples demonstrate the language's central design principle: each collection domain can express its own evidence hierarchy while using the same federated execution and governance infrastructure. A rule also identifies the relationship that it is allowed to propose. An exact mineral species rule may propose a same-type or same-concept relationship, whereas a contextual rule may propose close-match or related-to. Separating the relationship type from the similarity score is important because two objects can be strongly similar without being identical, and a high score should not automatically imply semantic equivalence. The curator can therefore assess both the numerical evidence and the meaning of the proposed link. Rule versioning is another practical requirement. When a museum changes a threshold, adds a synonym, or modifies the relative importance of an evidence field, the resulting decisions should remain traceable to the rule version that produced them. The prototype records rule activations in the explanation log, which provides the basis for future versioned governance. In a larger deployment, institutions could maintain local rule profiles while also sharing community-approved rule libraries for common collection domains.

4. Representative Operational Scenario

Consider a museum that registers a fossil specimen with a scientific or local name, a specimen subtype, a geological period, and a discovery locality. After the record is saved, the museum can initiate a federated search. The source metadata is sent only to selected participating nodes. Candidate objects returned by other museums are normalized to M-CORE, and the fossil rule family evaluates taxonomic correspondence, subtype similarity, geological age, and locality. A candidate with strong taxonomic and chronological agreement may be proposed as a close match, whereas an object that shares only a broad category may be rejected. If the score falls within the review band, the curator receives the evidence rather than an automatic decision being made.

The same workflow can be applied in the opposite direction. A museum that adopts the same interoperability software can search other participating institutions when its own staff registers or reviews an object. Consequently, the architecture does not depend on a single central museum or a privileged aggregator. Each node can initiate discovery, and each institution can decide whether to expose metadata or accept proposed links. Over time, the result can become a distributed network of curator-validated relationships among museum objects. The prototype interface visualizes this process by allowing an initiating node and the active remote nodes to be selected, executing a federated query, and presenting the returned candidates with their source node, title, category, material, score, decision, and proposed link type. Separate evidence panels record the rule traces and field contributions. The interface is intentionally simple because the research contribution focuses on the interoperable workflow and the rule model rather than on a final production user experience.

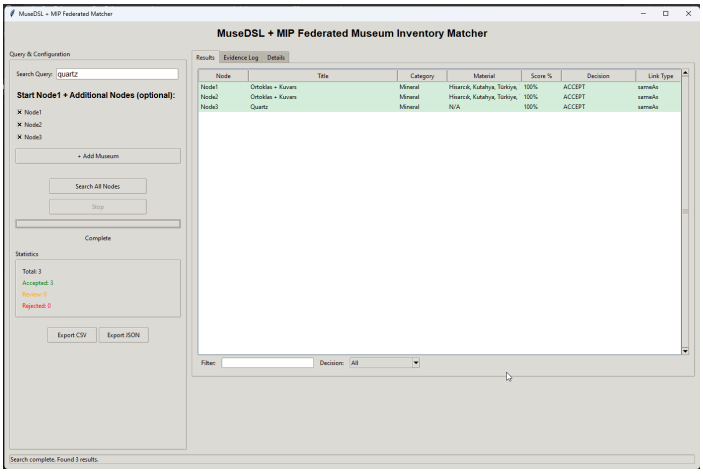

Figure 3. Prototype federated query interface showing candidate objects, decision states, and proposed link types.

5. Reproducibility, Security, and Deployment Considerations

The prototype and the representative rules are published as open-source software so that the architecture can be inspected and extended. Reproducibility in a federated setting, nevertheless, involves more than just source code. Live endpoints can change, external authority services may return updated records, and museum systems may apply access restrictions. For this reason, a robust reproducibility package should contain anonymized sample inventories, fixed API response snapshots, example rule files, exported explanation artifacts, and scripts that replay selected evaluation tasks without relying on live services.

Security and institutional control also require attention in future deployments. A production MIP implementation should define authentication, authorization, rate limiting, request logging, and provenance, along with clear policies for which fields may be exposed. Relationship proposals should be digitally attributable to their initiating node, and validation actions should record the responsible institution and the rule version. These features are not fully formalized in the current pilot, but they are compatible with the layered architecture, as communication, processing, and governance are separated.

Scalability will depend on query routing and candidate reduction. Broadcasting every object to every museum would be inefficient in a large network. Future implementations can use collection profiles, category-aware routing, lightweight node registries, caching of authority normalization, and staged retrieval in which broad filters are applied before expensive rule evaluation. Because MuseDSL rules expose their scope, they can also guide query planning by declaring which categories and fields are required before candidate data are requested. These deployment considerations reinforce the conference paper's role as the architectural and feasibility foundation for a broader research program. The short form establishes the language, protocol concept, agent workflow, governance logic, and the initial multi-node pilot. A full journal extension can then evaluate performance and generalisability using larger networks, stronger baselines, controlled ablations, multilingual collections, curator user studies, and formal protocol specifications, without simply repeating the same contribution.

6. Governance, Rule Maintenance, and Institutional Adoption

Institutional adoption requires more than successful retrieval. Museums need to know who is responsible for a proposed relationship, which version of the rule produced it, what evidence was used, and whether an authorized expert has reviewed the proposal. MuseDSL, therefore, treats the provenance of decisions as part of interoperability. A production deployment should retain the initiating node, the target node, the rule identifier, the rule version, the evaluation time, the explanation artifact, and the curator action. These records can support later auditing and can prevent a validated relationship from becoming detached from the reasoning that originally justified it. Rule maintenance should also be collaborative but controlled. A shared rule library can accelerate adoption across institutions, yet museums may legitimately apply different thresholds or local vocabularies. The framework can therefore distinguish community rules from local profiles. A community rule defines reusable domain logic, while an institutional profile can adjust synonyms, optional fields, thresholds, or review policies without changing the underlying protocol. This approach preserves interoperability at the level of interaction while allowing museums to retain scholarly and organizational autonomy. A further adoption challenge is the curator's workload. Fully automated linking may create an unacceptable number of false positives, whereas sending every candidate to human review can make the system impractical. The three-state decision model is intended to balance these risks: high-confidence proposals can be prioritized for rapid confirmation, clearly incompatible candidates can be filtered out, and only ambiguous cases enter the review queue. Future evaluations should therefore measure not only precision and recall, but also the number of review cases generated per object, the time required for expert validation, and the extent to which explanation artifacts reduce review effort. These measures will be essential for judging whether federated object linking is operationally sustainable in day-to-day museum practice.

VIII. CONCLUSION

This paper introduced MuseDSL, an explainable and federated framework for curator-governed museum object linking. The framework combines distributed discovery, an operational normalization layer, a domain-specific rule language, agent-oriented processing, explanation generation, and human-in-the-loop validation. Its purpose is to extend museum interoperability beyond static metadata exchange towards accountable semantic interaction among autonomous collection systems. A prototype was evaluated in a web-based pilot with five museum inventory nodes and a 1,000-record inventory. A 100-object task pool was processed through the agent workflow, and mineral records were also evaluated against Mindat as an external authority. The mineral authority matching process achieved a rate above 90% after normalization. The prototype also generated inspectable rule traces, field-level evidence, composite scores, and decision states for candidate object relationships. The results provide initial evidence that meaningful cross-institutional object discovery can be implemented without centralizing complete museum inventories. That explainability and curator review can be embedded as first-class architectural requirements. The open-source prototype and the rule examples are available at https://github.com/cyasar/MuseDSL. Future work will extend the current pilot with larger federated networks, broader collection domains, comparative baselines, ablation studies, threshold analysis, and structured curator-centered evaluation.

ACKNOWLEDGEMENT

The authors thank the institutional and technical contributors who supported the development and testing of the MuseDSL prototype, and acknowledge the value of the open cultural heritage and mineralogical data infrastructures that enable interoperable museum research.

Abstract

As part of this study, a machine learning-based decision support system was developed for the classification of Alzheimer's disease, and the effects of different hyperparameter optimization algorithms on model performance were examined. The Decision Tree (DT) and Random Forest (RRF) algorithms, selected as classification models, were optimized using Grey Wolf Optimization (GWO), Bayesian Optimization (BO), and a Genetic Algorithm (GA). While there are studies in the literature on artificial intelligence for disease diagnosis, research comparing multiple optimization algorithms on the same models remains limited. Experimental results have shown that hyperparameter optimization improves model performance. Compared to unoptimized base models, the Random Forest model achieved an increase of approximately 0.39% in Receiver Operating Characteristic Area Under the Curve (ROC-AUC). In comparison, the Decision Tree model achieved an increase of approximately 1.39%. While the highest ROC-AUC was achieved with the Random Forest + Genetic Algorithm combination, Bayesian Optimization proved to be the most time-efficient approach. In conclusion, the models' discriminative performance demonstrates the impact of hyperparameter optimization on medical decision support systems.

Keywords: alzheimer's disease, decision tree algorithm, random forest algorithm, grey wolf optimization algorithm, Bayesian optimization algorithm, genetic algorithm

I. INTRODUCTION

Artificial intelligence (AI) applications are becoming increasingly widespread in the healthcare sector, particularly for their advantages in high-risk clinical decision-making. However, for these systems to be used safely in clinical practice, they must adhere to the principles of Trustworthy AI, such as fairness, transparency, reliability, and accountability [1]. One of the areas where this requirement is most evident is the diagnosis of Alzheimer's disease, a progressive and irreversible neurodegenerative disorder. Alzheimer's is particularly prevalent among individuals aged 65 and older, and the number of patients worldwide is increasing each year [2], [3]. Since there is no definitive cure for the disease, early diagnosis is critical for the timely implementation of appropriate medical interventions and the effective management of its course [4], [5]. Deep learning and machine learning methods offer significant potential for the early diagnosis of Alzheimer's disease, particularly given their strong performance in analyzing Magnetic Resonance Imaging (MRI) data [3], [6]. However, the performance of these models depends largely on the proper selection of hyperparameters. Failure to properly optimize hyperparameters—such as the learning rate, number of iterations, activation functions, and regularisation parameters—can reduce model performance and lead to problems such as overfitting [7], [8]. Therefore, this study aims to maximize predictive performance by optimizing the hyperparameter spaces of

machine learning models using various metaheuristic optimization methods to predict Alzheimer's disease early and with high accuracy [7],[9].

This study aims to improve the diagnostic performance of Decision Tree and Random Forest models for diagnosing Alzheimer's disease. To this end, the models' hyperparameters were optimized using Grey Wolf Optimization (GWO), Bayesian Optimization (BO), and Genetic Algorithm (GA). The Receiver Operating Characteristic - Area Under Curve (ROC-AUC) values obtained were compared to identify the most successful meta-heuristic optimization approach. Additionally, method runtime was analyzed to provide a comprehensive evaluation of accuracy and performance. The specific objectives for achieving this general goal are as follows;

1. What are the optimal hyperparameter values obtained for DT and RF models using GWO?
2. What are the optimal hyperparameter values obtained for DT and RF models using BO?
3. What are the optimal hyperparameter values obtained for DT and RF models using GA?
4. When comparing the performance of the GWO, BO, and GA optimization methods, which method produces more successful results, and is there a performance difference between the optimized and unoptimized models?
5. When examining the ROC curves of the models obtained after optimization, what is their classification performance?

II. RELATED STUDIES

A comprehensive literature review was conducted on artificial intelligence methods used in the diagnosis of Alzheimer's disease and the optimization techniques applied to them. It has been observed that artificial intelligence (AI) methods are increasingly being employed in the diagnosis of Alzheimer's disease. Mishra and Li [10] reported positive results for the application of AI in genetic analyses. Lale [11] and Özaltın [12] achieved high accuracy rates with the models they developed. At the same time, Bechir and Atasoy [13], Sukamto et al. [14], Zhang [15], and Bloch and Friedrich [8] reported that hyperparameter optimization improves model performance. El-Sappagh et al. [16] developed an explainable AI-based model for diagnosing Alzheimer's disease. Additionally, while Minesh [17] evaluated deep learning approaches, Vrahatis et al. [4] emphasized the significant potential of AI-assisted early-diagnosis studies. The literature indicates that artificial intelligence, machine learning, and deep learning methods are widely used in the early diagnosis and staging of Alzheimer's disease. Studies conducted using MRI images, clinical data, and biological markers demonstrate that these methods can achieve high accuracy. Research has shown that model performance depends not only on the algorithm used but also on hyperparameter optimization. While methods such as Grid Search, Bayesian Optimization, and Optuna can improve model performance, they can also reduce computational costs. However, challenges such as data insufficiency, class imbalance, interpretability, and high computational cost persist. Therefore, machine learning models supported by hyperparameter optimization represent an important area of research for the early, reliable prediction of Alzheimer's disease.

III. METHODS

The methodological workflow of the study begins with the collection and analysis of the dataset. Next, data preprocessing steps were applied, and training and test datasets were created. Class imbalance was addressed during this process, after which DT and RF models were built. Hyperparameter optimization was performed on these models, and their performance was evaluated using cross-validation. In the final stage, the results were compared to identify the best model.

1. Dataset Used

In this study, an Alzheimer's dataset comprising 2,149 patients, obtained from the "Kaggle" platform, was used to train machine learning models. The dataset was prepared to examine factors associated with the disease and to develop predictive models; however, it is synthetic. The dataset, which contains 35 numerical features, is categorized into groups such as patient ID, demographics, lifestyle, medical history, clinical measurements, cognitive assessments, and diagnostic information. No missing data was found in the dataset during the analysis.

In this study, the "PatientID" and "DoctorInCharge" attributes were removed from the patient dataset to ensure they did not influence the machine learning models, as they had no impact on disease diagnosis. Subsequently, 32 of the remaining 33 attributes were assigned to the set of independent variables, $X = \{x_1, x_2, \ldots, x_n\}$, while the remaining attribute was designated as the target variable for disease detection, $y \in \{0, 1\}$. The dataset was then split into 80% training data and 20% test data for the machine learning algorithms used in the study, and the "stratified sampling" approach was employed to preserve the class distributions. Finally, since the target class distribution in the dataset was not perfectly balanced and to prevent "majority class bias" in disease diagnosis, SMOTE (Synthetic Minority Over-sampling Technique) was applied to the training data to generate new synthetic examples belonging to the minority class, thereby balancing the data distribution in the training set used for machine learning.

2. Machine Learning Models

In this study, the Decision Tree (DT) and Random Forest (RF) algorithms were used to classify Alzheimer's disease based on patient data. The reasons for choosing these algorithms include their interpretability, their widespread use in medical datasets, and the fact that they offer structures suitable for hyperparameter optimization.

1) *Decision tree (DT) algorithm:* In machine learning, the decision tree (DT) algorithm is one of the most popular supervised learning algorithms used today and can be applied to both classification and regression tasks [18],[19]. The decision tree algorithm divides data into different groups based on specific conditions. Each node in this structure represents a test for a specific variable, while each branch represents a possible outcome or decision of that test. The final decision at the end of the process is represented by a leaf node [18; 20]. In this study, the Gini impurity technique was used to split the data in the DT algorithm. The Gini index serves as an indicator of how "pure" the leaf nodes are for classification—that is, it indicates how mixed the training data assigned to each node is [21]. In this algorithm, the features that best separate the data and the threshold value are determined at each node. Therefore, the hyperparameters optimized in this algorithm are: "max_depth (maximum depth)," "min_samples_split (minimum number of samples per split)," and "min_samples_leaf (minimum number of samples per leaf node)." The formula for the Gini impurity technique used in the algorithm is: $Gini(D) = 1 - \sum_{i=1}^{C} p_i^2$, where the variable "pi" represents the class probability and the value "C" represents the total number of classes [21].

2) *Random forest (RF):* The basic operating principle of the RF algorithm is to combine a collection of random decision trees. The goal is to optimize a set of predictors (which are not necessarily optimal) by combining them, rather than optimizing a single predictor "at once" [22]. In this study, the RF algorithm—used for patient diagnosis—is an "ensemble learning" method that combines numerous decision trees. In this algorithm, each tree is created using the bootstrap sampling method. In the algorithm, the final class prediction is determined by majority voting, where "$\hat{y}$ = mode($T_1(x)$, $T_2(x)$, …, $Tn(x)$)" [23]. In this formula, "Ti(x)" represents the prediction of the i-th decision tree. The hyperparameters optimized in this algorithm are:

"n_estimators (number of estimators)", "max_depth (maximum depth)", "min_samples_split (minimum number of samples per split)", and "min_samples_leaf (minimum number of samples per leaf node)".

3. Hyperparameter Optimization

One of the most significant challenges in machine learning is the need to set initial parameter values for each learning algorithm before training begins; these parameters are referred to as hyperparameters. Hyperparameters can cause significant changes in the resulting model. Hyperparameters configure various aspects of a learning algorithm, such as the learning rate, kernel parameters, and network architecture [24]. In this study, the "Mean Cross-Validated ROC-AUC" was selected as the fitness function for hyperparameter optimization. The primary reason for choosing "ROC-AUC" in this comparison is that the study involves medical classification, and therefore, using the accuracy metric alone could be misleading. "ROC-AUC," on the other hand, is a threshold-independent metric that measures the balance between sensitivity and specificity. In this study, all optimization algorithms were evaluated using the same fitness function. The formula for the fitness function used in the study is: "$q^* = \arg max_{q \hat{I} W} f(q)$". Here, "θ" represents the hyperparameter values, "Ω" represents the search space, and "f(θ)" represents the objective function. The formula for "$f(q) = \frac{1}{K}\sum_{i=1}^{K} ROC_AUC_i$" and the "K" value in the formula is the "K-fold" number used in the "Stratified K-Fold Cross-Validation" method; in this study, this value was set to 5. The hyperparameter vectors required for the machine learning algorithms in this study are, in order:

- For DT: θ_DT=[max_depth, min_samples_split, min_samples_leaf],
- For RF: θ_RF=[n_estimators, max_depth, min_samples_split, min_samples_leaf]

4. Meta-heuristic Optimization Algorithms

Using the optimization algorithms employed in this study, the hyperparameter search performance of the machine learning algorithms DT and RF was evaluated. This made it possible to compare the effects of each optimization algorithm on classification performance.

1) Grey wolf optimization algorithm (GWO): GWO is an optimization algorithm based on swarm intelligence that mathematically models the hunting behavior of grey wolves [25]. In this algorithm, individuals within the swarm are classified as "alpha," "beta," "delta," and "omega." The best solution is considered to be the alpha wolf in the algorithm. The formulas for position updates [25] are: "$D = |C \cdot X_\alpha - X|$" and "$X(t+1) = X_\alpha - A \cdot D$", and the coefficient vectors here are "$A=2\sigma r_1 - \sigma$" and "$C = 2r_2$," where the values of "r_1" and "r_2" are random number vectors. The value of "σ" represents the control parameter that decreases throughout the iteration. In this study, the GWO algorithm was applied at each iteration as follows: the fitness value of each wolf was calculated; the wolf with the best fitness was selected as alpha; the other wolves were updated to converge toward alpha; new hyperparameter combinations were generated; and the ROC-AUC was recalculated. In this study, the number of wolves in the GWO algorithm was set to 10, and the number of iterations was set to 30.

2) Bayesian optimization algorithm (BO): In the BO algorithm, this approach is aimed at optimizing objective functions that take a long time to evaluate. It quantifies these functions using Gaussian process regression—a Bayesian machine learning technique—and then decides where to sample using a learning function defined by this model [26]. The general form of the formula used in the algorithm [27] is "$f(x) \sim GP(\mu(x), k(x, x'))$," where "GP" denotes the Gaussian process, μ(x) represents the mean function, and k(x, x′)

represents the covariance function. New hyperparameter points are selected using the acquisition function, and the formula [27] is "$x_{next} = \text{argmax}\alpha(x)$". In this study, the Bayesian Optimization algorithm was implemented using the "Optuna" library. Additionally, in this study, the "n_trials" value—the number of iterations—was set to 30. The implementation of the BO algorithm in this study was as follows: the first few trials were conducted randomly; the results obtained were modeled using a Gaussian or Parzen-based surrogate model; then, a balance between exploration and exploitation was achieved using the acquisition function; during this process, the most promising new parameters were selected; and finally, the ROC-AUC value was recalculated.

3) Genetic algorithm optimization olgorithm (GA): GA is a method for optimizing search algorithms for difficult problems based on the principle of genetic selection. The working principle of GA is as follows: similar to chromosome production in biology, it relies on genetic operations—such as selection, crossover, and mutation—applied to an initially random population to generate solutions across successive generations [28]. At the start of the algorithm, a population of randomly generated individuals is created and represented as "P(t) = {x_1, x_2, ..., x_n}". Each individual's fitness value is calculated using the objective function as follows: "$Fitness(x_i) = f(x_i)$". The progression of the GA algorithm involves the following steps in each generation (iteration): first, the selection process is performed to identify the best individuals; then, crossover is applied to recombine the parameters of the selected individuals; finally, in the mutation phase, random changes are made to the individuals. As a result of these operations, a new population was formed, and the fitness values were recalculated. In the GA algorithm, the population size was set to 10, and the number of generations (iterations) was set to 30; these parameters were used to search for the global optimum.

5. Performance Evaluation Criteria

In this study, results from models optimized with optimization algorithms were evaluated with the ROC-AUC metric. The ROC-AUC value provides a general assessment of model performance. This metric illustrates the relationship between the true positive rate (TPR) and the false positive rate (FPR). The calculations for TPR and FPR are as follows [29]: "$TPR = \frac{TP}{TP+FN}$" and "$FPR = \frac{FP}{FP+TN}$". In these calculations, the abbreviations used to evaluate the test and prediction performance of classification models denote the following states: TP for true positive, FN for false negative, FP for false positive, and TN for true negative.

IV. FINDINGS AND ANALYSIS

In this study, ROC-AUC was used as the primary metric to evaluate the performance of algorithms for diagnosing Alzheimer's disease. This metric was chosen because it more accurately reflects the model's ability to distinguish between disease classes. In addition, the model optimization times were compared. The results show that hyperparameter optimization directly affects the classification performance of both Decision Tree (DT) and Random Forest (RF) models.

1. Optimizing Hyperparameter Results with Meta-Heuristic Optimization Algorithms

1) Hyperparameter spaces obtained with the GWO algorithm: In this study, the GWO algorithm was used to identify the optimal hyperparameter spaces for both the DT and RF algorithms. The optimal hyperparameter space obtained for the DT model is as follows: "max_depth: 6.14269925," "min_samples_split: 6.23506442," and "min_samples_leaf: 5.8006925." The decimal values in this hyperparameter space were converted to integers for use in the algorithm. Upon examining this hyperparameter space obtained for the DT model, it can be seen that the tree depth is kept limited, the minimum number of samples per split is increased, and more samples are retained at the leaf nodes. The optimal hyperparameter space obtained for the RF model is as

follows: “n_estimators: 281.45510932”, “max_depth: 15.82994271”, “min_samples_split: 2.53040449”, and “min_samples_leaf: 1.13892439”. These results indicate a high number of trees, a deeper tree structure, and low leaf node thresholds, suggesting that the model is oriented toward higher representational capacity. Since the RF uses an ensemble learning approach, the risk of overfitting is lower, enabling the selection of more aggressive parameters with the GWO optimizer.

2) *Hyperparameter spaces obtained using the Bayesian optimization (BO) algorithm:* In this study, the BO algorithm was used to identify the optimal hyperparameter spaces for both DT and RF. The optimal hyperparameter space obtained for the DT model is as follows: “max_depth: 5”, “min_samples_split: 17”, “min_samples_leaf: 9”, and “Criteria: entropy”. Looking at this hyperparameter space, the BO algorithm produced parameters that are more resistant to change; in particular, the model maintains a simpler structure with “low max_depth,” “high min_samples_split,” and “high min_samples_leaf” values. Selecting entropy as the criterion, along with the metaheuristic optimization algorithm, also indicates that an information-gain-based splitting strategy was preferred in the DT model. Thus, a more orderly and controlled hyperparameter search was achieved using the BO algorithm. The optimal hyperparameter space obtained for the RF model is as follows: “n_estimators: 282,” “max_depth: 24,” “min_samples_split: 14,” “min_samples_leaf: 1,” and “criterion: entropy.” An evaluation of this hyperparameter space reveals that a high number of trees were generated for the RF model, resulting in a very deep structure. This enables the model to learn complex patterns while also limiting unnecessary branching.

3) *Hyperparameter spaces obtained with genetic algorithms (GAs):* In this study, the GA algorithm was used to identify the optimal hyperparameter spaces for both the DT and RF algorithms. The optimal hyperparameter space obtained for the DT model is as follows: “max_depth: 7,” “min_samples_split: 6,” and “min_samples_leaf: 8”—that is, a Decision Tree structure with medium complexity was established using the GA optimization algorithm. With this structure, the model maintains a balance between learning capacity and generalization ability. The optimal hyperparameter space obtained for the Random Forest (RF) model is as follows: “n_estimators: 222”, “max_depth: 28”, “min_samples_split: 3”, and “min_samples_leaf: 1”—that is, a Random Forest structure with high complexity was established using the GA optimization algorithm. Furthermore, because of the ensemble nature of the Random Forest, this complexity did not lead to significant overfitting.

2. Results Obtained with Optimization Algorithms

The results obtained from the optimization algorithms used in the study are given in Table 1. ROC-AUC sorts the results in Table 1.

Table1. Optimization algorithm results

Model	Meta Heuristic Optimization Algorithms	ROC-AUC	Time (s)
Random Forest (RF)	GA	0.942777	183.56
Decision Tree (DT)	Bayesian	0.942683	2.33
Random Forest (RF)	Bayesian	0.942517	27.64
Random Forest (RF)	GWO	0.942091	286.69
Decision Tree (DT)	GA	0.942067	18.29
Decision Tree (DT)	GWO	0.941239	27.69
Random Forest (RF)	-	0.939000	4.40

Decision Tree (DT)	-	0.929800	6.38

An examination of Table 1 reveals that machine learning models with an optimizer achieved better results than those without one. It is observed that the ROC-AUC scores of machine learning models that use an optimizer are very similar, hovering around 0.94. This result demonstrates that the optimization algorithms applied to the machine learning models can successfully classify the dataset. Additionally, the best ROC-AUC was obtained with the RF model using the GA algorithm. When comparing the results of the RF model without the Meta-Heuristic optimization algorithm to the best result from the RF model using an optimization algorithm, the model's success rate increased by approximately 0.39% with the optimization algorithm. Similarly, when examining the results using the DT algorithm, the model's success rate increased by approximately 1.39% with the optimization algorithm. This demonstrates that optimizing the hyperparameter spaces of machine learning models using optimization algorithms can yield better results.

In models using metaheuristic optimization algorithms, computation times generally increased compared to models without optimization. In particular, it was determined that the RF model with BO performed faster and produced ROC-AUC values close to those of the RF model obtained with GA. This indicates that BO can deliver high performance with lower computational cost. It was observed that the GWO and GA algorithms, due to their swarm- or population-based structures, require longer computation times.

3. ROC Curve Analysis

Figure 1 shows the ROC curve plots for all machine learning models to which meta-heuristic optimization algorithms were applied. Looking at this figure, the curves for all models are positioned quite close to the upper-left corner. This indicates that the models produced a high true positive rate and a low false positive rate.

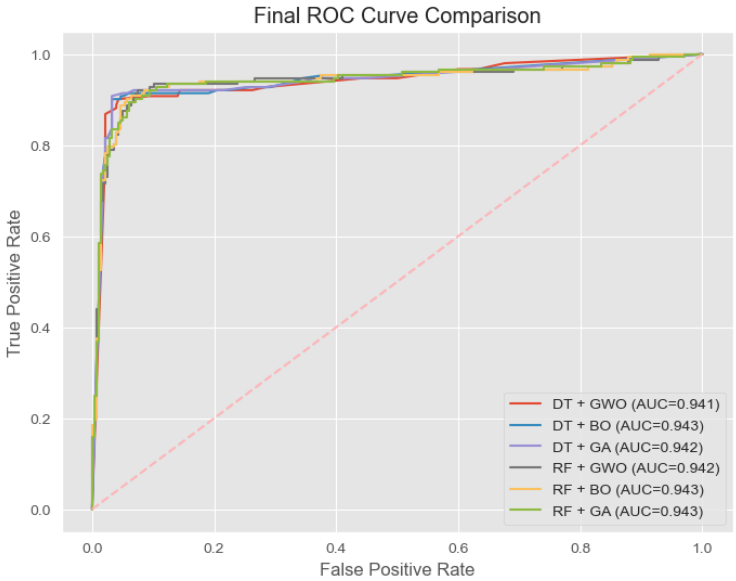

Figure 1. ROC curve for all algorithms.

Furthermore, as shown in the ROC curve, there are no significant differences in performance among the models. The main reasons for this are that the dataset used contains strong discriminative features and that all meta-heuristic optimization algorithms were able to reach suitable hyperparameter regions.

V. CONCLUSION

In this study, a comprehensive review of the literature was conducted on artificial intelligence models used in the diagnosis of Alzheimer's disease and the metaheuristic optimization methods employed for these models; studies that included literature reviews were examined in detail. Within this scope, machine learning models—specifically Decision Trees (DT) and Random Forests (RF)—were used to classify Alzheimer's disease. Meta-heuristic optimization techniques were applied to these machine learning models. The optimization processes were carried out using the GWO, BO, and GA algorithms. To evaluate the performance of machine learning models trained with these optimization algorithms, the ROC-AUC metric was used as the primary criterion for comparison.

A review of the literature revealed that artificial intelligence methods are widely used in the diagnosis of Alzheimer's disease, particularly in recent studies. Some studies have also shown that meta-heuristic optimization methods have been integrated into these models. However, no studies were found that directly compared the performance effects of applying multiple optimization methods to the same machine learning model.

The findings indicate that hyperparameter optimization directly affects model performance. When models without metaheuristic optimization were compared with optimized models, the ROC-AUC increased by approximately 0.39% for the RF model and 1.39% for the DT model. This increase was particularly pronounced in the DT model, indicating that hyperparameter optimization is more effective in simple models prone to overfitting. ROC-AUC values of approximately 0.94 were achieved across all methods, indicating high classification accuracy. The best results in DT were obtained with BO, while in RF they were achieved with GA; the RF+GA combination yielded the highest ROC-AUC.

In contrast, BO was observed to require less optimization time and to provide a more efficient search. The GWO algorithm, on the other hand, exhibited more stable convergence behavior. While the ROC curves revealed that all models demonstrated strong discrimination, with high TPR and low FPR, the RF model produced more balanced results than DT due to its ensemble structure.

A literature review shows that hyperparameter optimization improves model performance in studies aimed at predicting Alzheimer's disease. The findings of this study also support this approach. Throughout the process, the low computational cost of BO, GA's ability to search a wide solution space, and GWO's stable convergence behavior have highlighted the advantages of these different methods. In conclusion, metaheuristic and probabilistic optimization algorithms are effective in improving the performance of medical decision support systems.

Abstract
This report presents a comprehensive analysis of 44 research papers from the George B. Moody PhysioNet Challenge 2022 (Computing in Cardiology), focusing on automated heart murmur detection and clinical outcome prediction from Phonocardiogram (PCG) recordings. We examine the CirCor DigiScope dataset's clinical correlations, demographic distributions, and preprocessing requirements. To map the methodology landscape, we introduce an NLP-based framework comprising keyword co-occurrence analysis, spatial distance network visualization, and semantic text embeddings with Sentence Transformers. We demonstrate that a four-cluster taxonomy (k=4) effectively categorizes published approaches into traditional feature engineering, end-to-end deep learning, sequence/ensemble models, and advanced representation/multi-task learning. This review provides a structured overview of state-of-the-art modeling strategies and dataset characteristics for pediatric heart sound classification.

Keywords: Heart Murmur Detection, Phonocardiogram (PCG), Clinical Outcome Prediction, Deep Learning, PhysioNet Challenge

I. INTRODUCTION

This paper analyzes 44 research papers presented at the Computing in Cardiology Conference for the 2022 George B. Moody PhysioNet Challenge. The primary objective is to evaluate automated strategies for Heart Murmur Detection and Clinical Outcome Prediction from Phonocardiogram (PCG) recordings. Rather than proposing a new classification algorithm, this paper introduces a systematic, NLP-empowered review methodology for reliably analyzing mass publications in this domain. Our approach creates an easily replicable framework to cross-check methodological trends across literature. Using this pipeline, we identify top-performing architectures—such as hybrid Parallel Hidden Semi-Markov Models [1], Hierarchical Multi-Scale CNNs [2], and multi-task branches [3]—and systematically categorize the literature into four distinct paradigms: traditional feature engineering [4], standard end-to-end deep learning [5], sequence-to-sequence modeling with ensembles [6], and advanced representation learning [7].

II. DATA SOURCE CIRCOR DIGISCOPE DATASET

The dataset utilized in this analysis originates from The George B. Moody PhysioNet Challenge 2022 [8], which is built upon the CirCor DigiScope Phonocardiogram Dataset. To acquire the dataset reproducibly, raw files were downloaded directly from PhysioNet using the standard PhysioNet command-line utility (`wget -r -N -c -np https://physionet.org/files/challenge-2022/1.0.0/`).

The dataset comprises 3,163 recordings from 942 pediatric patients (1,452 unique patients across 1,568 encounters). Because 116 patients attended both screening campaigns, GroupKFold cross-validation grouped by patient ID is required to prevent data leakage. Processing this raw dataset requires aggressive denoising due to noisy clinical environments. For instance, to eliminate artificial interference from stethoscope placement and removal, Team MetaHeart discarded the first 5 seconds and last 3 seconds of every recording [9]. Similarly, Team IITH applied Butterworth bandpass filters (0.1 Hz to 300 Hz) to strip baseline wander and high-frequency ambient noise before feature extraction [10].

1. Signal Specifications

All recordings are sampled at 4,000 Hz, ensuring consistency and eliminating the need for resampling. However, sample durations range from 5.15 to 64.51 seconds, with most recordings lasting 20 or 30 seconds (Figure 1). A major protocol shift occurred between campaigns: 2014 recordings averaged 29.7 s, whereas 2015 recordings averaged 19.9 s. This discrepancy must be accounted for in dataset splits to prevent duration-based shortcut learning (Figure 2). The average recording duration is consistent across primary auscultation sites in both years (AV: Aortic Valve, PV: Pulmonic Valve, TV: Tricuspid Valve, MV: Mitral Valve), with only 4 recordings labeled as 'Phc' denoting uncommon recording locations (Figure 3).

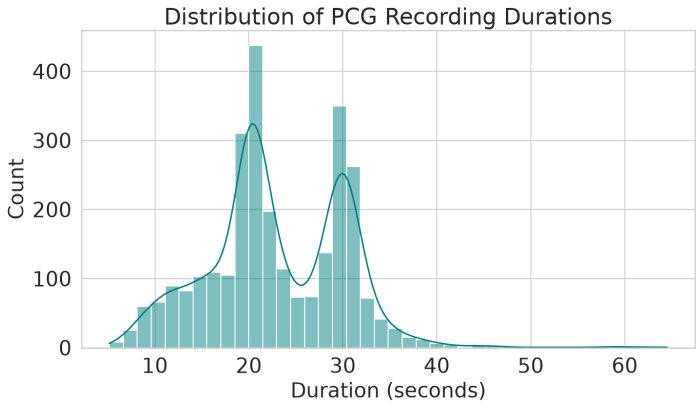

Figure 1. Signal Durations Distribution.

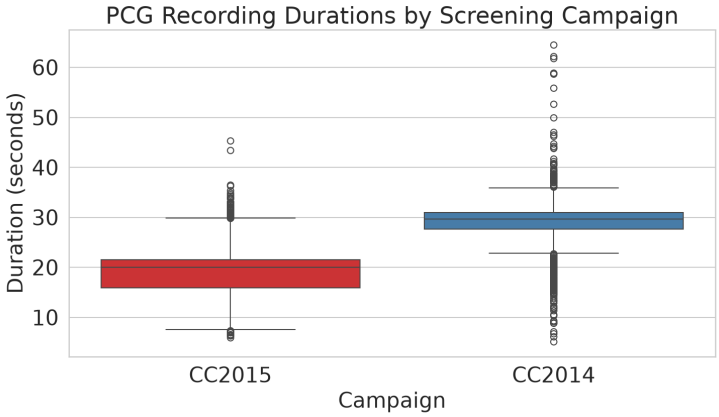

Figure 2. Signal Durations by Campaign.

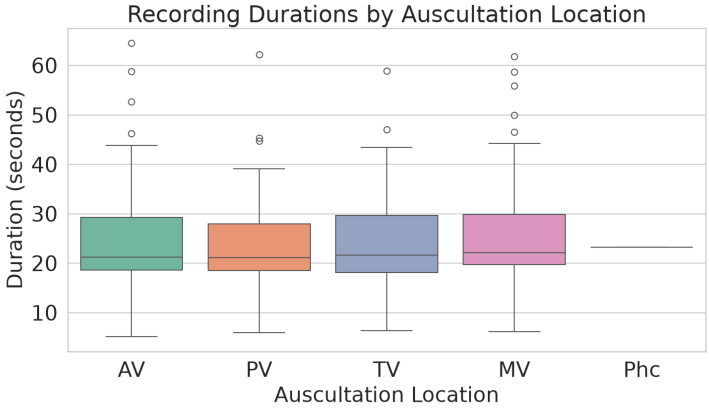

Figure 3. Signal Durations by Valve Location.

2. Demographic and Modalities

The dataset consists predominantly of school-aged children and is gender-balanced (Figure 4), with a 7.4% pregnancy rate (ages are anonymized for privacy). Approximately 11–12% of patients have missing physical metrics (Figure 5). Given this low missingness rate, discarding incomplete records presents a practical alternative to complex imputation.

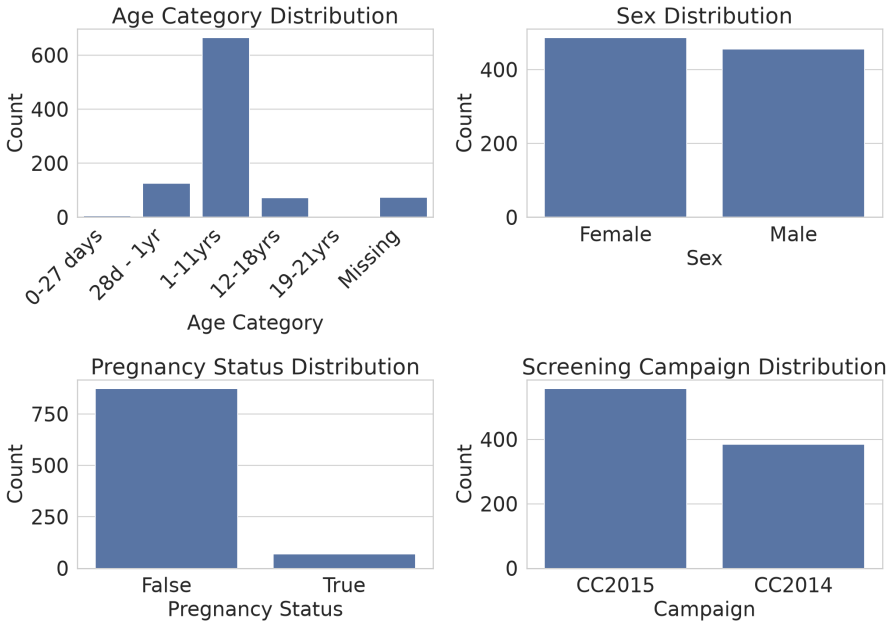

Figure 4. Patient Demographics.

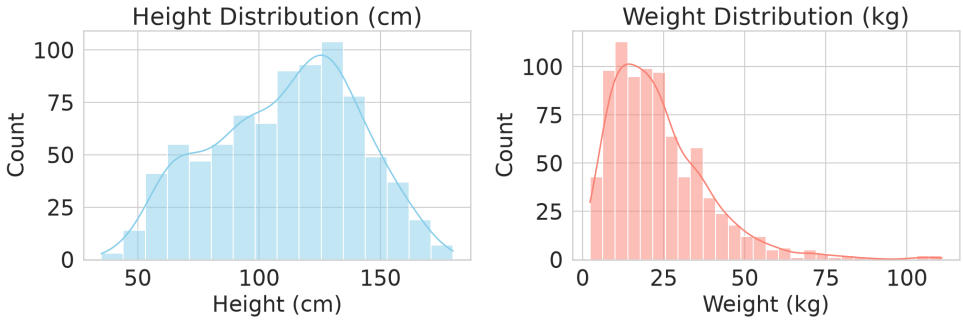

Figure 5. Height and Weight Distributions.

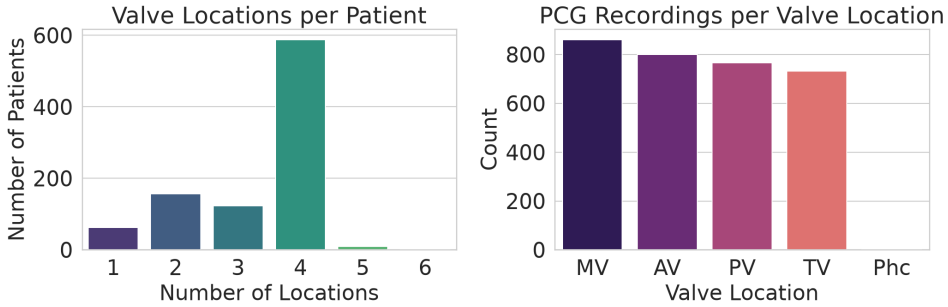

Figure 6. Modality Coverage.

Only 62.4% of patients had recordings across all four primary valves (Figure 6). This channel variability requires attention mechanisms or average pooling to dynamically aggregate features across varying input channels. To address the risk of overfitting due to missing leads, Team uke-cardio pioneered a novel CutMix augmentation strategy applied directly to auscultation locations. By artificially mixing PCG leads from different patients during training and generating soft-smoothed target labels, they forced their CNN to learn generalized acoustic features rather than patient-specific valve combinations [11].

3. Clinical Correlations and Targets

A severe class imbalance exists for murmur labels: 74% Absent vs. 19% Present (Figure 7). This imbalance necessitates weighted loss functions, such as Focal Loss. Conversely, clinical outcomes are relatively balanced, making a multi-task architecture with dual output heads an effective strategy. Team MetaHeart practically demonstrated this approach: to stabilize their 30-layer ResNet, they implemented a joint loss function that combined Center Loss (to contract intra-class variance in the deep feature space) with Class-Distinguished Focal Loss to heavily penalize false negatives on the minority "Present" class [9].

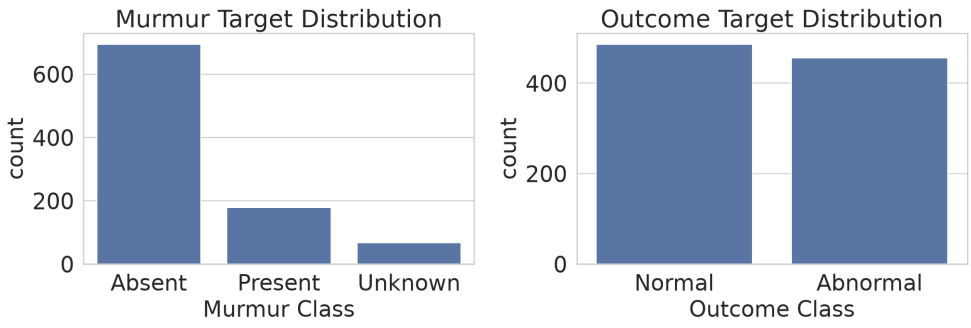

Figure 7. Class Imbalance.

Higher Levine grades are strongly associated with abnormal clinical outcomes (Figure 8), indicating that classifiers should leverage sound-intensity features to improve diagnostic accuracy. Because sound intensity and cardiac cycle phases (S1, systole, S2, diastole) are closely tied to clinical outcomes, top architectures utilize explicit segmentation as a regularization mechanism. For example, Team matLisboa trained a 567,000-parameter Transformer backbone with a dedicated auxiliary segmentation head, ensuring predictions were grounded in physiologically meaningful cardiac boundaries [12].

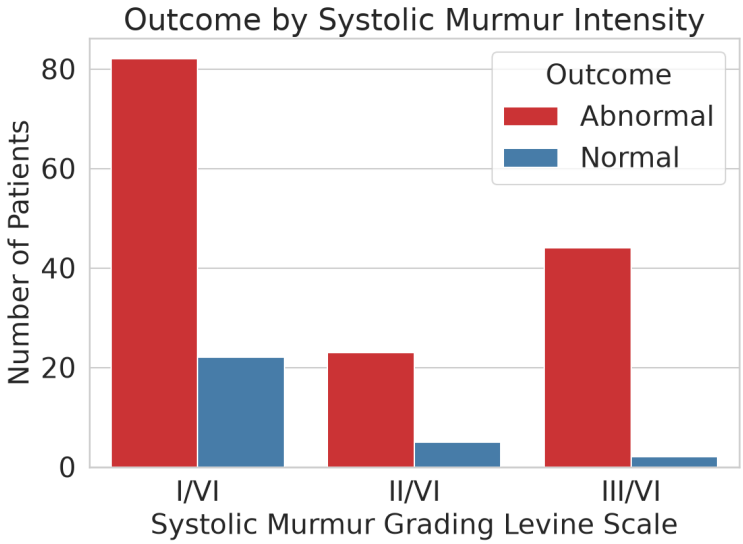

Figure 8. Murmur Grading vs. Outcome.

III. METHODOLOGY AND ANALYSIS

1. Data Acquisition and Preprocessing

To ensure complete reproducibility, all 44 challenge papers were programmatically downloaded from the PhysioNet 2022 open-source repository using Python's `requests` and `BeautifulSoup` libraries, and subsequently converted into structured Markdown text using `pymupdf4llm` for precise text-mining. This standardization allows for the robust application of NLP techniques across the entire corpus.

2. Keyword Co-occurrence

To reliably extract methodological trends, we used an automated NLP pipeline to parse the standardized Markdown abstracts and methodology sections of all 44 papers. The algorithm counts explicit mentions of predefined architectural keywords to generate a co-occurrence matrix (Figure 9). The matrix reveals that the strongest meaningful co-occurrence is between Segmentation and Cross-validation (as prominently seen in works such as [1] and [12]), indicating that explicit structural heart-cycle division, paired with rigorous validation, is the foundational standard for combating overfitting. Conversely, we identified rare, non-traditional combinations—such as pairing Wavelet Scattering directly with Support Vector Machines [4] or integrating Transformers with Ensemble methods [6]—which show minimal overlap with standard CNN baselines. Generic pairings, such as standard optimizers coupled with deep networks, were excluded from this analysis to isolate core architectural choices.

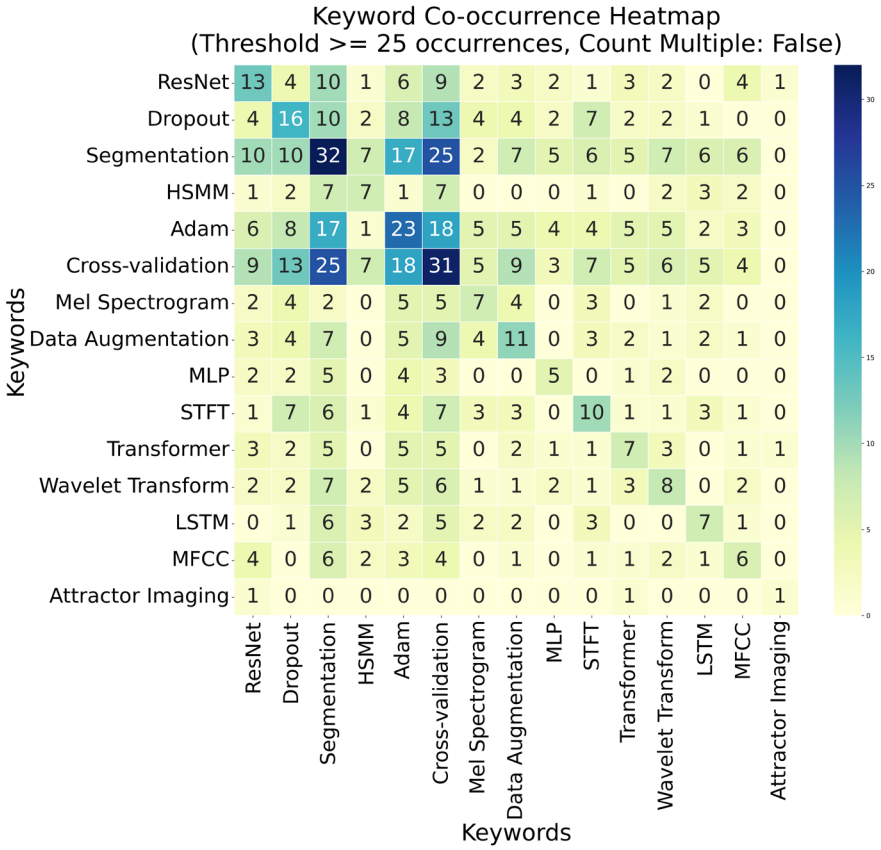

Figure 9. Keyword Co-occurrence Heatmap

3. Keyword Spatial Distance Networks

Beyond simple co-occurrence, the absolute character distance between methodology keywords was computed to build spatial semantic networks (Figure 10) at different thresholds. Visual inspection of the resulting network graph reveals a highly interconnected structure, particularly among classical machine learning methodologies. The thickest and darkest edges form a distinct, tight topological triangle between Principal Component Analysis (PCA), Support Vector Machines (SVM), and Random Forests. Furthermore, SVM maintains a prominent connection directly to Segmentation. This dense clustering suggests that classical machine learning approaches in the literature are treated as an inseparable package rather than dynamic, mixed methodologies. The consistently short character distances between these terms indicate a rigid standard workflow: audio segmentation, followed by dimensionality reduction via PCA, culminating in classification using standard algorithms. Conversely, an analysis of modern deep learning architectures, such as ResNet and Transformer, shows them to be positioned somewhat independently. They lack the strong connections observed in the classical feature-extraction clusters. This separation highlights a clear divide in literature: studies either rely on standardized classical pipelines or employ end-to-end deep learning networks, with very little hybridization between the two.

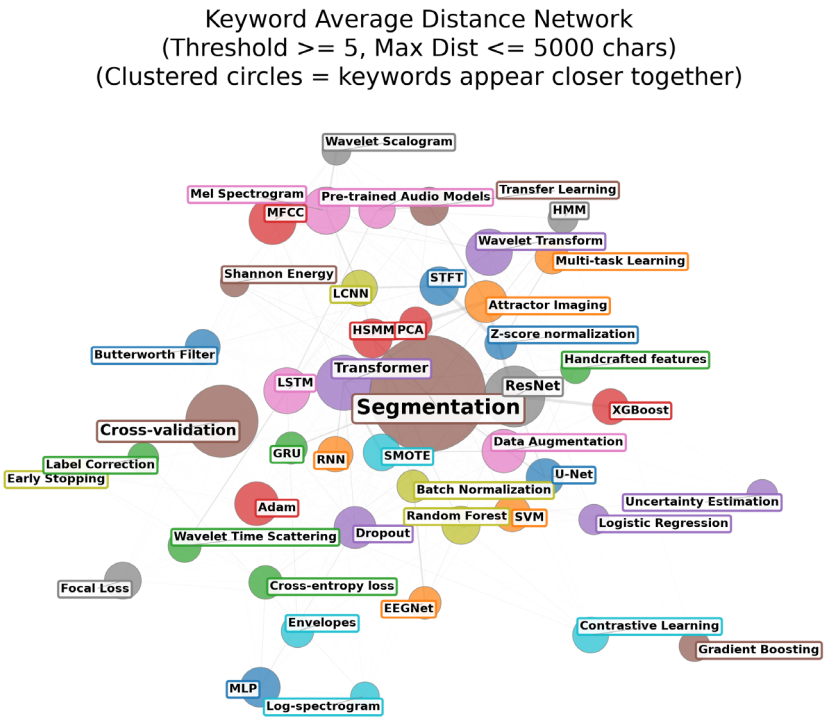

Figure 10. Keyword Distance Network

It must be acknowledged that textual proximity within a document is a relatively weak proxy for semantic relatedness when compared to high-dimensional contextual embeddings. While it successfully captures rigid, boilerplate descriptions of classical workflows (where methods are often listed in immediate succession, e.g., "features were extracted and classified using SVM"), it can fail to capture complex structural relationships that span multiple paragraphs. For this reason, true semantic categorization is performed using transformer-based models.

4. Semantic Embedding Clustering

To categorize publications semantically beyond simple keyword matching, we generated 384-dimensional text embeddings using a pre-trained sentence transformer (all-MiniLM-L6-v2). We clustered them directly on this high-dimensional space via K-means.

IV. RESULTS AND DISCUSSION

Following semantic embedding clustering, through heuristic trial-and-error and evaluation of the semantic coherence of the resulting groupings, we observed that k=2 is overly broad (grouping basic CNNs [5] with complex self-supervised architectures [7]), while k=5 results in severe over-segmentation due to trivial stylistic variations. Therefore, k=4 effectively segregates the core architectural differences. However, we acknowledge that this study currently lacks solid quantitative internal validation (such as computing silhouette scores or assessing stability across random seeds) to establish k=4 definitively. Formalizing a quantitative method to

determine optimal k alongside semantic embeddings remains a necessary focus for future work. The analysis concludes that k=4 effectively categorizes the solutions into four distinct paradigms. Cluster 1 represents traditional feature engineering, relying heavily on handcrafted heuristics such as wavelet time scattering, paired with classical classifiers, as in the works of Cornely et al. [4] and Imran et al. [13]. Cluster 2 groups supervised end-to-end deep learning baselines, where standard 1D/2D CNNs and ResNets process Mel-spectrograms without complex auxiliary objectives, as demonstrated by Peng et al. [5] and Lu et al. [14]. Cluster 3 captures sequence-to-sequence modeling and ensemble fusion, heavily featuring Transformer and LSTM networks to handle label noise and the unknown murmur class, as seen in studies by Alkhodari et al. [6] and Gemke et al. [15]. The most structurally complex approaches fall under Cluster 4 (advanced representation of learning and multi-task learning). Due to dataset class imbalance and variable recording lengths, these works move beyond simple supervised learning. Instead, they incorporate self-supervised pre-training [7] and multi-task optimization (using heart sound segmentation as an auxiliary task) to prevent overfitting. Additionally, these approaches target the challenge's asymmetric, cost-based scoring metric, which penalizes false negatives much more heavily than false positives. To optimize this metric directly, Cluster 4 architectures utilize custom loss functions—often paired with hybrid signal processing frontends or state predictions, as seen in McDonald et al. [1] and Rohr et al. [16].

V. CONCLUSION

In summary, this NLP-driven analysis provides a structured taxonomy of the PhysioNet 2022 Challenge, mapping the evolution from traditional feature engineering to advanced representation learning. By making the Python-based extraction and parsing pipeline transparent, this easily replicable methodology offers a clear view into the current state-of-the-art modeling strategies for automated heart sound classification. While our current taxonomic division into four paradigms aligns with the field's logical progression, we acknowledge that a heuristic evaluation of the embedding space initially guided it. Future iterations of this pipeline will employ rigorous quantitative internal validation to confirm the optimal number of paradigms mathematically.

Abstract
Cardiovascular diseases remain one of the leading causes of mortality worldwide. Electrocardiography (ECG) is a widely used noninvasive diagnostic tool for detecting both electrical and structural cardiac abnormalities. While standard 12-lead ECG systems provide comprehensive clinical information, they are not suitable for continuous daily monitoring. Recent wearable devices such as smartwatches and portable ECG patches enable long-term ECG acquisition but typically provide only one to three leads, resulting in substantial information loss. This study proposes a deep learning framework for detecting left ventricular hypertrophy (LVH) and related cardiac pathologies using reduced-lead ECG signals. Unlike existing approaches that primarily focus on arrhythmia detection or explicit lead reconstruction, the proposed framework aims to transfer clinically meaningful representations from 12-lead ECG recordings to wearable reduced-lead configurations through a teacher–student knowledge distillation strategy. The PhysioNet/Computing in Cardiology Challenge 2021 dataset will be utilized for model development and evaluation. The proposed approach seeks to bridge the gap between clinical-grade ECG interpretation and wearable healthcare technologies, enabling early detection of structural heart abnormalities in everyday settings.

Keywords: Reduced-Lead ECG, Knowledge Distillation, Wearable Health, Left Ventricular Hypertrophy, Deep Learning, Hybrid Neural Networks

I. INTRODUCTION

Cardiovascular diseases constitute a major global health burden and account for millions of deaths annually. Early diagnosis of cardiac abnormalities is critical for reducing morbidity and mortality [1]. Electrocardiography remains one of the most accessible and cost-effective diagnostic modalities [2]. Conventional 12-lead ECG systems provide multiple spatial views of cardiac electrical activity and are routinely used for diagnosing arrhythmias, myocardial ischemia, conduction disorders, and structural abnormalities [2]. In contrast, wearable ECG devices have recently gained widespread adoption due to their ability to provide continuous monitoring outside clinical environments [3]. However, these devices are generally limited to one to three ECG leads, which significantly reduces the spatial information available for diagnosis [4]. Current wearable ECG research largely focuses on rhythm abnormalities such as atrial fibrillation. Structural cardiac abnormalities, particularly left ventricular hypertrophy (LVH), remain comparatively underexplored despite their clinical importance. This work investigates whether clinically meaningful information associated with LVH can be extracted from reduced-lead ECG recordings using modern deep learning techniques [1],[4].

II. BACKGROUND

LVH refers to abnormal thickening of the left ventricular myocardium, commonly caused by chronic hypertension and pressure overload [1]. LVH is associated with increased risks of heart failure, arrhythmias, stroke, and sudden cardiac death [1]. Traditional ECG-based LVH diagnosis relies on voltage criteria such as the Sokolow-Lyon and Cornell indices [4]. Although these criteria are clinically established, they often exhibit limited sensitivity and substantial inter-patient variability [4].

III. RELATED WORK AND LIMITATIONS

The PhysioNet/Computing in Cardiology Challenge 2021, entitled "Will Two Do?", evaluated algorithm performance across multiple lead configurations, including 2-, 3-, 4-, 6-, and 12-lead ECGs [5]. Top-performing solutions predominantly employed ensemble Convolutional Neural Network (CNN) architectures, attention modules, data augmentation strategies, and class-balancing techniques [6]. The PhysioNet Challenge 2021 provided a massive dataset of over 120,000 multi-lead ECGs to evaluate reduced-lead diagnostics [7]. A review of state-of-the-art methodologies reveals several critical limitations for wearable deployment [4],[5].

1. The Computational Burden of Ensembles

Top-performing architectures extensively utilized Deep Ensembles. Teams combined multiple deep Residual Convolutional Neural Networks (ResNets) or Squeeze-and-Excitation Wide ResNets to maximize the classification benchmark score [5],[6]. While highly accurate on cloud servers, executing deep networks in parallel requires significant memory and computational power, rendering them unsuitable for continuous execution on Edge IoT wearable microcontrollers [8].

2. Explicit Generative Reconstruction

To compensate for missing channels, some studies employ Generative models, Generative Adversarial Networks (GANs), or Autoencoders for medical time-series generation and signal reconstruction, explicitly reconstructing the missing 11 leads from a single lead before running a classifier [9]. In the medical domain, this introduces a severe risk of "hallucination"—the generative model might synthesize a healthy waveform over an actual ischemic event, potentially leading to clinically misleading predictions [1],[4].

3. Our Algorithmic Shift

Our approach explicitly rejects signal reconstruction and heavy ensembles [4]. Instead, we focus on representation learning. We hypothesize that the subtle morphological footprint of LVH is implicitly present in Lead I, albeit imperceptible to human cardiologists. Through Knowledge Distillation (KD), we guide a lightweight student network to map these subtle temporal features into a robust spatial latent space [10],[11]. Recent studies have highlighted the potential of KD in single-lead monitoring systems [12], establishing a strong baseline for expanding its application to structural pathologies.

IV. PROPOSED METHODOLOGY

The proposed framework is based on teacher–student representation learning. A conceptual overview of the proposed framework is shown in Figure 1. During training, a teacher network receives complete 12-lead ECG recordings and learns rich latent clinical representations from the full spatial information available in the signals. A student network receives only reduced-lead ECG signals (1–3 leads) and is trained to imitate the teacher's internal representations through knowledge distillation [10]. Unlike explicit lead reconstruction approaches, the

primary objective is not to regenerate missing ECG channels but rather to preserve diagnostically relevant information required for LVH detection [4],[9].

The overall pipeline consists of:

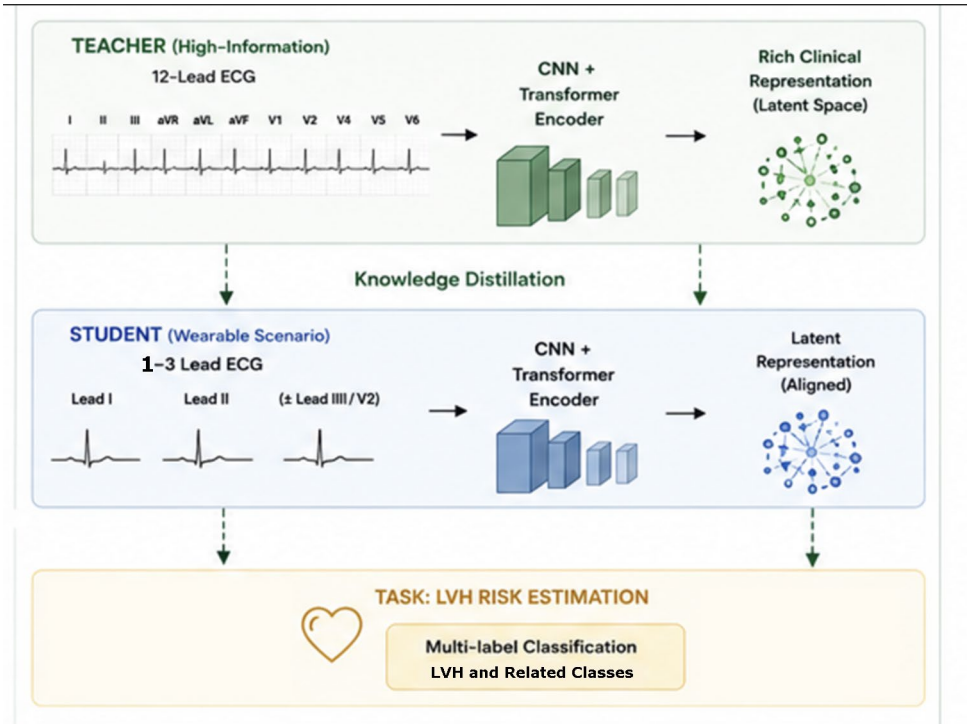

Figure 1. Overview of the proposed teacher–student knowledge distillation framework

V. DATASET AND EXPERIMENTAL PLAN

The study will utilize the PhysioNet/CinC 2021 Challenge dataset [5],[7]. The dataset contains approximately 121,144 ECG recordings collected from multiple institutions across different countries and patient populations [7]. The dataset incorporates recordings from multiple publicly available ECG databases, including CPSC, PTB-XL, INCART, Georgia, Chapman-Shaoxing, Ningbo, and UMich databases [7].

The training partition presents non-uniform signal properties that simulate deployment across heterogeneous wearable hardware:

- Signal Duration: The vast majority of records are exactly 10.0 seconds long, though the database exhibits a dynamic duration range from a minimum of 5.0 seconds to a maximum of 1,800.0 seconds (30-minute Holter monitoring) [7].
- Sampling Frequencies: The primary acquisition hardware operates at 500 Hz (99% of the records). Minor variations include 1,000 Hz (< 1%) and 257 Hz (only 74 records), necessitating a uniform resampling step during preprocessing [7].

- Lead Subsets: To evaluate wearable scenarios, the student network will be systematically tested by isolating discrete low-resource channel combinations, specifically 6-lead, 4-lead, 3-lead, and 2-lead (Leads I and II) setups [5].

Models will be validated using robust standard classification metrics, including Precision, Recall (Sensitivity), F1-Score, and the Area Under the Receiver Operating Characteristic (AUROC) curve. To ensure alignment with the international literature, the primary emphasis will be on optimizing reduced-lead LVH Recall and the official macro-weighted Challenge score [5]. Special emphasis will be placed on reduced-lead LVH detection performance and representation of transfer effectiveness.

VI. EXPECTED RESULTS AND DISCUSSION

We anticipate that the Student network, guided by KD, will significantly outperform baseline 1-lead models that lack Teacher supervision [12]. While the 1-lead Student may not completely match the absolute diagnostic precision of the 12-lead Teacher, the framework is expected to close the performance gap sufficiently to serve as a reliable probabilistic risk estimator [2], [10]. Furthermore, by avoiding Deep Ensembles, the resulting Student model will have a drastically reduced parameter footprint, making it well-suited for quantization and deployment on Edge AI microcontrollers embedded in smartwatches [8]. To prevent the model from operating as a black box, Explainable AI (XAI) techniques, such as Attention Saliency Maps, will be utilized to visually verify that the Student focuses on genuine physiological markers rather than background noise [13].

VII. CONCLUSION

This paper outlines a computer science solution to a critical medical problem: detecting structural cardiac diseases, such as Left Ventricular Hypertrophy (LVH), using comfortable, everyday wearable devices. By replacing computationally expensive ensembles and explicit generative reconstructions with a Teacher-Student Knowledge Distillation framework, the proposed approach aims to transfer deep clinical spatial representations to low-resource environments [10],[12]. Ultimately, this representation-level learning approach has the potential to bridge the gap between standard 12-lead clinical ECGs and reduced-lead wearables, eliminating the strict need for specialized clinical equipment [1]. It paves the way for a non-invasive, daily early-warning system that makes advanced, continuous cardiac screening widely accessible to everyone.

Abstract
Breast cancer is one of the most prevalent cancers globally among women and remains a leading cause of death caused by cancer. A major way to improve patient survival rates is to detect cancer early, before it spreads to other parts of the body. However, mammographic screening relies heavily on radiologists, thereby making the diagnostic process time-consuming and susceptible to interpretive variability. In Kenya, these challenges are further aggravated by a shortage of radiologists, often resulting in delayed diagnosis and treatment. This study developed an automated breast cancer screening system using mammographic X-ray images and deep learning techniques. An experimental quantitative research design was adopted to evaluate three families of deep learning architectures: Capsule Neural Networks, Vision Transformer architectures, and Convolutional Neural Networks. The models were trained using 90% of the VinDr-Mammo dataset and evaluated on a locally collected dataset obtained from level 5 and level 6 hospitals in Kenya. Performance was assessed using accuracy, precision, recall, and F1 score metrics. According to the results, CapsNet achieved the highest accuracy of 90.09% with a recall of 89%. The vision transformer model achieved comparable recall and F1score performance while maintaining a significantly smaller model size of 12.3 MB. The findings suggest that both CapsNet and Vision Transformer models have significant potential for supporting breast cancer screening in resource-constrained healthcare environments. Their adoption could improve access to quality diagnostic services, facilitate earlier detection, reduce diagnostic delays, and ultimately improve patient outcomes in Kenya.

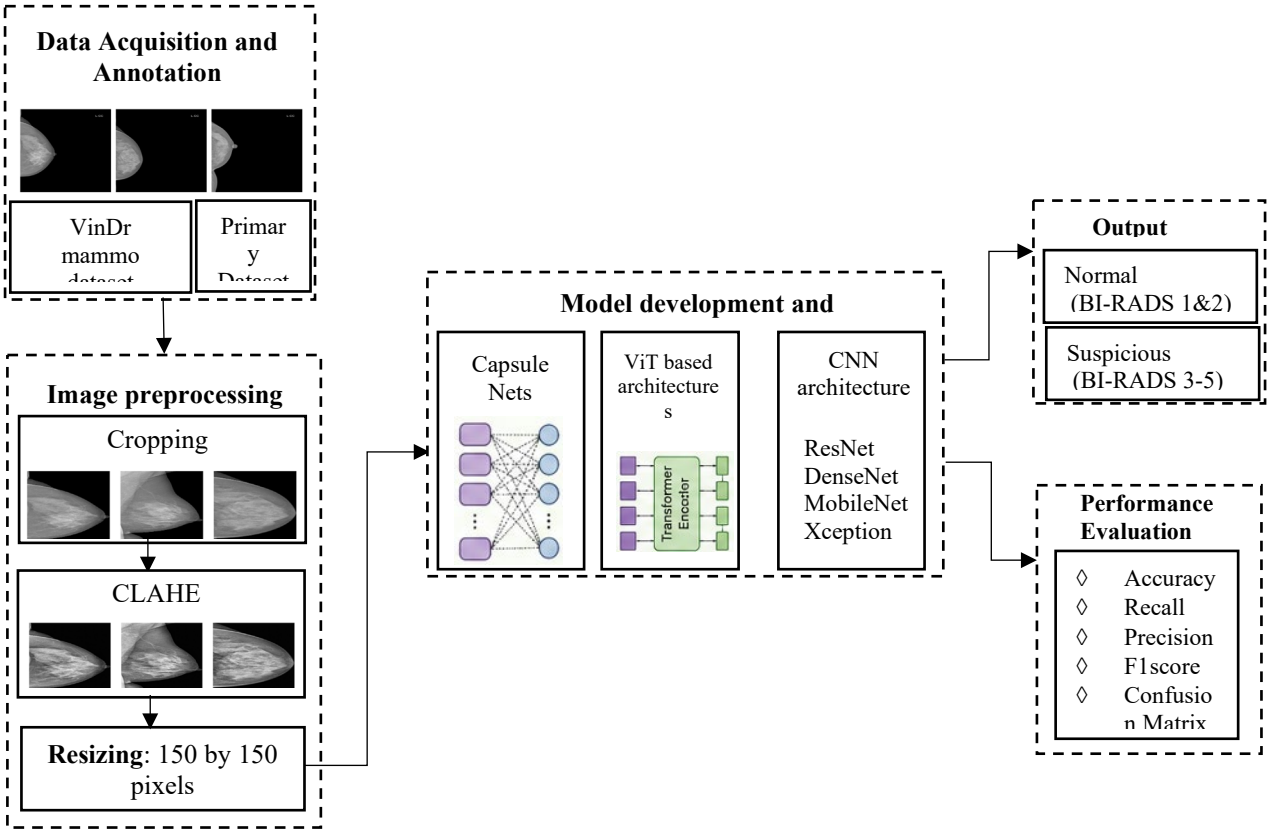
Keywords: Breast cancer; Mammography; Automated detection; Deep learning; Convolutional Neural Networks; Capsule Networks

I. INTRODUCTION

Breast cancer is one of the leading global health concerns and continues to be the most frequently diagnosed cancer in women [1]. Despite advances in prevention, it accounts for a substantial portion of cancer-related deaths. In 2022, breast cancer accounted for an estimated 2.3 million new cases worldwide and approximately 670,000 deaths [2]. If the current trend continues, the global burden of the disease is expected to rise substantially, with new cases projected to increase by 38% and breast cancer-related deaths by 68% by 2050 [3]. Early detection is essential for improving breast cancer survival and treatment outcomes. Despite its importance, access to screening services varies considerably across countries, with low and middle-income countries facing greater challenges than high-income countries, therefore leading to disparities in health outcomes [4]. In Kenya, breast cancer remains a significant public health challenge and contributes substantially to the country's disease burden. The Ministry of Health, Kenya, reported an age-standardized incidence rate (ASR) of 41 cases and a mortality rate of 19.4 deaths per 100,000 women [5]. Despite ongoing efforts to control the disease, breast cancer is responsible for approximately 3,100 deaths annually [6]. Several interconnected factors continue to hinder effective breast cancer detection in Kenya. Access to screening services remains limited, particularly in rural regions where mammography facilities and specialized diagnostic services are scarce [7]. Furthermore, the cost of screening, diagnosis, and treatment poses a significant barrier, often resulting in delayed healthcare-seeking [8]. Traditional breast cancer screening, primarily through mammography, also relies heavily on manual interpretation by radiologists, making the diagnostic process time-consuming and dependent on expertise [9]. In Kenya, the shortage of trained radiologists further aggravates this challenge, contributing to delayed diagnosis and, consequently, poor patient outcomes [10]. Advances in deep learning offer a promising opportunity to improve breast cancer detection by enabling automated feature extraction and accurate classification of medical images [11]. Such approaches have the potential to support radiologists by reducing diagnostic workload and facilitating early disease detection, thereby improving survival rates. This study, therefore, focused on developing an automated breast cancer detection system using mammographic X-ray images. Specifically, it conducted a comparative evaluation of Capsule Networks (CapsNets), Vision Transformers (ViTs), and Convolutional neural networks (CNNs) for the detection and classification of breast cancer tissues. The aim was to identify the most effective model for accurate and reliable breast cancer diagnosis. The findings are expected to provide evidence for the adoption of deep learning-based diagnostic tools for breast cancer screening and diagnosis in Kenyan hospitals.

II. RELATED WORK

In recent years, deep learning has been widely used to address challenges such as tuberculosis detection [12], lung cancer detection [13], masked face recognition [14], and early breast cancer detection [15]. Among the various deep learning approaches, Convolutional Neural Networks (CNNs) have emerged as one of the most widely adopted architectures for medical image analysis due to their ability to learn hierarchical spatial features from images [16] automatically. For example, a CNN-based cancer detection system developed in [17] achieved accuracies of 86.42% on the BreakHis dataset and 98.97% on the MIAS dataset. Similarly, Yuan et al. [18] conducted a comparative evaluation of fourteen deep learning models on the BreakHis dataset and reported excellent performance, with ConvNeXT achieving 99.2% accuracy in binary classification. However, the accuracy dropped to 94.2% with multiclass classification. Lightweight CNN models such as LBNet have also demonstrated strong performance while reducing computational complexity, achieving 97.28% accuracy [19]. Despite their success, CNNs generally require large training datasets and may struggle to capture long-range contextual relationships within images. To overcome some of these limitations, researchers have explored Capsule Networks (CapsNets), which preserve spatial relationships between image features and can perform effectively with limited training data. For instance, UCapsNet combined segmentation and classification to



achieve 99.22% accuracy in breast ultrasound image analysis [15]. Similarly, TTDCapsNet reported an accuracy of approximately 95.01% on breast cancer datasets, demonstrating competitive performance against several state-of-the-art approaches [20]. However, CapsNets often require architectural enhancements to handle complex medical images effectively. More recently, transformers have gained attention in breast cancer detection for their ability to capture global relationships in images using self-attention mechanisms. A recent study combined CNNs and Vision Transformers for mammogram classification, achieving 90.1% accuracy on CLAHE-enhanced mammographic images [21]. Similarly, a study evaluating transformer-based models, including Swin Tiny, DeiT, BEiT, and ViT, reported that the ViT model achieved the highest accuracy of 99.32% on mammographic image datasets [22]. Despite these promising results, transformer-based models typically require substantial computational resources and large training datasets. Although CNNs, CapsNets, and Transformers have all demonstrated promising results in breast cancer detection, most studies evaluate these architectures independently, making direct comparison difficult. Furthermore, the majority of existing studies rely on publicly available datasets that largely originate from non-African populations. Consequently, there is limited evidence regarding the relative performance of these architectures and their suitability for deployment in Kenyan healthcare settings. This study addresses this gap by conducting a unified comparative evaluation of CNNs, Capsule Networks, and Vision Transformers for breast cancer detection, aiming to identify the most effective architecture to support breast cancer diagnosis in Kenyan hospitals.

III. METHODOLOGY

1. Research Design

The study adopted an experimental quantitative research design to develop and evaluate deep learning models for automated breast cancer detection using mammographic X-ray images. It conducted a comparative assessment of Capsule Networks (CapsNets) and vision transformer architectures, and Convolutional Neural Networks (CNNs), including ResNet, DenseNet, MobileNet, EfficientNet, and Xception.

1. Figure 1.Research Design

The objective was to identify the most accurate and efficient architecture for breast cancer detection and provide evidence on its suitability for deployment in Kenyan healthcare settings. The study was conducted in four stages: data acquisition and annotation, image preprocessing, model development and training, and performance evaluation. Mammographic images were obtained from both the publicly available VinDr-Mammo dataset and selected level 5 and 6 hospitals in Kenya. The images were preprocessed to enhance quality and ensure consistency before being used to train CapsNet, Transformer, and CNN-based models for breast cancer classification. The performance of the models was evaluated using accuracy, precision, recall, and F1 Score to identify the most effective. architecture for breast cancer detection. Figure 1 shows the research design.

2. X-ray Image Acquisition

The study used two mammographic datasets for model development and evaluation. The first dataset was the publicly available VinDr-Mammo dataset, which consists of 20,000 full-field digital mammograms (FFDM) annotated by expert radiologists and labeled according to the Breast Imaging Reporting and Data System (BI-RADS) scores ranging from 1 to 5, with higher categories indicating a greater likelihood of malignancy. Figure 2 shows the distribution of images per BI-RAD class. The second dataset comprised 8,789 locally collected and curated mammographic images from selected level 5 and level 6 hospitals, namely Kerugoya County Referral Hospital, Nyeri County Referral Hospital, Meru Level 5 Hospital, Outspan Hospital, and Embu Level 5 Hospital. The images were anonymized and annotated by certified radiologists in accordance with BI-RADS standards. Figure 3 shows the distribution of the dataset per BIRAD classes. The local dataset was used to validate the models and improve their applicability in Kenyan healthcare settings. Due to the substantial class

imbalance across the BI-RADS categories, as shown in Figures 2 and 3, BI-RADS 3, 4, and 5 were combined into a single suspicious class, while BI-RADS 1 and 2 were grouped as normal/benign. This binary classification was adopted to provide more balanced sample sizes and support stable model training and evaluation compared to a multiclass classification approach. Similar grouping strategies have been applied in previous breast imaging machine learning studies [23]. The classification was intended to distinguish normal or benign examinations from those requiring further assessment or diagnostic work-up. However, BI-RADS 3, 4, and 5 have different malignancy risks and clinical management recommendations. Therefore, the combined class represents a machine learning classification decision and should not be interpreted as indicating the same level of clinical risk across these categories.

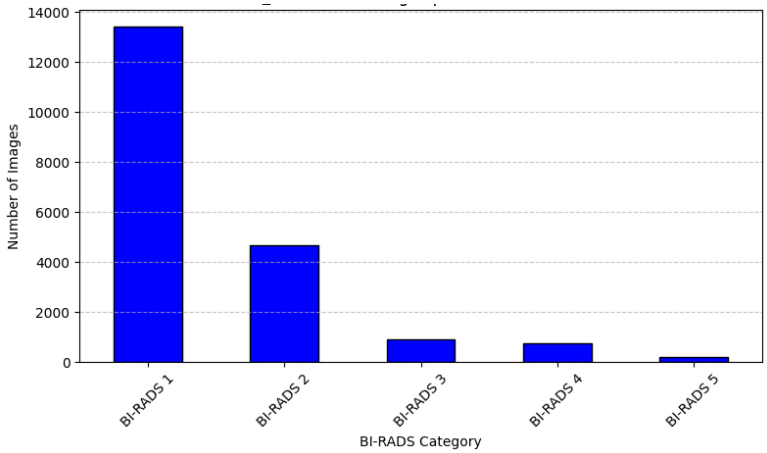


Figure 2. Distribution of Vin Dr-Mammo Dataset per BI-RAD Class

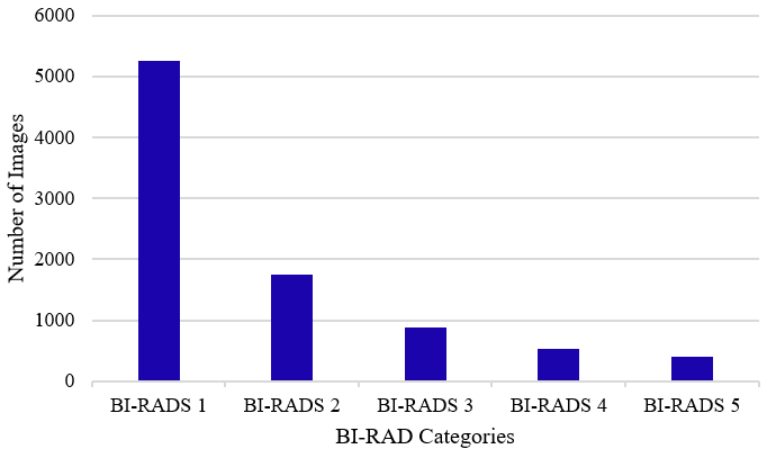

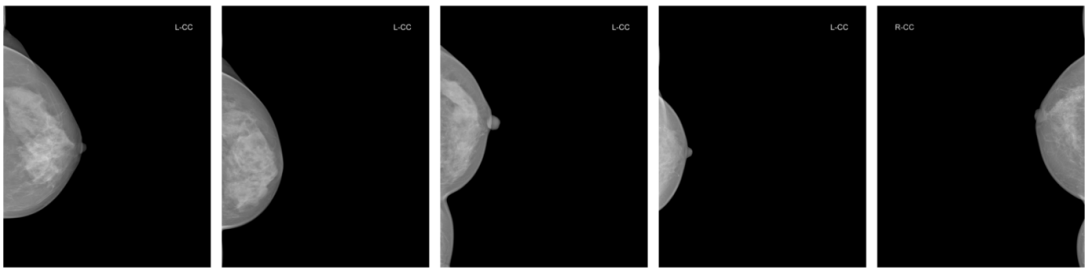

Figure 3. Distribution of the locally collected Kenyan Dataset per BI-RAD Class

To ensure image quality and uniformity, preprocessing involved cropping each mammogram to isolate the breast region, as shown in Figure 4. Afterward, Contrast Limited Adaptive Histogram Equalization (CLAHE) was applied to the cropped mammograms to enhance local contrast, as shown in Figure 5. Finally, all the

preprocessed images were resized to 150 × 150 pixels to standardize input dimensions and reduce computational complexity. No additional preprocessing techniques were applied to ensure that the models learn from realistic

clinical data. The VinDr-Mammo dataset was then divided into training (90%) and validation (10%) subsets for model development, while the locally collected mammographs from Kenyan hospitals were reserved exclusively for testing.

Figure 4. Sample Breast Mammogram Images before preprocessing

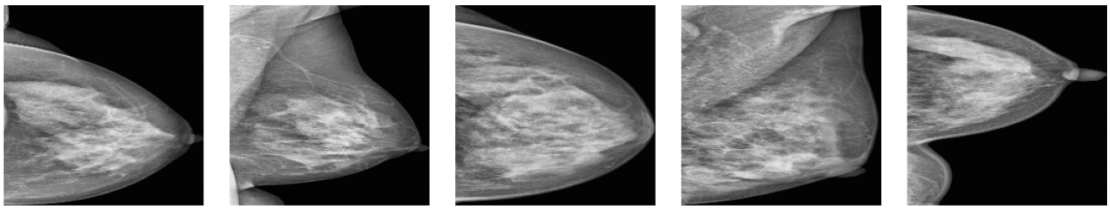

Figure 5. Breast Mammogram images after cropping and applying CLAHE

3. Feature Extraction and Classification

The study evaluated three categories of deep learning architectures for breast cancer detection: Capsule Neural Networks (CapsNets), vision transformers, and Convolutional Neural Networks (CNNs). CapsNets, introduced by Hinton et al. [24], were selected for their ability to preserve spatial hierarchies and positional relationships among image features. Unlike conventional CNNs, CapsNets represent features as multidimensional vectors and employ a dynamic routing mechanism that maintains meaningful relationships between lower and higher-level features. The architecture also incorporates a reconstruction mechanism that improves regularization and model interpretability. Vision Transformers (ViTs) were evaluated for their ability to model global contextual relationships within mammographic images through self-attention mechanisms. By capturing long-range dependencies between image regions, ViT models can effectively identify distributed abnormalities that may not be easily detected through local feature extraction alone [21]. To provide benchmark performance, five widely used CNN architectures were implemented: ResNet, DenseNet, MobileNet, EfficientNet, and Xception. ResNet and DenseNet were selected for their deep feature extraction capabilities and efficient gradient propagation, while MobileNet and EfficientNet were chosen for their lightweight, computationally efficient designs. Xception was included due to its use of depth-wise separable convolutions, which improve computational efficiency while maintaining high classification performance. The same preprocessing procedures, training parameters, and evaluation metrics were applied to all models to enable a consistent and unbiased comparison of their performance.

4. Model Training and Evaluation

Model training and evaluation took place in a Linux environment with an NVIDIA A30 GPU, 24GB of RAM, 64GB of RAM, 1TB SSD, and 24 vCPUs. All models were trained using the Adam optimizer, a batch size of 32, 100 epochs, and a learning rate of 1e-4. To minimize overfitting and enhance model generalization, early stopping was incorporated throughout training. Model performance was validated using the local dataset collected from Level 5 and Level 6 hospitals in Kenya. The evaluation assessed the models' ability to classify mammograms according to BI-RADS categories accurately and to distinguish between normal and abnormal breast tissues. A confusion matrix was used to compare predicted and actual labels, summarizing results as true positives (TP), false negatives (FN), false positives (FP), and true negatives (TN). These values were subsequently used to compute performance metrics: accuracy, precision, recall, and F1 score. Accuracy was used to determine the overall proportion of correctly classified mammograms. Precision measured the proportion of positive predictions that were correctly identified, while recall evaluated the models' ability to detect positive breast cancer cases. The F1 score, which represents the harmonic mean of precision and recall, provided a balanced assessment of model performance predictions, particularly in the presence of class imbalance.

IV. RESULTS AND DISCUSSION

1. Training and Validation Performance

The trained models were evaluated using training and validation accuracy and loss over 100 epochs. MobileNet demonstrated rapid convergence with high accuracy and minimal overfitting, as shown in Figure 10. At the same time, DenseNet and Xception exhibited stable learning behavior throughout training, achieving consistent performance across epochs, as illustrated in Figure 11 and Figure 8, respectively. ResNet achieved competitive accuracy but exhibited fluctuations in validation performance, suggesting sensitivity to hyperparameter settings, as shown in Figure 9. CapsNet demonstrated strong learning and generalization capabilities, characterized by high validation and a small gap between training and validation performance, as shown in Figure 6. Similarly, the vision transformer-based model maintained stable validation metrics throughout training, suggesting good generalization to unseen data, as illustrated in Figure 7.

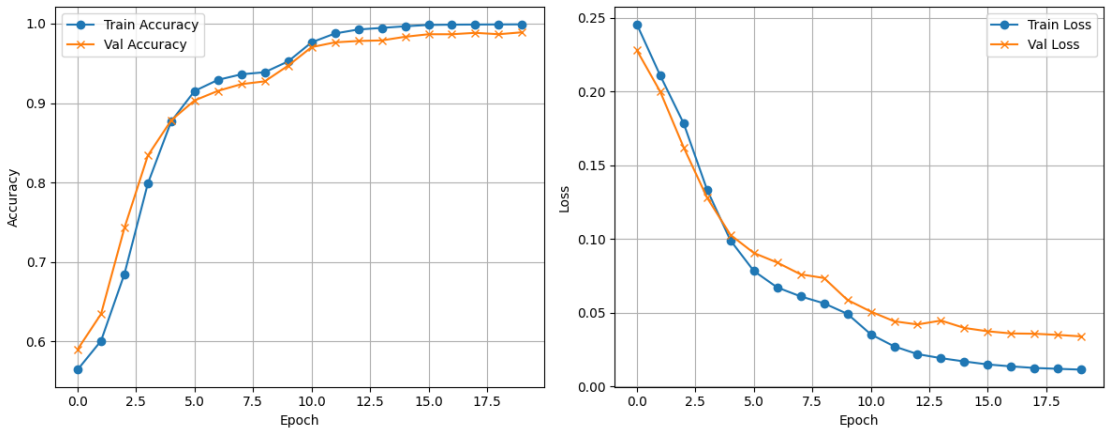

Figure 6. Capsule Nets training and validation accuracy and loss curves

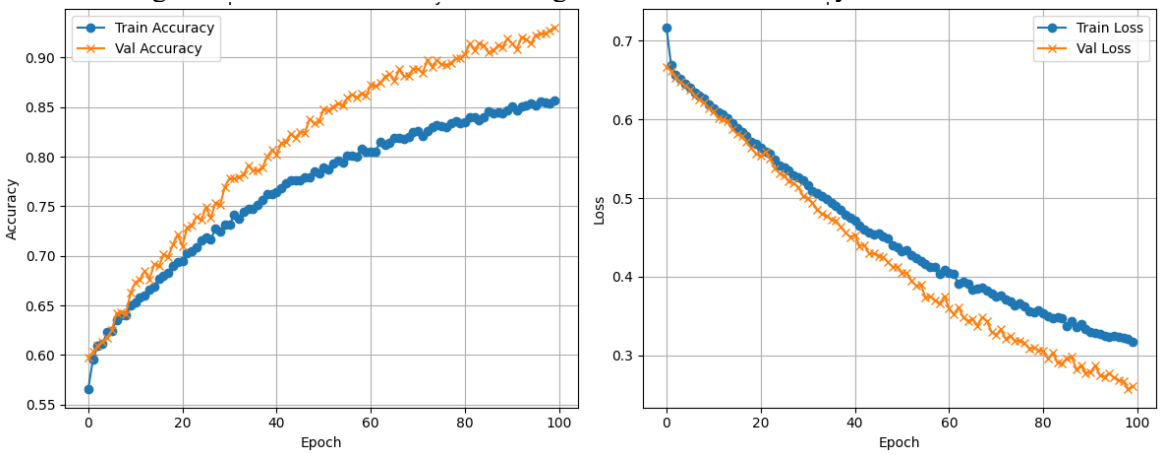

Figure 8. Xception training and validation accuracy and loss curves

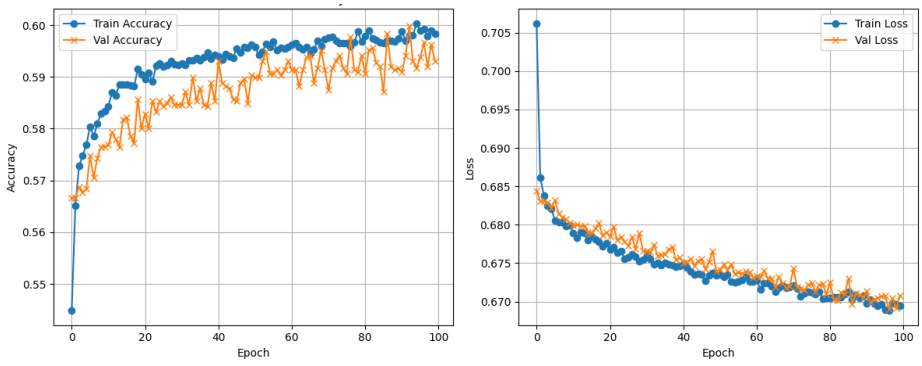

Figure 9. ResNet training and validation accuracy and loss curves

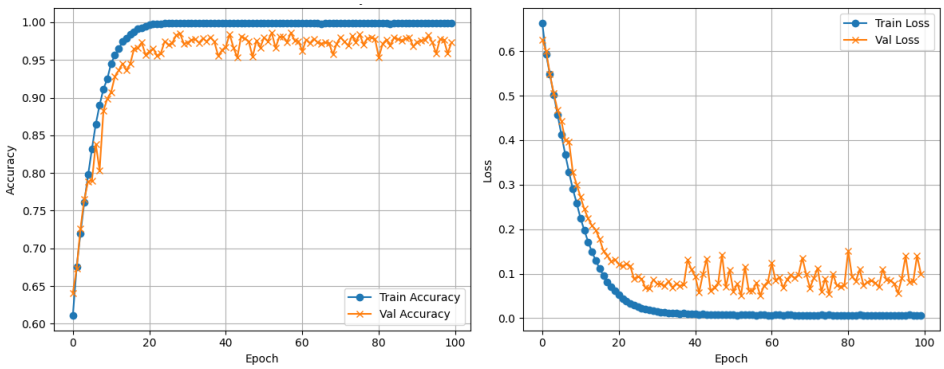

Figure 10. MobileNet training and validation accuracy and loss curves

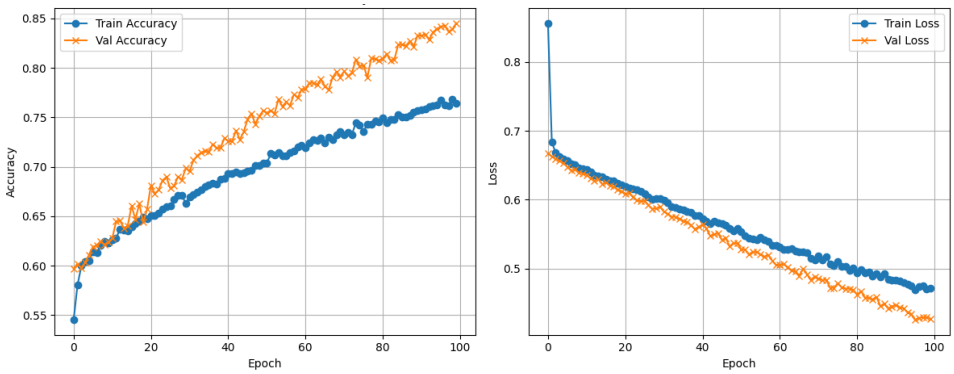

Figure 11. DenseNet training and validation accuracy and loss curves

2. Confusion Matrix

A confusion matrix was generated for each model to assess classification performance across the BI-RADS categories. CapsNet achieved the highest number of correctly classified benign cases (1771) and the lowest number of false positives (37), indicating strong specificity, as shown in Figure 12. ResNet and the vision transformer model showed similar performance, correctly classifying most benign cases but detecting fewer suspicious cases, as shown in Figure 13 and Figure 10, respectively. MobileNet achieved a more balanced performance by identifying more suspicious cases while maintaining a relatively low false-positive rate, as shown in Figure 11. In contrast, DenseNet and Xception recorded higher misclassification rates, as shown in Figures 14 and 15. Overall, CapsNet excelled in reducing false alarms, while MobileNet achieved a better balance between sensitivity and specificity.

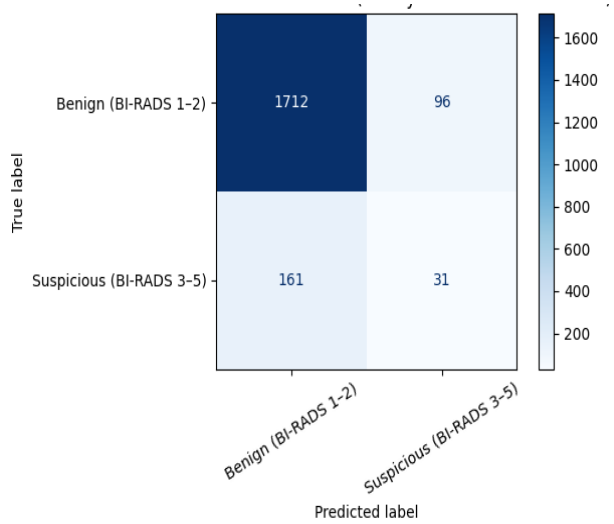

Figure 12. MobileNet Confusion Matrix

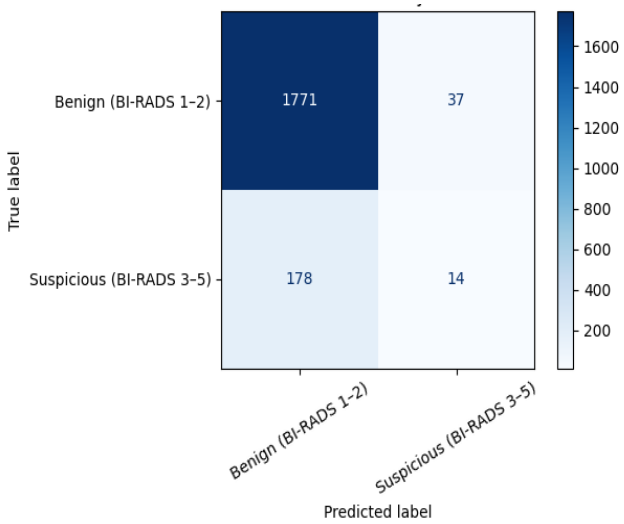

Figure 13. CapsNet Confusion Matrix

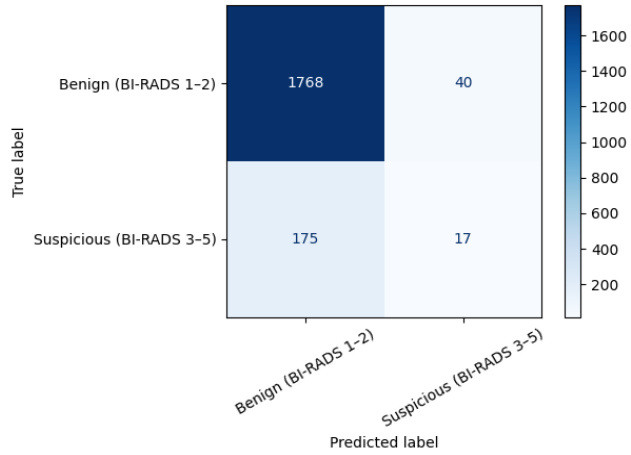

Figure 14. Vision Transformer Confusion Matrix

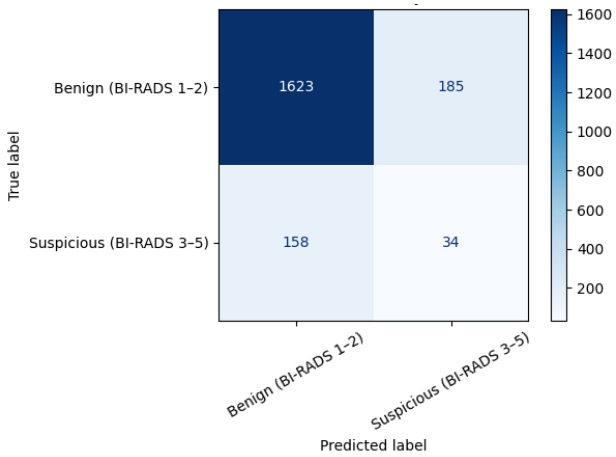

Figure 15. DenseNet Confusion Matrix

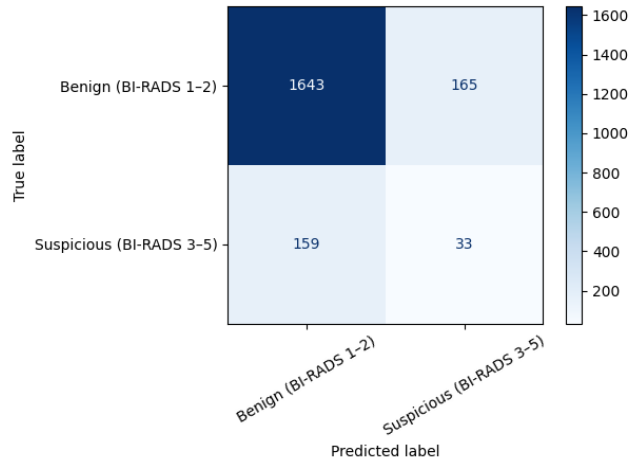

Figure 16. Xception Confusion Matrix

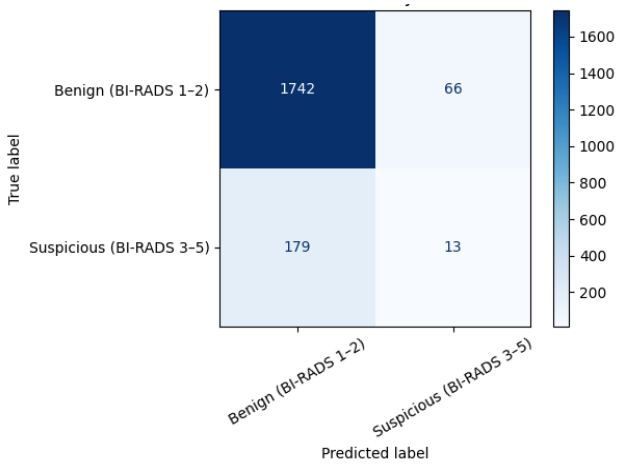

Figure 17. ResNet Confusion Matrix

3. Model Performance Evaluation

The evaluation results indicated that CapsNet achieved the highest overall accuracy of 90.09%, accompanied by a strong recall score. These results suggest that CapsNet is effective at identifying malignant cases and capturing relevant spatial relationships in mammographic images. The Vision Transformer model followed closely, with comparable recall and F1-score performance, while maintaining a smaller model size of 12.3 MB. Therefore, demonstrating its potential as a computationally efficient alternative for breast cancer detection, as shown in Table 1. Baseline CNN and ResNet models demonstrated moderate but consistent performance, although they required larger model sizes. MobileNet provided a favorable balance between classification accuracy and computational efficiency, making it suitable for deployment in resource-constrained environments. In contrast, DenseNet and Xception recorded lower performance, which may be attributed to limited generalization capability or overfitting to the training data. Overall, the findings suggest that CapsNet and Vision Transformer architectures offer improved classification performance and model efficiency compared to conventional CNN-based approaches for mammographic breast cancer detection.

Table 1. A Performance Comparative Table for all Trained Models

Model	Params (M)	Size (MB)	Acc (%)	Loss	Prec (%)	Rec (%)	F1 (%)
CapsNet	5.29	60.6	90.09	0.10	85	89	86
ViT	0.07	12.3	89.90	1.15	85	89	87
CNN	11.17	55.3	89.24	1.47	84	89	86
ResNet	0.13	93.6	88.43	0.55	84	88	85
MobileNet	3.23	14.4	87.76	0.90	85	87	86
Xception	0.13	83.0	84.47	0.43	84	84	84
DenseNet	0.13	29.6	83.84	0.46	84	83	83

4. Model Prototype

A prototype of the proposed breast cancer screening system was developed and deployed on the Hugging Face Platform. The prototype was subsequently evaluated using mammographic images collected from selected Kenyan hospitals. It was designed to classify BI-RADS categories 1 and 2 as normal and BI-RADS categories 3 to 5 as suspicious. Figures 18 and 19 illustrate the operation of the prototype for both classification outcomes.

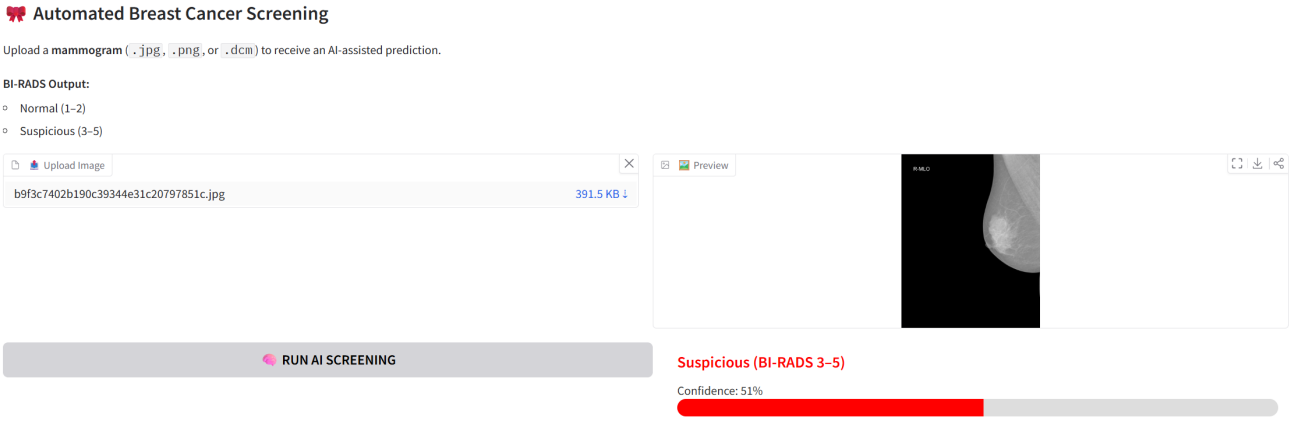

Figure 18. Prototype performance on a normal mammographic image

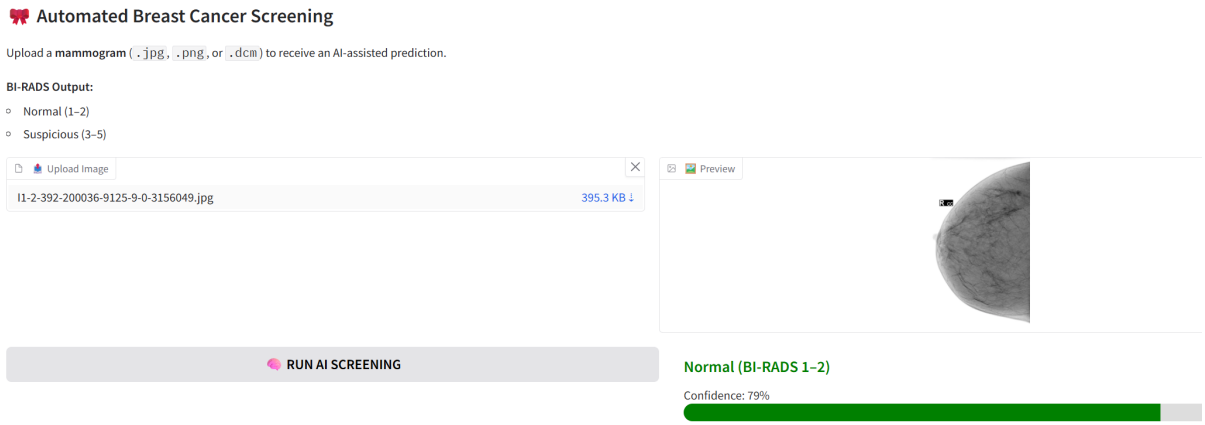

Figure 19. Prototype performance on a suspicious mammographic image

V. CONCLUSION

This study compared Convolutional Neural Networks (CNNs), Vision Transformers, and Capsule Networks for breast cancer detection using mammographic images. The results showed that CapsNet achieved the highest overall accuracy of 90.09%, demonstrating strong capability in capturing spatial relationships and identifying malignant cases. The Vision Transformer model achieved comparable performance while maintaining a smaller model size. Among the CNN architectures, MobileNet provided the best balance between classification performance and computational efficiency. Overall, the findings suggest that CapsNet and Vision Transformer-based architectures offer promising approaches for breast cancer detection, while lightweight CNNs remain practical alternatives where computational resources are limited.

ACKNOWLEDGEMENT

The authors gratefully acknowledge the National Cancer Institute of Kenya (NCI-Kenya) for funding this research. The authors also thank the Kenya Education Network (KENET) for providing the computational infrastructure and resources that supported this study.

ETHICAL CONSIDERATIONS

Ethical approval for the use of locally collected mammographic data was obtained from the relevant participating hospitals and the Kenya Ministry of Health. All patient data were anonymized before analysis and handled in accordance with medical privacy regulations. The publicly available VinDr-Mammo dataset was used in compliance with its open-access research guidelines. Throughout the study, principles of research integrity, confidentiality, data security, and responsible use of Artificial intelligence in healthcare were strictly observed.

Abstract
Registered crime exhibits a heterogeneous and multidimensional territorial distribution that cannot be adequately explained through absolute counts or administrative rankings alone. This study aims to classify and characterize territorial crime patterns in Peru using unsupervised learning and K-Medoids for the period 2015–2024. A balanced analytical matrix was built with 250 region-year observations, covering 25 regions and 12 crime categories expressed as rates per 100,000 inhabitants. Data were obtained from DATACRIM–INEI, harmonized by territory, converted into population-adjusted rates, and transformed into a multivariate machine-learning matrix. K-Medoids was applied using Manhattan distance and robust scaling. Cluster solutions from k = 2 to k = 10 were evaluated through the silhouette coefficient, Davies-Bouldin index, Calinski-Harabasz index, and Gap Statistic. The variation of internal validation metrics identified k = 10 as the optimal clustering solution, achieving the best overall performance across the Davies–Bouldin index, Calinski–Harabasz index, and Gap Statistic. Longitudinal validation for the 2015–2021 period yielded an Adjusted Rand Index (ARI) of 0.6046, confirming a statistically significant and stable structural agreement over time. The final partition revealed ten distinct granular region-year crime profiles, isolating specific dynamics associated with public safety, property-patrimonial offenses, domestic conflict, gender-based violence, and drug markets. This study contributes a replicable framework for classifying territorial crime in Latin American contexts through official data, normalized crime rates, and interpretable unsupervised learning.

Keywords: crime rates; DATACRIM; K-Medoids; Peru; public safety; territorial crime; unsupervised learning

I. INTRODUCTION

Crime is a territorially heterogeneous, dynamic, and multidimensional phenomenon whose distribution cannot be understood solely through absolute counts or administrative rankings [1]. Criminological evidence has shown that crimes tend to be spatially concentrated in certain territories and that this concentration responds to conditions of opportunity, mobility, exposure to risk, availability of victims, and the presence or absence of

formal and informal control mechanisms. In this sense, the analysis of crime requires approaches capable of identifying distinct patterns across territorial units [2], especially in countries with high geographic, social, and institutional diversity, such as Peru. The inadequacy of traditional classifications in the Peruvian and regional contexts lies in their inability to address the complexity of criminal governance, a phenomenon in which armed actors establish mechanisms of social and economic regulation that coexist with the State. This dynamic generates territorial criminal "signatures" where daily life is mediated by illegal actors in vulnerable areas [3]. This demonstrates that urban victimization in Peru is not uniform but follows distinct spatial patterns determined by the size of population centers. In large cities, high density increases opportunities for crime. At the same time, in medium and small centers, community cohesion can act as a protective factor, even generating a negative correlation between population growth and crime [4]. Recent developments in machine learning have expanded the analytical possibilities in quantitative criminology. Models such as Random Forest, Support Vector Machines, neural networks, LSTM, ConvLSTM, and deep spatiotemporal architectures have been used to predict risk zones, map hotspots, and model rare or unbalanced crime events [5]. These approaches have shown advantages in capturing spatial and temporal dependencies. However, they also often require large datasets, high geographic resolution, and complex training processes—conditions that are not always available in regional registries from Latin American countries [6]. Given these limitations, unsupervised learning methods offer a relevant alternative for exploring latent structures in crime databases without requiring prior labeling [7], [8]. Clustering allows grouping of territorial units based on similarities in their crime profiles, rather than solely on their positions in incidence rankings [8]. Among these methods, K-Medoids is particularly suitable when extreme values or regions with atypical behavior exist, because it uses real-world observations as representative centers of the groups [9]. The study's contribution is threefold. First, it proposes a regional-year matrix based on crime rates per 100,000 inhabitants, which enables comparison of territories with different population sizes and overcomes the limitations of absolute counts [9], [10]. Second, it applies K-Medoids to identify a granular partition of ten distinct territorial typologies of crime (k=10), prioritizing the multi-variable interpretability of the groups and the robustness of the algorithm in the face of extreme values or regions with atypical behavior [8], [9]. Third, it incorporates a spatial reconfiguration analysis by comparing profiles over a decade, which allows for the differentiation of persistent, emerging, declining, or volatile regions [1], [5]. With this, the article seeks to provide empirical evidence for the design of differentiated public policies, moving beyond the logic of uniform intervention based solely on national incidence rankings [10], [11]. Therefore, the objective of this research is to classify and characterize territorial crime patterns in Peru using unsupervised learning and K-Medoids [8], [9], employing regional rates per 100,000 inhabitants for the period 2015–2024 and validating the model's stability to ensure the consistency of the findings [1], [12]. This approach allows us to determine which regions share similar crime profiles, which types of crimes define each cluster, and which territories show signs of spatial reconfiguration during the period under analysis, thereby facilitating more efficient resource management [8], [10].

II. METHODOLOGY

1. Study design

This study adopts a quantitative, longitudinal, exploratory, and unsupervised learning design, aimed at classifying territorial crime patterns in Peru during the period 2015–2024 [1], [8]. The longitudinal approach enables analysis of the evolution of regional crime profiles over time [11], [13], while unsupervised learning identifies latent structures without imposing prior categories of risk or criminality [9]. This type of strategy is relevant to studies of territorial crime, since crimes are not distributed homogeneously but tend to concentrate in specific areas and periods depending on conditions of opportunity, mobility, institutional control, and risk exposure [1], [11], [12], [13]. The choice of an unsupervised model also stems from the limitations of purely predictive approaches when reliable labels or sufficient historical data are unavailable [9], or when the target variable may be biased by administrative records [6]. Therefore, this study does not seek to predict the aggregate number of crimes, but rather to classify territories using multivariate profiles constructed from specific rates for

each type of crime [8], [10]. This decision avoids tautological relationships between aggregate variables and their components. It shifts the focus from artificial prediction to the identification of interpretable territorial typologies, a relevant methodological requirement in applied criminological studies to guarantee transparency and accountability [5], [14].

2. Extraction, purification, and territorial homologation

The information downloaded from DATACRIM (https://datacrim.inei.gob.pe/panel/mapa) underwent a data cleaning and territorial standardization process before being incorporated into the machine learning model. The original tables were organized in a matrix format, with territorial units in rows and years in columns. To ensure territorial comparability, these tax units were standardized to the 25 regional units considered in the study: the 24 departments of Peru and the Constitutional Province of Callao. Population data from the INE (National Institute of Statistics and Informatics) were used to calculate the total population, estimated and projected as of June 30, by year, sex, and age group, 2000-2026 (https://www.inei.gob.pe/estadisticas/indice-tematico/poblacion-y-vivienda/).

3. Study period

The main analysis period spans the years 2015–2024. This time frame was selected because it provides comprehensive and comparable coverage of the crime categories included in the model and allows observation of the evolution of territorial patterns before, during, and after the COVID-19 pandemic. Choosing a ten-year time series strikes a balance among temporal breadth, data consistency, and statistical stability for the clustering analysis. As a validation strategy, the analysis is replicated for the period 2015–2021, enabling backtesting to confirm whether historical patterns remain valid or whether drastic changes have occurred that require recalibration [6], [15]. This validation allows us to assess whether the territorial profiles identified over the full 2015–2024 period are maintained in a more conservative time subset, thereby verifying whether the clusters are stable and persistent or represent transitory fluctuations [1], [13]. Furthermore, it allows us to compare the stability of the clusters using population estimates, ensuring that the findings capture a structural crime "signature" that is consistent across years [1], [11]. This logic of temporal validation is consistent with the spatiotemporal modeling literature, which recommends evaluating the stability and robustness of the patterns identified in different segments of the series [1], [15], [16].

4. Inclusion and exclusion criteria

For the main model (2015-2024), crime categories were selected that met five of DATACRIM's methodological criteria (such as regional coverage, complete annual data, rates per 100,000 inhabitants, and criminological relevance). These categories include crimes against property, against public administration, against the family, against liberty, against public safety, against public trust, against life, body, and health, reports of illicit drug trafficking, juvenile offenders, crimes against public order, domestic violence, and sexual violence against women. The year 2025 was excluded because only partial data (January-August) were available, thus avoiding unequal comparisons.

5. Transformation to long format for machine learning

This format organizes each record as a unique combination of region, crime, and year, with their respective values for recorded crimes, population, and rate. The general structure adopted was as follows:

$$REGION, CRIME, YEAR, CRIMES, POPULATION, RATE_100K$$

Subsequently, for the application of K-Medoids, the long-format database was transformed into a wide-format, where each row represents a region-year observation and each column corresponds to a crime category, expressed as a rate per 100,000 inhabitants. This transformation allows each region in each year to be represented as a multivariate vector of crime (equation 1):

$$X_{r,t} = (x_1, x_2, x_3, \ldots, x_p) \quad (1)$$

Here:$X_{r,t}$: represents the crime profile of the region in year t.

- $x_1, x_2, \ldots, x_p$: represent the rates per 100,000 inhabitants for each crime category.
- p: represents the total number of criminal variables included.

6. Final analytical matrix

The main matrix of the study comprises 25 regions and 10 years, resulting in a total of:

$$25 \times 10 = 250 \text{ region-year observations}$$

Each observation contains the rates per 100,000 inhabitants for the selected crime categories. This configuration allows for the simultaneous incorporation of territorial heterogeneity and the temporal evolution of crime. Unlike a static classification based on regional averages, the region-year unit allows observation of changes, stability, or reconfiguration in regional crime profiles over the period 2015–2024.

The validation matrix considers the period 2015–2021, generating:

$$25 \times 7 = 175 \text{ region-year observations}$$

This second matrix allows us to test whether the cluster structure obtained in the main model holds when the analysis is restricted to the most conservative time frame. Methodologically, this validation increases the credibility of the results and reduces the risk that the identified patterns depend exclusively on the 2022–2024 period.

7. Standardization of variables

Standardization was performed using z-scores; as a sensitivity analysis, robust standardization based on the median and interquartile range will also be evaluated (equation 2):

$$z_{i,j}^{rob} = \frac{x_{i,j} - Mediana(x_j)}{IQR(x_j)} \quad (2)$$

Where:

- i: represents the specific region-year observation.

- j: represents the specific crime category or variable.$z_{i,j}^{rob}$: represents the robust standardized value for the region-year observation i in crime category j.
- $i.,i,x_{i,j}$: represents the original crime rate per 100,000 inhabitants for the region-year observation i in crime category j.
- $Mediana(x_j)$represents the median rate of crime category j across all N observations.
- $IQR(x_j)$represents the interquartile range of crime category j, calculated as the difference between the 75th and 25th percentiles (Q3 - Q1).

This alternative is relevant when there are regions with extreme rates, given that territorial crime can exhibit asymmetric distributions, high spatial concentration, or outliers associated with specific territories. The literature on machine learning applied to crime data recognizes that spatial heterogeneity, territorial concentration, and the presence of sparse or extreme data pose significant challenges to building stable and interpretable models [14], [15].

8. Classification Algorithm: K-Medoids

The main algorithm used was K-Medoids, an unsupervised learning technique that groups observations according to their multivariate similarity. Unlike K-Means, which represents each cluster by its centroid, K-Medoids uses real observations as representative centers, or medoids [9]. This feature facilitates the substantive interpretation of the groups. It reduces sensitivity to extreme values, which is especially relevant in territorial crime databases where some regions may exhibit atypical rates for certain crimes, preventing these extreme cases from distorting the overall structure of the clusters [10], [11] (equation 2).

$$\min \sum_{k=1}^{K} \sum_{x_i \in C_k} d(x_i, m_k) \tag{3}$$

Where:

- $The\ K\ represents\ the\ number\ of\ clusters.$: represents the set of observations assigned to the cluster k.
- $i.\bullet\ represents$ the observation.
- m_k: represents the medoid of the cluster.
- $d(x_i, m_k)$: represents the distance between the observation and the medoid.

9. Ethical and interpretative considerations

The study uses aggregated regional-level information and therefore does not involve personal data or individual identification. However, it is acknowledged that territorial classification models can pose interpretive risks if clusters are used as deterministic labels for danger, which could lead to unjustified over-patrolling in specific communities. Therefore, the results are interpreted as statistical profiles of recorded crime, not as normative

judgments about regions or populations, recognizing that official data capture only a fraction of the reality of crime.

10. Processing Reproducibility

To ensure reproducibility, the processing is documented in four stages: download from DATACRIM, territorial standardization, conversion to rates per 100,000 inhabitants, and transformation into a machine learning matrix. Each stage maintains traceability between the source and the final matrix used in the model.

The methodological flow can be summarized as follows:

$$Datos\ DATACRIM \rightarrow Homologación\ territorial \rightarrow Conversión\ a\ tasas\ 100K \rightarrow Formato\ largo \rightarrow Formato\ ancho \rightarrow Estandarización \rightarrow K\text{-}Medoids$$

III. RESULTS

1. Evolution of crime rates

The evolution of crime rates shows that crime in Peru did not follow a uniform trajectory between 2015 and 2024. Instead, differentiated trends were observed across crime categories. The greatest relative increase was observed in crimes against life, body, and health, whose regional average rate rose from 255.38 to 1,154.44 per 100,000 inhabitants, representing a 352.05% increase. This result demonstrates a substantial reconfiguration of the recorded crime profile, particularly in crimes associated with direct harm to personal integrity. Likewise, significant increases were recorded in crimes against the family (87.89%), juvenile offenders (75.94%), sexual violence against women (71.54%), and crimes against property (59.51%), as detailed in Table 1 and Figure 1. More moderate increases were observed in crimes against liberty (41.30%), public safety (33.37%), public administration (25.04%), illicit drug trafficking (9.99%), and public trust (2.53%). In contrast, crimes against public order (-13.03%) and domestic violence (-98.00%) showed declining average rates over the study period. These findings are consistent with the literature indicating that crime patterns vary significantly according to the type of crime, the specific criminal opportunities of each location, territorial structure, and institutional conditions [1], [11], [12], [17].

Table 1. Evolution of cases and average rates by type of crime, 2015–2024.

Crime	Cases 2015	Average rate 2015	Cases 2024	Average rate 2024	Growth in cases (%)	Average growth rate (%)
against liberty	40969	151.4	68905	213.93	68.19	41.3
against life, body, and health	64490	255.38	375779	1154.44	482.69	352.05
against property	188869	714.45	405846	1139.63	114.88	59.51
against public administration	51000	205.15	74867	256.51	46.8	25.04
against public order	4547	10.71	3150	9.31	-30.72	-13.03
against public safety	71053	266.11	105674	354.92	48.73	33.37
against public trust	23737	75.18	25529	77.08	7.55	2.53
against the family	45895	194.96	97240	366.32	111.87	87.89
domestic violence	137181	527.92	1964	10.58	-98.57	-98.0
illicit drug trafficking	14453	39.91	15882	43.9	9.89	9.99

juvenile offenders	13557	47.8	25375	84.09	87.17	75.94
sexual violence against women	5311	21.51	10111	36.9	90.38	71.54

Note: Average rates are the annual regional averages per 100,000 inhabitants.

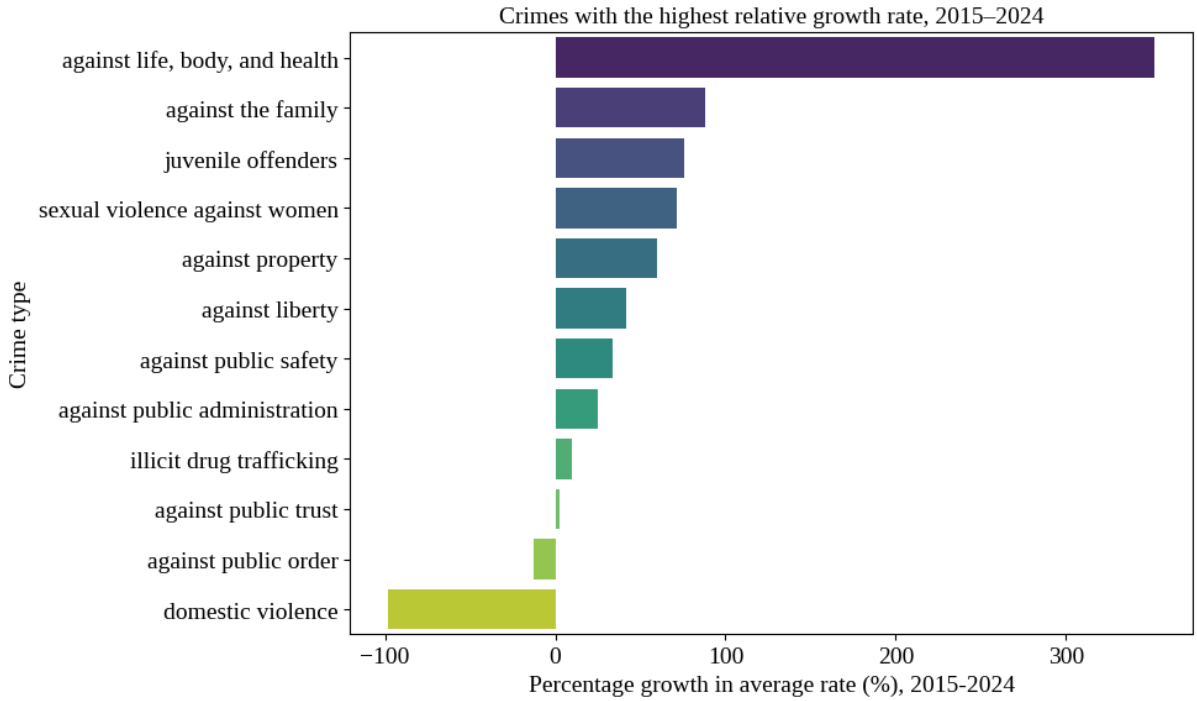

Figure1. Crimes with the highest relative growth rate, 2015–2024.

The figure shows that the largest relative increases correspond to crimes against life, body, and health, crimes against the family, juvenile offenders, sexual violence against women, and crimes against property.

2. Selection of the optimal number of clusters

To determine the optimal partition, solutions with k = 2 to 10 were evaluated using multiple internal validation metrics. The results identified k = 10 as the optimal clustering solution, as it achieved the lowest Davies–Bouldin index, the highest Calinski–Harabasz index, the largest Gap Statistic, and the best overall average ranking (Table 2, Figure 2).

Table 2. Internal validation for the selection of the number of clusters.

k	Manhattan Cost	Silhouette	Davies-Bouldin	Calinski-Harabasz	Gap Statistic	Average ranking
2	2171.4022	0.1112	3.2566	7.9006	1.0822	3.2
3	2044.772	0.0002	4.1628	5.5264	1.0271	4.0
4	2014.6868	-0.0283	4.5453	4.6123	0.9945	5.4

5	1950.832	-0.0711	5.6668	4.3017	0.9856	6.2
6	1940.8765	-0.0904	5.4279	3.4839	0.9538	7.0
7	1871.319	-0.1454	5.8565	3.5531	0.9632	7.0
8	1843.265	-0.1805	4.3412	5.2538	0.9685	5.0
9	1861.6794	-0.206	3.7777	5.1684	0.9391	5.8
10	1560.0176	-0.0202	2.6714	74.3815	1.0963	1.4

Note: The optimal solution was selected at k = 10, as it achieved the best overall performance across the internal validation metrics, including the lowest Davies–Bouldin index, the highest Calinski–Harabasz index, the largest Gap Statistic, and the best average ranking.

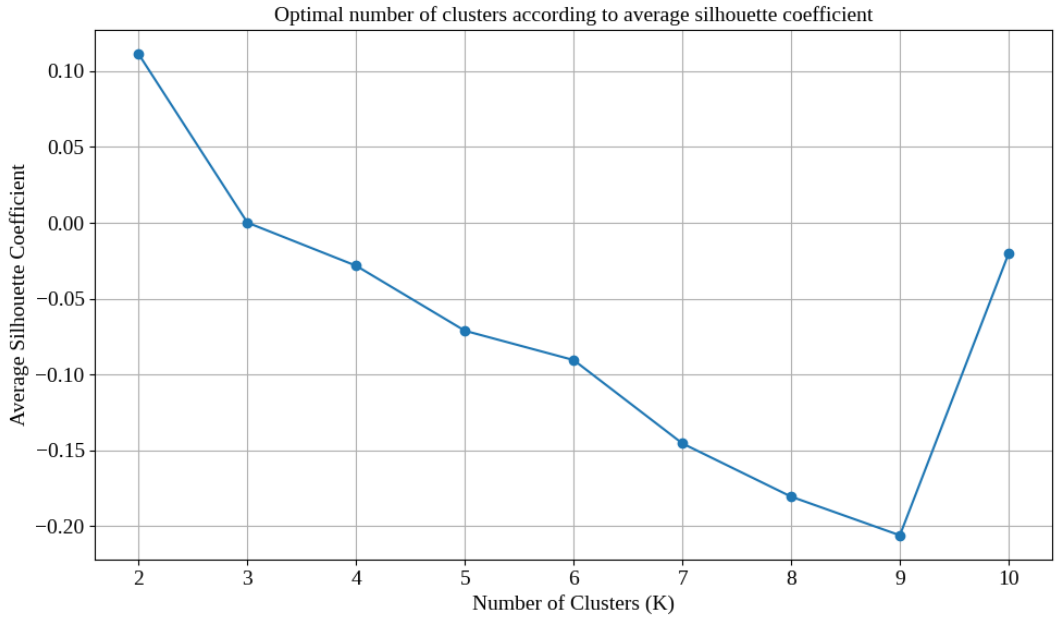

Figure 2. Optimal number of clusters according to the average silhouette coefficient.

The variation of the internal validation metrics (Figure 2) indicates that k = 10 provides the best overall clustering performance, supporting its selection as the final partition.

It is critical to note that although the silhouette coefficient attains its highest value at k = 2 (Silhouette = 0.1112), this partition was discarded due to its limited practical utility and excessive analytical overgeneralization in criminological analysis. When evaluating the joint behavior of the remaining internal validation metrics, the k = 10 solution achieves the optimal global performance: it records the lowest Davies–Bouldin index (2.6714), a critical and robust increase in the Calinski–Harabasz index (74.3815), and the largest Gap Statistic (1.0963). This multi-criteria consensus mathematically justifies selecting a granular partition of 10 territorial crime profiles.

3. Main classification with K-Medoids

The final K-Medoids solution (k = 10) identified ten distinct territorial crime profiles across the region-year observations. Cluster sizes ranged from 7 to 54 observations and involved between 4 and 18 regions, indicating

that the identified clusters represent dynamic region-year crime profiles rather than fixed regional groupings. This classification captures the temporal and spatial heterogeneity of recorded crime patterns across Peru. The dominant crime composition varied substantially across clusters (Table 3 and Figure 3). While some clusters were characterized by higher standardized averages of illicit drug trafficking, domestic violence, and crimes against public order, others were dominated by crimes against public safety, crimes against property, juvenile offenders, crimes against public administration, or crimes against life, body, and health. These differences reveal heterogeneous crime profiles, highlighting the coexistence of multiple territorial patterns rather than a single nationwide crime structure.

Table 3. Summary of the main classification with K-Medoids, k = 10.

Cluster	**Region-year observations**	**Regions involved**	**Dominant crimes according to the standardized average**
1	16	6	illicit drug trafficking; against public order; against liberty; against public safety
2	20	8	domestic violence; juvenile offenders; sexual violence against women; against public order
3	13	5	domestic violence; against property; illicit drug trafficking; against the family
4	18	9	illicit drug trafficking; against public trust; against public safety; domestic violence
5	24	13	domestic violence; illicit drug trafficking; sexual violence against women; against public safety
6	7	4	illicit drug trafficking; juvenile offenders; against public safety; against the family
7	42	7	domestic violence; sexual violence against women; against public order; against the family
8	19	18	domestic violence; against public order; against public trust; illicit drug trafficking
9	54	13	against public safety; against property; juvenile offenders; against public order
10	37	10	against public administration; domestic violence; against public trust; against life, body, and health

Note: The dominant crimes correspond to the variables with the highest standardized means within each cluster.

Figure 3. Average criminal profile by cluster.

The heat map visualizes the relative intensity of each crime type within the clusters, expressed as a robust standardized mean.

4. Longitudinal validation 2015–2021

To assess the model's temporal stability, the clustering procedure was replicated for the period 2015–2021. This validation allowed comparison of whether the crime profiles identified in the main period (2015–2024) were preserved when the analysis was restricted to a shorter time frame. The validation again selected k = 10 as the optimal solution, indicating consistency in the identified clustering structure. The agreement between the partitions was assessed using the Adjusted Rand Index (ARI), yielding a value of 0.6046 based on 175 comparative observations. This result indicates a moderate level of agreement between the main and validation solutions, suggesting that the identified crime profiles remain relatively stable over time despite temporal variations. Methodologically, these findings support the robustness of the clustering model, demonstrating that the classification is not exclusively dependent on the selected observation period but reflects persistent spatial patterns of recorded crime [1], [11], [13]. Longitudinal validation (Table 4) is particularly relevant in spatiotemporal studies, where crime patterns may vary according to the observation period, spatial scale, and the dynamics of administrative records [1], [9], [11], [15].

Table 4. Longitudinal validation of the K-Medoids model.

Model	Period	Optimal k	Comparative observations	ARI
Main model	2015-2024	10	175	0.604614
Validation model	2015-2021	10	175	0.604614

Note: The ARI measures the agreement between partitions adjusted for chance. Values close to 1 indicate greater stability between solutions.

5. Territorial reconfiguration

The transition analysis between 2015 and 2024 allowed us to assess whether regions maintained their membership in the same crime profile or shifted clusters over the study period. The transition matrix reveals movements across the ten identified profiles, confirming that recorded crime should not be understood as a fixed territorial condition, but rather as a dynamic process of spatial and temporal reconfiguration [5], [11]. This approach complements the static classification with a longitudinal perspective of regional mobility, consistent with previous research on crime displacement, concentration, and territorial change [1], [17]. The transition matrix between clusters (Figure 3) is particularly useful for identifying persistent regions, emerging profiles, and territories undergoing changes in their relative crime structure [13]. This approach moves beyond isolated rankings, as a region may not consistently occupy the highest positions in absolute crime levels but may experience substantial changes in its crime composition or temporal pattern [11]. From a public policy perspective, this analysis helps distinguish territories with persistent crime profiles from those undergoing transformation, supporting more targeted resource allocation and decision-making adapted to the dynamic evolution of crime patterns [18].

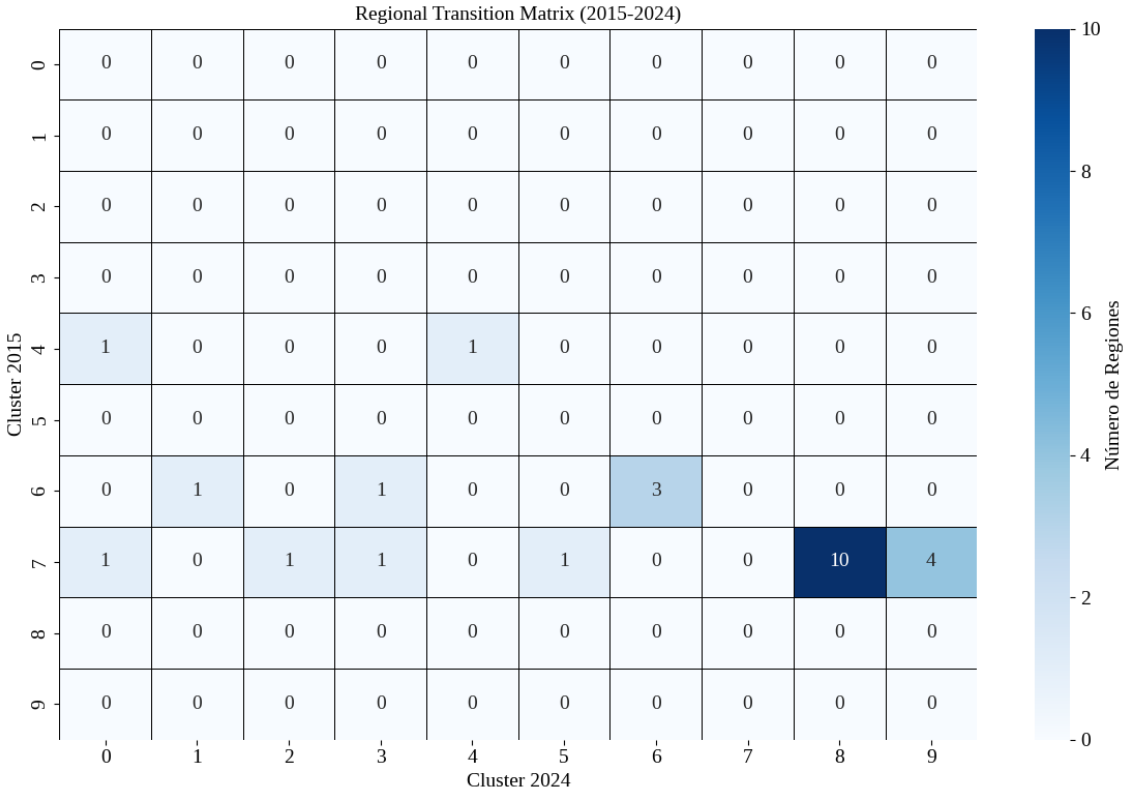

Figure 4. Regional transition matrix between clusters, 2015–2024.

The figure shows changes in cluster membership among Peruvian regions between 2015 and 2024. The matrix values indicate the number of regions that remain within the same cluster or transition between the ten identified territorial crime profiles.

6. Summary of results

Taken together, the results show that recorded crime in Peru during 2015–2024 exhibits a heterogeneous territorial structure. The primary solution using K-Medoids with k = 10 identified ten distinct territorial crime profiles, supported by multiple internal validation metrics and reinforced through longitudinal validation, which showed moderate agreement between the main and validation partitions (ARI = 0.6046).

These findings fulfill the study's objective by demonstrating that unsupervised learning enables the classification of territorial crime patterns without relying on aggregated dependent variables or tautological models. Furthermore, using rates per 100,000 inhabitants and temporally validating clusters strengthens the methodological robustness of the analysis, indicating that the identified profiles reflect persistent criminal patterns rather than random fluctuations. Additionally, incorporating territorial transition analysis highlights crime as a dynamic phenomenon shaped by spatial and temporal changes. Overall, this approach goes beyond descriptive and fragmented interpretations of criminality by providing a multivariate characterization of regional crime profiles, integrating diverse dimensions of crime to support more precise, evidence-based public policies.

IV. DISCUSSION

The multidimensional crime structure identified in Peru (2015–2024) confirms that territorial crime is not randomly distributed, but rather responds to differentiated socio-spatial dynamics. The selection of the optimal partition of k=10 clusters, supported by the best overall performance in internal validation metrics (lowest Davies–Bouldin index and highest Calinski–Harabasz index), demonstrates that the country's crime reality requires granular segmentation to avoid masking critical patterns. The silhouette coefficient for this solution reflects the inherent complexity of the social data, in which regional boundaries naturally overlap due to territorial interconnections and demographic variability. The model's temporal stability is one of its most robust methodological components. The Adjusted Rand Index (ARI = 0.6046) from the longitudinal validation (2015–2021) indicates a moderate and statistically significant level of agreement between the partitions. This ensures that the clustering with k=10 identifies structural and persistent criminal signatures over time, rather than responding to random annual fluctuations or artifacts derived from population projections. Detailed multivariate analysis isolated profiles with high criminological specificity. For example, Cluster 9 shows a critical concentration of crimes against public safety and property, as well as juvenile offenses. At the same time, Clusters 2, 5, 7, and 10 demonstrate the persistence of domestic and gender-based violence dynamics at varying relative intensities. This overview provides direct practical value for public safety planning by overcoming the ineffectiveness of absolute administrative rankings. It thus facilitates the transition from uniform interventions to differentiated strategies: situational and targeted policing for property-related profiles, and intersectoral coordination (health and justice) in regions dominated by interpersonal violence. Finally, the shifts recorded by the transition matrix corroborate the view that criminal behavior is not a static geographical condition but rather a dynamic process of spatial reconfiguration. Although the model is limited by the "dark figure" of unreported crimes, the methodological traceability based on DATACRIM-INEI records establishes a reproducible standard for regional criminological analysis.

V. LIMITATIONS

The study has methodological limitations that must be considered when interpreting the findings. Firstly, the data analyzed correspond exclusively to the crime recorded administratively by DATACRIM–INEI, which implies that the results may be influenced by under-reporting or the "black figure" of crime, regional variations in the propensity to report, and disparities in institutional recording capacities. Secondly, the regional aggregation scale, although it guarantees comparability at the national level, tends to mask heterogeneity at the provincial, district, or intra-urban level. Thirdly, the initial omission of specific categories such as homicide restricts the analysis of lethal violence, which has logics of social gravity and spatial dynamics different from property crimes. Finally, the K-Medoids algorithm classifies multivariate profiles and temporal reconfigurations but does not establish direct causal relationships. Future developments must incorporate socioeconomic variables (poverty, inequality, urbanization) to deepen the model's predictive and preventive scope.

VI. CONCLUSIONS

This study successfully classified and characterized territorial crime patterns in Peru (2015–2024) using normalized rates per 100,000 inhabitants and unsupervised learning with K-Medoids. The results demonstrate that crime exhibits a heterogeneous and dynamic spatial structure that goes beyond the linear interpretations of traditional rankings. The evolution of rates revealed a profound reconfiguration of the crime landscape, highlighting the asymmetric relative growth of crimes against life, body, and health (+352.05%), followed by substantial increases in crimes against the family and juvenile offenders. The modeling indicated that the partition with k=10 clusters is the statistically most appropriate solution for describing the complexity of the

Peruvian territory. The stability of this structure was corroborated by longitudinal validation from 2015 to 2021, yielding an ARI of 0.6046, confirming consistent structural patterns despite variations in the observation period. The resulting taxonomy allowed for the isolation of specific criminal dynamics (such as drug markets, crimes against public administration, or interpersonal violence), providing a detailed analytical map of the coexistence of multiple regional criminal profiles. The central contribution of this research is a parsimonious, reproducible, and ethically aligned methodological framework that promotes transparency in the use of official data for evidence-based decision-making. From an applied perspective, the findings indicate that security policies in Peru must abandon uniform patrolling strategies and shift toward targeted, multidimensional interventions: situational crime prevention in areas with high property values and intersectoral coordination between the justice and health sectors in regions vulnerable to domestic and gender-based violence.

Abstract
Recommender systems are techniques created to provide tailored suggestions for airlines and their ancillaries that are most pertinent to each passenger. The Passenger Cold Start Problem occurs when a new passenger cannot be properly recommended because there is insufficient historical data to suggest airlines or ancillaries that align with the passenger's interests. The proposed techniques efficiently personalize recommendations for each passenger using available historical data to satisfy each passenger's experience. The dataset comprises three airline carrier datasets detailing every commercial flight within Libya, the UAE, and Turkey. The Python platform was used to actualize the algorithm. Initial flight recommendations to new passengers are made while the model continuously updates their profiles based on their interactions with the airline booking engine, thereby enabling continuous learning. As more data becomes available, the algorithm refines its recommendations, leveraging ongoing interactions to optimize the accuracy using the Bipartite Network Algorithm (BNA). The Pearson correlation coefficient was used to compute the passenger-Airline matrix of passenger preferences. $\mathbf{W_u}$), and the minimum similarity threshold is set to η to determine the similarity. The performance of the proposed model was evaluated using Mean Absolute Error (MAE) and Precision, which measured the proximity of predicted grades to true ratings. The results show that for new passengers, the Emirates Airlines data has an MAE of 1.248 for SVD, 0.947 for Bipartite-Cluster, and 0.916 for the proposed algorithm (BNA). Turkish Airlines data has an MAE of 1.319 for SVD, 1.291 for Bipartite-Cluster, and 0.946 for the proposed algorithm, and Afriqiyah Airways has an MAE of 1.319 for SVD, 1.291 for Bipartite-Cluster, and 0.964 for the proposed algorithm. The result clearly indicates that the Optimized Bipartite Algorithm outperformed SVD and Bipartite-Cluster.

Keywords: Recommender System, Cold Start problem, Bipartite Algorithm, Transfer Learning, sentiment Analysis, Mean Absolute Error, Execution Time, passenger, Pearson correlation coefficient, and Airlines.

I. INTRODUCTION

Sentiment analysis has become highly valuable in various fields, including e-commerce, customer relationship management, and social media. By providing insights into users' opinions, attitudes, and feelings, emotion analysis could significantly improve the reliability of recommendation techniques. Integrating emotion analysis into these techniques implies more precise, tailored recommendations, eventually enhancing user satisfaction and their interaction. Recommender techniques can be implemented using two

methods: collaborative filtering and the content-based approach. Many systems rely on a hybrid of these methods.
Content-based approaches assume that if a user were concerned with an item in their last experience, they would be concerned with the same item in the next experience as well. By building a user account based on their historical attitude (actions) and gathering identical items by their properties, the engine will suggest new items to the user. Furthermore, Collaborative filtering aims to provide intelligent recommendations based on past user experience, represented as an interaction matrix between users and items. This method could be described as a generalization of classification and regression issues in which the features cannot be distinguished from the targets. i.e., the algorithm examines to predict the value of each cell in the said matrix.

Sentiment analysis of user ratings and attitudes has become an important basis for recommender systems [1], enabling them to predict users' future interests based on their experience. Taken together, this improves the system's ability to suggest accurate recommendations to users individually. Significant challenges face recommender techniques, especially the collaborative filtering approach [1], which suffers from the cold-start issue for new users or items. Totally, content-based recommender techniques usually lack variety in their suggestions and recommendations, which implies lower system accuracy. Handling the said challenge could enhance the performance of sentiment-based recommender techniques. Integrating methods such as deep learning and hybrid approaches can significantly enhance performance. A recommendation system can help users quickly and accurately find information that meets their needs [2]. This improves user satisfaction and user experience [3]. Today, recommendation techniques play a crucial role in e-commerce [4], [5] and other domains [6-11], [3], [12-15]. Moreover, Recommender techniques play a crucial role by providing users with services tailored to their preferences.

In this research, we examined the most important challenges in recommendation techniques. We address the cold-start issue for new passengers by merging sentiment analysis from existing passenger ratings. This method helps us determine what is interesting to new passengers and suggest an airline with the highest ratings, even if the new passenger's required data is still unknown. However, the cold-start issue is common in recommender techniques [16], [17]. Table 1 elaborates on the cold-start issue and clarifies it by providing an example of a recommendation based on passenger ratings. In Table 1, rows represent passengers. The columns represent n airlines. The matrix shows passenger reviews of the airlines in the range {1, 2, 3, 4, 5}, where the reviews are integers. Values 0-5 represent passengers' reviews of the airline, and if a passenger has not reviewed the airline, it is denoted by '?'.

Table 1. Illustration Sample of cold-start problem in the passenger-airline rating matrix

Passenger/ Airline	**Airline 1**	**Airline 2**	**Airline 3**	**.....**	**Airline n**
Passenger 1	3	4	?	.....	?
Passenger 2	?	5	4	……	?
Passenger 3	1	0	4	……	?

II. LITERATURE REVIEW

Several studies on the cold-start issue for new users are presented in the following paragraphs. Panda and Ray [18] performed research and a review of ninety-one papers on cold-start mitigation. The research aimed to categorize the several methods into data-driven and method-driven techniques. It also classified method-driven techniques into five main methods depending on the models used by the scientists. The research also

emphasized dozens of algorithms for comparison, and some of the metrics used were analyzed to evaluate the cold-start issue. However, the study was unable to distinguish user cold starts from cold starts in the project. Since there is no relation between these two issues, the solutions to each problem should be determined separately.

Son [19] also conducted an important study on the cold-start issue for new users. The examiners introduced a study aimed to analyze the compression of three methods for the problem, involving (i) utilizing some available information from other sources, (ii) selecting the foremost matching user classifications, and (iii) using hybrid methods to improve prediction. He presented a comparative study of several algorithms, including HU-FCF, MIPFGWC-CS, and FARAMS. Nevertheless, his systematic study was completed in 2014, and many statistical techniques that it didn't address have been developed recently.

Abdullah et al. [20] have offered a detailed categorization and an introduction to models to identify the new-user issue through promoted information. The study presented a comprehensive explanation of how supporting data can be acquired and extracted. The systematic study introduces a data-driven solution to the new-user cold-start problem. On the other hand, the study has given less focus to the method-driven technique. In short, their study has some issues with how the user cold-start problem could be solved. (i) The Issue is figured out in dated Literature's evaluations. Their analysis to figure out the Issue focuses entirely on one particular model. They do not consider other methods such as ML or DL.

H. Yuan et al. [21] stated in their article that the "user cold start problem" occurs when a new user cannot be effectively recommended due to a lack of historical information. This issue could obstruct the use of the recommendation system.

Their study covered all literature reviews conducted and published by candidates from January 2016 to April 2023, spanning 8 years. This study analyzed the literature on models, techniques, and approaches deployed to address the issue over the last eight years and classified them into two categories: Data-Driven Approaches and model-driven techniques. The study analyzed the existing evaluation criteria for these techniques to provide robust references for researchers in related areas.

Ke Yin Cao et al.[22] proposed a community detection algorithm for a cold start issue. Using the bipartite network, the similarity in this work has been calculated between the user and their preferred item. Community detection is performed using the Louvain algorithm on the projected One-Mode network.

Z. Zhang et al.[23] The proposed technique uses a link prediction method to simulate user identification and their preferences, reducing the range of possible recommendations. In addition, a Convolutional Neural Network (CNN) is used to predict the likelihood of flight cancellations or delays, enabling the model to provide passengers with recommendations that align with their preferences based on available information and flight details. The proposed model used clustering to simplify the handling of massive flight datasets and speed up processing. In their technique, the K-Means algorithm partitions the data into clusters, and the recommendation process is based on the cluster closest to the user's features. The outcome of the proposed technique was tested using actual flight data.

Aditya Naidu et al.[24] Presented a hybrid recommender system that combines content-based filtering, collaborative filtering, and sentiment analysis to give more accurate and user-centric tourism recommendations. By analyzing both item attributes and user interactions and incorporating feedback from user ratings, the model improves its predictions to better meet user needs. Their model is designed to eliminate information overload and optimize the efficiency and satisfaction of the journey-planning process. Their paper also evaluated the effectiveness of variety recommendation techniques and emphasized the Advantages and trade-offs connected with integrating hybrid models in travel techniques.

Karthiyayini, J [25] has proposed using multi-criteria recommendation techniques that consider multiple attributes, rather than relying solely on user ratings as in traditional recommendation systems. This strategy is based on a hybrid filtering technique. Furthermore, the model uses two-way automatic decoding (BDA) to personalize recommendations based on different user profiles. The introduced technique was tested using

several real-world datasets gathered from diverse travel platforms. The pilot evaluations showed its superior effectiveness at enhancing prediction accuracy compared with existing techniques. The proposed model not only addresses the challenges associated with large and diverse datasets but also provides personalized travel plans tailored to each user's preferences, thereby optimizing the user experience in travel recommendation systems.

III. RESEARCH METHODOLOGY

1. Transfer-learning-enabled BNCD for a new passenger

The proposed BNCD algorithm is trained in two phases. In the first phase, the model is trained on historical data from existing passengers. In this phase, BNCD learns a shared representation of passenger preferences and evaluates passenger-specific latent parameters. In the second phase, when a new passenger is introduced, the knowledge learned from existing passengers is transferred to the new passenger through three mechanisms:

1. Shared model initialization: the global BNCD parameters learned from existing passengers are utilized to initialize the model for the new passenger.
2. Bayesian prior transfer: the posterior distribution learned from existing passengers is used as the prior distribution for the new passenger.
3. Similarity-based passenger adaptation: the new passenger is compared to the majority of similar existing passengers or passenger clusters, and their learned parameters are utilized to initialize or systematize the new passenger model.

Transfer learning is embedded directly into the BNCD training and inference procedures.

1. Inputs

   Let there be *N* existing passengers. For passenger i, the Historical dataset is given by equation (1).

$$D_i = \{(x_{i,j}, y_{i,j})\}_{j=1}^{n_i},$$

   Where $B\ddot{u}y\ddot{u}k$put feature vector aand $\text{yndy}_{i,j}$ points to the corresponding target, as shown in equation (2).$D_S = \{D_1, \dots, D_2\}$

   For a new passenger, the available data may be one of the following:

   1. No data, i.e., a cold-start scenario demonstrated in equation (3):

$$D_t = \emptyset$$

   2. A small support set illustrated in equation (4):

$$D_t^{sup} = \{(x_{t,j}, y_{t,j})\}_{j=1}^{n_t},$$

   Where $n_t It\ It\ It\ It$ is often small.

Optionally, side information for the new passenger may also be available, such as demographic attributes, travel preferences, historical route information, or other profile features. Let this information be denoted by

$$a_t.$$

Therefore, the complete inputs to the proposed algorithm are mentioned in equation (5):-

$$\{D_S\ , D_t^{sup}, a_t.\}$$

2. Model parameters

The BNCD model contains two types of parameters.

2.1 Global parameters

The global parameters are shared across passengers and are denoted by:

$$\theta.$$

The parameters, such as general behavioral structure, feature representations, or common latent factors, are called model common patterns and are shared by variant passengers

2.2 Passenger-specific parameters

For the passenger, the passenger-specific parameters are denoted by

$$\theta_i$$

These parameters capture individual differences among passengers. For the new passenger t, the corresponding passenger-specific parameters are:

$$\theta_t$$

The full parameter set for the passenger is therefore

$$\Theta_i = \{\theta, \phi_i\}.$$

3. Source training process

Firstly, BNCD is trained utilized the source dataset. The aim is to learn the shared parameters, the passenger-specific parameters, and the posterior distribution over them. The source training function is shown in equation (6):

$$L_S(\theta, \{\varphi_i\}) = \sum_{i=1}^{N} \sum_{(x,y)\in D_i} l\left(f_{\theta,\varphi}(x), y\right) + \lambda_{reg} R(\theta, \{\varphi_i\}) + \lambda_{KL} KL(q_S(\theta, \{\varphi_i\}) \| p_0(\theta, \{\varphi_i\}))$$

After source training, the model obtains as illustrated in equation (7):

$$\theta_S, \{\varphi_i\}_{i=1}^{N}, q_S(\theta, \{\varphi_i\}).$$

In addition, the algorithm stores transfer statistics, such as:

- passenger embedding or latent representations;
- passenger cluster assignments;
- cluster centroids;
- posterior means and covariances;
- Sufficient statistics required for Bayesian updating.

The knowledge is being transferred to a new passenger using the stored quantities mentioned.

3. Transfer learning mechanism

Once a new passenger t appears, the algorithm does not train from scratch. Instead, the information learned from existing passengers is transferred to the new passenger.

The transfer mechanism is defined as follows.

First, the source posterior is used to construct an initial target prior for the new passenger as demonstrated in equation (8):

$$q_t^0(\theta, \varphi_t) = T(q_S(\theta, \{\varphi_i\}))$$

Where T (.) is the transfer operator.

In the simplest case,

$$q_t^0(\theta, \varphi_t) = q_S(\theta, \{\varphi_i\}))$$

Meaning that the new passenger is initialized using the global source posterior.

In more personalized details, the algorithm calculates the similarity between the new passenger and each existing passenger by using equation (9):

$$w_i = \frac{\exp(s(a_t, a_i)/\tau)}{\sum_{k=1}^{N} \exp(s(a_t, a_k)/\tau)},$$

The transferred prior for the new passenger is then computed as a similarity-weighted combination of source-passenger posteriors as shown in equation (10):q alt t üssü 0 , sol parantez teta ,fi alt t, sağ parantez eşittir toplam alt limit i eşittir 1 üst limit N of w alt i, q alt i , sol parantez teta ,fi alt $i(\theta, \phi_t) = \sum_{i=1}^{N} w_i\, q_i(\theta, \phi_i)$.

Equivalently, if BNCD uses passenger clusters, the new passenger is assigned to the most relevant cluster, and the cluster posterior is used as the initialization.

Thus, the transferred information includes:

1. The global BNCD parameters ;
2. The posterior distribution learned from existing passengers;
3. Passenger embeddings or cluster centroids;
4. Similarity weights identifying the most relevant existing passengers;
5. Sufficient statistics required for fast Bayesian updating.
6. Adaptation for a new passenger

Once the transfer is prior q_t^0 Once it is obtained, the model adapts to the new passenger using any available information.

Data D_t^{Sup} .

The adaptation objective is illustrated in equation (11):

$$L_t(\theta, \phi_t) = \sum_{(x,y)\in D_t^{sup}} \ell\left(f_{\theta,\phi_t}(x), y\right) + \beta\, KL\left(q_t(\theta, \phi_t) \,\|\, q_t^0(\theta, \phi_t)\right) + \lambda_t \|\phi_t - \phi_t^0\|^2,$$

The adapted posterior is obtained by minimizing the above function, as shown in equation (12): q_altin equation (12):$q_t^* = \underset{q}{\operatorname{argmin}} L_t(\theta, \phi_t)$.

If only a very small amount of data is available, the global parameters may be frozen, and only the Passenger-specific parameters are updated:$\theta = \theta_S \phi_t = \underset{\phi_t}{\operatorname{argmin}} L_t(\theta_S, \phi_t)$.

This prevents overfitting when the new passenger has very limited data.

7. Prediction for a new passenger

After adaptation, predictions for the new passenger are made using the posterior predictive.

Distribution. For a new input x, the prediction is demonstrated in equation (13):

$$\hat{y}_t(x) = \mathrm{E}_{q_t^*(\theta,\phi_t)}\left[f_{\theta,\phi_t}(x)\right].$$

The pseudocode for the proposed BNCD Algorithm is shown in Figure 1.

```
Algorithm: Transfer-Learning-Enabled BNCD for a New Passenger
Input:
   Source datasets D = {D_1, ..., D_N}
   Optional support set D_t^sup
   Optional passenger profile a_t
   Hyperparameters λ_reg, λ_KL, β, λ, τ, M
Output:
   Adapted posterior q_t^*
   Prediction function ŷ_t(x)
1. Preprocess source data:
     Normalize features
     Create passenger-level train/validation splits
2. Train source BNCD:
     Initialize θ, {ϕ_i}
     Minimize:
        L_S = Σ_i Σ_{(x,y)∈D_i} ℓ(f_{θ,ϕ_i}(x), y)
            + λ_reg R(θ, {ϕ_i})
            + λ_KL KL(q_S || p_0)
     Obtain θ_S, {ϕ_i^S}
     Store q_S and transfer statistics

3. Initialize new passenger t:
     If profile a_t is available then
        Compute weights:
           w_i = exp(s(a_t, a_i)/τ) / Σ_k exp(s(a_t, a_k)/τ)
        Set:
           ϕ_t0 = Σ_i w_i ϕ_i^S
           q_t0 = Σ_i w_i q_i^S
     Else
        Set:
           q_t0 = q_S
     End if
4. Adapt to new passenger:
     if D_t^sup is empty then
        q_t^* = q_t0
     Else
        Minimize:
           L_t = Σ_{(x,y)∈D_t^sup} ℓ(f_{θ,ϕ_t}(x), y)
               + β KL(q_t || q_t0)
               + λ || ϕ_t - ϕ_t0 ||^2
        q_t^* = argmin_{q_t} L_t
     End if
5. Predict:
     ŷ_t(x) = E_{q_t^*}[f_{θ,ϕ_t}(x)]
     Approximate by:
        ŷ_t(x) ≈ (1/M) Σ_{m=1}^M f_{θ^(m),ϕ_t^(m)}(x)
6. Online update:
     When new data arrive:
        q_t^new_prior = q_t^*
        Repeat adaptation step
        Optionally add passenger t to source pool
```

IV. EXPERIMENTS

We examine the outcome of our optimized algorithm by conducting a dozen attempts in the field of overlapping communities. The results will be compared with existing methods, such as the SVD method [17] and the enhanced bipartite cluster method [17], to evaluate the performance of our optimized algorithm. The required environment to conduct the practical work for this paper is an Intel i5-core (TM) CPU, 8 GB of RAM, and a Windows 10 laptop. All iterations were conducted in the same environment and repeated 10 times; the average was then calculated. The proposed optimized Bipartite Algorithm is implemented in Python, and the dataset comprises three airline carrier datasets detailing every commercial flight in Libya, the

UAE, and Turkey. To evaluate the performance of the proposed work, various parameters were measured under different execution environments. We have proposed an Optimized Bipartite Algorithm. The proposed algorithm furnishes better performance in terms of Precision and Execution time. Comparative analysis in Table 2 and Figures 3 and 4 shows that the proposed algorithm is more efficient than the existing SVD algorithm and an improved bipartite clustering method.

V. CONTRIBUTIONS

This paper builds qualitative scientific contributions to the use of the optimized BNCD Algorithm, with a focus on the personalized recommendation experience as the passenger engages further with the platform:

1) Algorithmic Innovations: To improve the performance of recommendation techniques and figure out the cold start issue for new passengers and required data expandability issues.
2) Supporting passenger Experience :
   The proposed techniques efficiently personalize recommendations for each passenger using available historical data to enhance the passenger experience.

VI. DATASET AND EVALUATION METRICS

1. Used Dataset

The dataset comprises 3 carriers' datasets to examine the proposed approach: Emirates (EK), Afriqiyah Airways (8U), and Turkish Airlines (TK). Each dataset contains 1543 records of daily passenger reviews and ratings from January 1, 2016, to January 31, 2025, as shown in Figures 2, 3, and 4. The dataset used includes the following attributes:
Review titles: Emotions or specific keywords to be engaging.

- Author information: The information belongs to the passenger.
- dates: The published date of the review determined by the passenger.
- ratings: does the passenger give a score.
- status: is a credibility label used on a travel review website.
- Aircraft.: The type of aircraft operated.
- Travel Type: indicates the specific style,purpose , or category of a trip.
- Route: A flight from Source city to Destination city.
- Date Flown: (or flight date) refers to the day of the departed flight.
- Staff Service: They facilitate a smooth and comfortable journey for passengers.
- Food Quality: relies on (presentation, variety,and menu).
- Entertainment: comprises visual content, games, and the internet.
- WiFi: The modern Aircraft connects to satellites, providing coverage to passengers.
- Ground Services: An essential part of airport operations, and some tasks are performed while the plane is on the ground.
- Value for Money: balances ticket fare compared to the service quality.
- Recommended: Factor for rating the airline.
- Overall Rating:
- Review: a passenger’s evaluation of their flight experience.
- Country: A Reviewer’s Country.

2. Performance Evaluation Metrics

To assess the performance of the proposed approach, we use two key parameters: the Mean Absolute Error (MAE), given by equation (14), and Precision, given by equation (15), to measure the proximity of predicted grades to true ratings.

$$\text{Son} = \sum_{i-1}^{N} \frac{|r_{p,i} - \hat{r}_{p,i}|}{N}$$

$$\text{Precision} = \frac{\sum_{i=1}^{N} P_i}{N}$$

VII. RESULTS AND DISCUSSION

The λ parameter is chosen from the set {0.1, 0.5, 2, 4, 8, 12}, and the threshold value η of the network projection is set from the set { 0.3, 0.4, 0.5, 0.6, 0.7, 0.8}. The best way to gather groups that are in smaller patterns within the calculation network is the Special Community. 80 percent of the data is used for training the proposed approach, and 20 percent is used for testing. Table 2 demonstrates that the proposed Optimized Bipartite Algorithm consistently outperforms both SVD and the conventional Bipartite-cluster method across all three airline datasets (EK, TK, and 8U). It achieves the lowest values of 0.916, 0.964, and 0.782 for the EK, TK, and 8U datasets, respectively. On average, the proposed approach reduces the evaluation metric by 27.6% compared with SVD and 12.3% compared with the Bipartite-cluster method, indicating superior effectiveness and robustness across different datasets.

Table 2. Comparison of Mean Absolute Error (MAE) Results for SVD, Bipartite-Cluster, and the Proposed Optimized Bipartite Algorithm across Different Airline Datasets.

Dataset	**New Airline**		
	SVD	***Bipartite-cluster***	***Optimized Bipartite Algorithm***
EK	1.248	0.947	0.916
TK	1.319	1.291	0.964
8U	1.112	0.799	0.782

Table 3 compares the Mean Absolute Error (MAE) of SVD, Bipartite-cluster, and the proposed Optimized Bipartite Algorithm on the new passenger dataset. The results indicate that no single algorithm consistently achieves the best performance across all datasets. SVD produces the lowest MAE on the EK dataset (0.792), while the proposed Optimized Bipartite Algorithm performs best on the TK dataset with an MAE of 1.091. For the 8U dataset, the Bipartite-cluster algorithm achieves the lowest MAE (0.774). These findings suggest that the effectiveness of each algorithm depends on the characteristics of the dataset.

Table 3. Comparison of Mean Absolute Error (MAE) Results for SVD, Bipartite-Cluster, and the Proposed Optimized Bipartite Algorithm on the New Passenger Dataset.

Dataset	**New Passenger**		
	SVD	***Bipartite-cluster***	***Optimized Bipartite Algorithm***
EK	0.792	0.841	0.832
TK	1.273	1.339	1.091
8U	0.906	0.774	0.819

Table 4 compares the Mean Absolute Error (MAE) of SVD, Bipartite-cluster, and the proposed Optimized Bipartite Algorithm in the non-cold start scenario. The results show that the proposed algorithm achieves the lowest MAE for the EK (0.733) and TK (0.955) datasets, demonstrating superior prediction accuracy over

both SVD and the conventional Bipartite-cluster method. For the 8U dataset, however, the Bipartite-cluster algorithm slightly outperforms the proposed approach, recording the lowest MAE of 0.715 compared to 0.726 for the proposed algorithm and 0.731 for SVD. Overall, the proposed Optimized Bipartite Algorithm delivers the best performance on two of the three datasets, indicating that the optimization enhances recommendation accuracy under non-cold-start conditions while remaining competitive across datasets.

Table 4. Comparison of Mean Absolute Error (MAE) Results for SVD, Bipartite-Cluster, and the Proposed Optimized Bipartite Algorithm on the Non-Cold Start.

Dataset	**Non-Cold Start**		
	SVD	***Bipartite-cluster***	***Optimized Bipartite Algorithm***
EK	0.965	0.746	0.733
TK	1.218	1.122	0.955
8U	0.731	0.715	0.726

The proposed optimized Bipartite Algorithm yields better results than other algorithms. To verify the performance of the recommended airline, this paper also tests precision and runtime on the Emirates Airline dataset. Table 5 and Figure 6 show the accuracy of the three approaches in several suggested airlines. The number of recommended airlines is set to [5, 10, 15, 20]. It's clear that as the number of recommended airlines increases, the accuracy of the studied approaches decreases. However, the accuracy of the proposed optimized BNCD Algorithm remained relatively stable and slightly higher than that of other approaches.

Table 5. Precision Results.

Precision Result			
N	***Optimized Bipartite***	***SVD***	***Bipartite-Cluster***
5	0.38	0.34	0.3
10	0.36	0.33	0.29
15	0.35	0.32	0.28
20	0.34	0.31	0.27

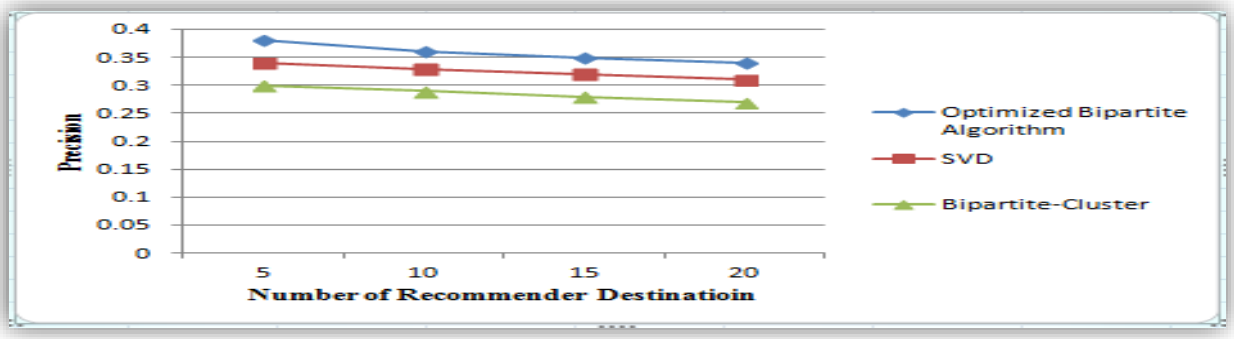

Figure 6. Precision Results

The Execution time of the Optimized BNCD Algorithm is demonstrated in Table 6 and Figure 7. To sum up, the optimized Bipartite Algorithm was noted to be capable when deployed to address the cold-start issue

in an Airline recommendation system. The optimized algorithm achieved a shorter runtime than other techniques.

Table 6. Execution Time (in seconds).

Execution time (in seconds)			
Iterations	***Optimized Bipartite***	***SVD***	***Bipartite-Cluster***
1	3	3	4
2	4	4	5
3	5	6	7
4	6	35	8
5	7	97	11
6	8	114	12

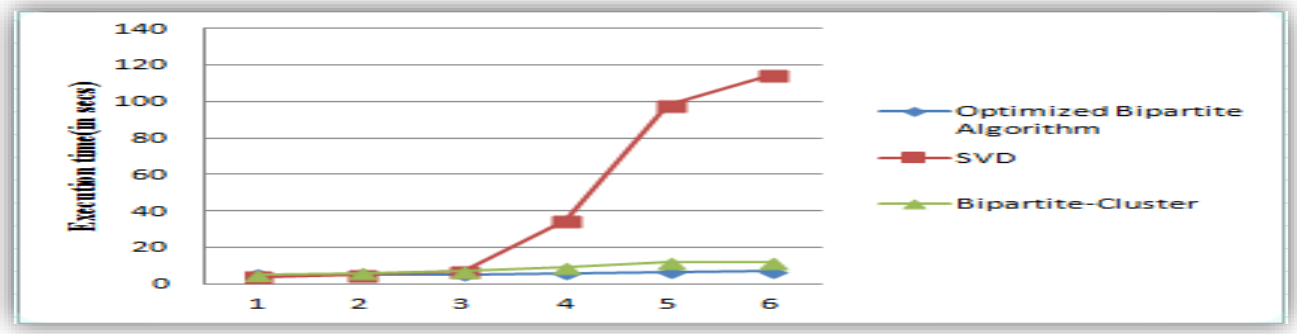

Figure 7. Performance Comparison and Analysis

VIII. CONCLUSION

In this paper, experimental results on three real airline evaluation datasets show that the proposed algorithm achieves higher recommendation accuracy and more stable performance. In future work, the algorithm will be further optimized to meet passenger needs, such as different destination classifications; it will also be tested on additional datasets to identify the structure in which passenger preferences overlap. We recommend implementing a comprehensive airline recommendation system and displaying the outcomes of preferred destination recommendations in a mobile App.

Abstract

Coreference resolution aims to identify and link mentions of the same entity in a text. While contextual language models produce strong representations for this task, they do not explicitly model the syntactic relations between words. In this study, the contribution of relation-labeled dependency information to Turkish coreference resolution is investigated. To this end, a relation-aware Graph Attention Network model was developed that integrates contextual word representations with syntactic representations derived from a dependency graph. The effects of the number of attention heads and enhanced dependency links for empty nodes on performance and stability were compared. All syntax-aware configurations outperformed the baseline model; the best configuration achieved an absolute improvement of 1.69 points with an average CoNLL F1 of 66.71%. The results indicate that relation-labeled dependency graphs support Turkish coreference resolution; however, increasing the number of attention heads and the number of empty node links does not yield a consistent additional gain.

Keywords: Turkish coreference resolution, relation-aware graph attention network, dependency graph, syntactic information, contextual representations

I. INTRODUCTION

Coreference resolution links information scattered throughout a document by grouping mentions of the same real-world entity or event into a single chain. Therefore, coreference resolution is considered an important component that supports various natural language processing tasks, such as question answering [1], text summarization [2], [3], and information extraction [4]. End-to-end neural models and pre-trained language encoders have significantly improved coreference resolution performance. While these models can learn context-aware representations of words, they often do not directly use explicit syntactic relations between words as a structured source of information. Consequently, representations obtained from the linear context of the text may not always explicitly reflect the dependency relations within a sentence. This limitation becomes more pronounced in Turkish, which has free word order and a rich morphological structure. Subject and possessive elements that are not explicitly present on the surface (dropped pronouns) can participate in coreference chains. Turkish-ITCC represents these dropped mentions using empty nodes and the relations between words through dependency annotations [5]. This structure allows modeling both syntactic connections between explicit mentions and relations between mentions not present on the surface and other nodes. However, the contribution of dependency relation labels and enhanced dependency links for empty nodes to Turkish coreference resolution has not been sufficiently investigated. In this study, a Graph Attention Network approach is examined that integrates contextual word representations from BERTurk with syntactic representations from

a relation-labeled dependency graph. Words and empty nodes are modeled as graph nodes, and dependency relations are modeled as labeled directed edges. The baseline model and graph configurations with different numbers of attention heads are compared across three random seeds; furthermore, the impact of DEPS links associated with empty nodes on performance and stability is evaluated.

II. RELATED WORK

Early learning-based studies on coreference resolution relied heavily on handcrafted shallow syntactic and semantic features. These approaches were developed as mention-pair models [6], [7], [8], that classify the coreference relation between pairs of mentions, entity-mention models [9], [10] that associate mentions with existing entity sets, and methods [11], [12] that rank candidate antecedents according to their relative suitability. Subsequent studies utilized neural representation learning methods in these processes to reduce reliance on hand-designed features [13], [14], [15], [16]. Following these developments, end-to-end neural models that learn mention detection and coreference linking within a joint architecture have come to the fore. Lee et al. [17] proposed an end-to-end model that treats possible text spans in a document as mention candidates and scores candidate antecedents for each mention. This approach was extended to support higher-order inference by reincorporating information from predicted coreference links into the mention representations [18]. Joshi et al. [19] showed that the SpanBERT model, which focuses on representing text spans, improves coreference resolution performance. However, most of these studies have focused on resource-rich languages; the detection of dropped mentions, which are not explicitly present on the surface in Turkish, and their linking to coreference chains have been examined to a more limited extent. A representation and evaluation approach for including dropped subject and possessive pronouns in coreference resolution has been presented for Turkish; in the Turkish-ITCC dataset, these mentions are represented by empty nodes and marked within the same coreference chains as explicit mentions [5], [20]. Thus, the dataset provided an evaluation environment that requires identifying mentions not present in the surface text and adding them to appropriate coreference chains, in addition to linking explicit mentions. Turkish-ITCC is part of CorefUD, a multilingual coreference collection compatible with Universal Dependencies [21]. Systems developed in different languages and on different datasets were compared in shared tasks organized around this collection [22]. In the CRAC 2024 shared task using CorefUD 1.2, empty nodes were removed from the system input, and models were expected to predict these nodes in addition to performing coreference resolution [23]. Straka [24] examined single- and two-stage CorPipe configurations that include empty-node prediction in the coreference resolution process. Pražák and Konopík [25], on the other hand, developed an end-to-end multilingual model that represents mentions by their head words and discussed the possible contribution of syntactic information to this representation. Although pre-trained language models produce strong contextual representations, explicit dependency links in datasets are not always transferred to these representations as structured information. Dependency parsing provides a natural graph structure in which words are represented as nodes and syntactic relations as edges. Graph Attention Networks weight the information transferred from neighboring nodes with learnable attention coefficients, ensuring the selective transfer of graph connections to node representations [26]. Previous studies have demonstrated the effectiveness of graph-based structures for coreference resolution. Jiang and Cohn [27] integrated dependency-based syntactic information with semantic role relations in a heterogeneous graph attention network, improving performance on the English and Chinese OntoNotes 5.0 datasets. Similarly, Yousfi et al. [28] proposed a heterogeneous graph-based model that combines dependency and semantic role information for the Arabic CoNLL-2012 dataset, outperforming BERT-based methods and achieving competitive results compared with sequence-to-sequence approaches. While standard graph attention networks learn the relative importance of neighboring nodes, they do not always model different edge types separately. Relation-aware graph attention networks address this by incorporating edge-type information into the attention and information-transfer processes. Meng et al. [29] combined BERT-based contextual representations with dependency-based syntactic representations using a relation-aware graph attention network. Experiments on

GAP and OntoNotes 5.0 showed that preserving dependency relation types can support coreference resolution performance.

In the CoNLL-U format, the HEAD and DEPREL fields represent the basic dependency tree, while the DEPS field represents enhanced dependency links added to this tree. Enhanced dependency representations have been reported to more explicitly encode syntactic relations that are not directly present in the basic tree [30], [31]. In Turkish-ITCC, the DEPS field is important because it can include syntactic connections between empty nodes, which have no explicit surface-word counterpart, and other nodes. However, the effect of transferring these links to the coreference model on performance remains unclear. Previous studies show that dependency information can be transferred to coreference resolution using graph-based methods and that modeling relation labels can support contextual representations. However, the contribution of enhanced dependency links (DEPS) associated with empty nodes in Turkish-ITCC, and the performance and stability of the dependency graph across different numbers of attention heads, have not been sufficiently compared. This study evaluates the contributions of the relation-labeled dependency graph, the effect of empty node links, and the model behavior across different attention head configurations.

III. MODEL

In this study, an end-to-end Turkish coreference resolution architecture is proposed that integrates contextual word representations with relation-labeled dependency information. The model consists of contextual encoding, syntactic graph processing, representation integration, mention detection, and coreference linking stages. The overall architecture is shown in Figure 1.

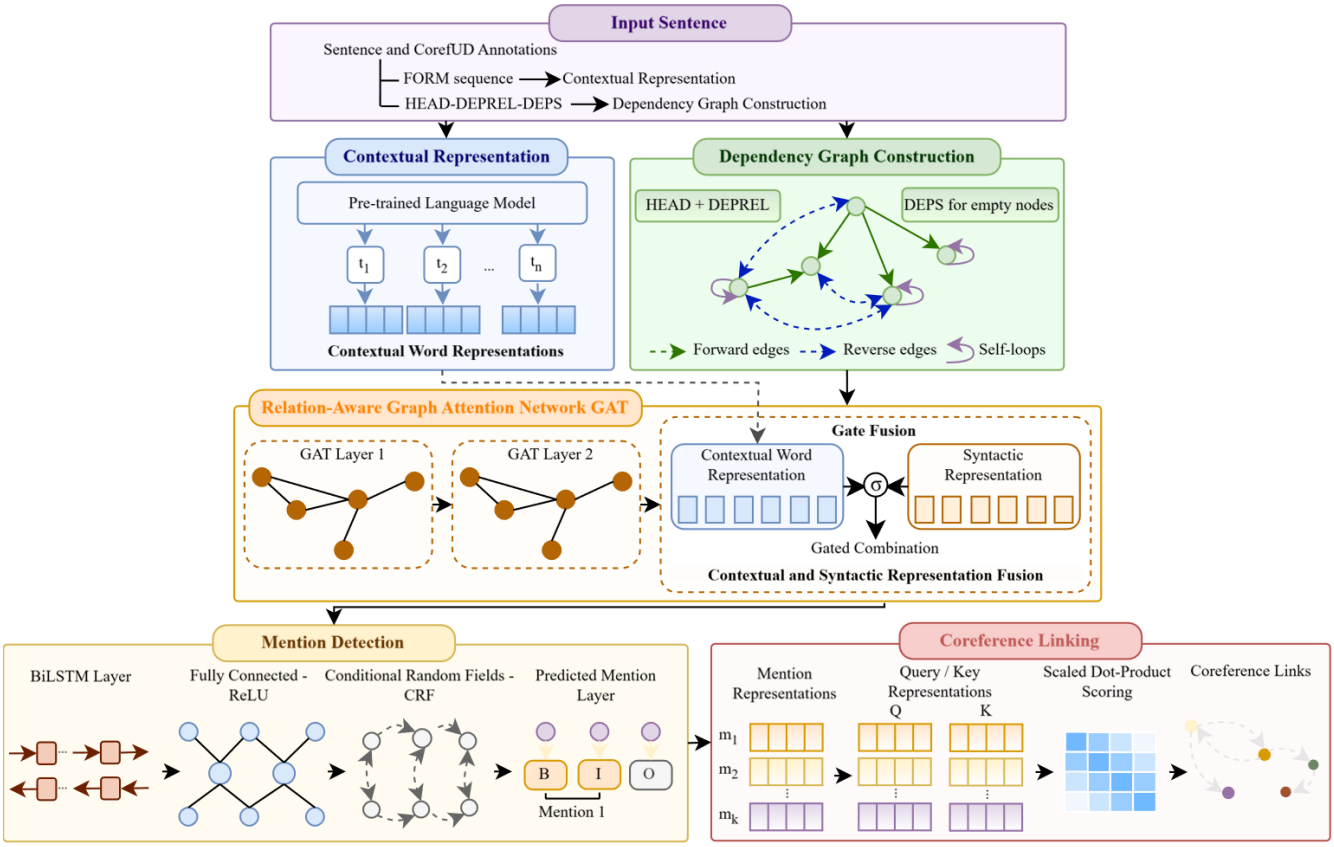

Figure 1. Overall architecture of the proposed relation-aware dependency graph attention model.

The input text is first transformed into contextual word representations ($i.$) using the BERTurk [32] encoder. In parallel, the words in the sentence and ttheir dependency relations are represented as a relation-labeled directed graph (). This graph structure is processed through a two-layer Relation-Aware Graph Attention Network (RGAT) to produce representations (i) eflecting the syntactic roles of the words:

$$s_i = RGAT_2(RGAT_1(x_i, G), G) \tag{1}$$

Contextual information ($i.$) $and\ syntactic\ information$ ($s\ alt\ i.$) obtained from the dependency graph are combined through a learnable gating mechanism. This mechanism dynamically balances the impact of both information sources on the final representation. The integrated node representation (f_i) is obtained as follows:

$$f_i = g_i \odot x_i + (1 - g_i) \odot s_i \tag{2}$$

Here, g_i denotes the gate value that determines the relative contribution of both sources and is calculated as follows:

$$g_i = \sigma\left(W_g[x_i; s_i] + b_g\right) \tag{3}$$

In this formula, σ represents the sigmoid activation function, and W_g and b_g represent learnable parameters.

Integrated representations are fed into a CRF [33] layer operating over two BiLSTM layers and BIO labels to determine mention boundaries. Identified mentions (m_i) are encoded by concatenating the representations at the start and end positions. In the final stage, the coreference similarity score (s_{ij}) between each i-th mention and candidate antecedents (j) is calculated using a query-key-based mechanism:

$$q_i = W_q m_i + b_q, \quad k_j = W_k m_j + b_k \tag{4}$$

$$s_{ij} = \frac{q_i^T k_j}{\sqrt{d_k}} \tag{5}$$

The model links each mention to the most appropriate coreference chain or starts a new chain based on these calculated scores.

IV. EXPERIMENTAL SETUP

1. Dataset and Evaluation Protocol

Experiments were conducted on the Turkish-ITCC dataset in the CorefUD 1.2 collection. Excluding single coreference sets, the dataset contains 24 documents, 4,732 sentences, 55,358 non-empty words, 11,584 empty nodes, 4,019 coreference sets, and 21,569 mentions [24]. The published data split consists of 19 training, two development, and three test documents [20]. Since gold test annotations are not publicly available, comparisons were conducted on the development set; performance was evaluated with MUC [34], B^3 [35], CEAFe [36], and the average of these three metrics, CoNLL F1 [37]. Each model was trained with three different random seed values (42, 43, and 44), and results are reported as mean ± standard deviation.

2. Training Settings and Model Configurations

Models were trained using the dbmdz/bert-base-turkish-128k-uncased encoder for 15 epochs, with a batch size of 8, a sequence length of 512, a learning rate of 2×10^{-5}, a dropout rate of 0.2, and LazyAdam optimization. In Syntax-GAT configurations, two relation-aware GAT layers and 64-dimensional relation embeddings were used. All experiments were conducted using TensorFlow on an NVIDIA GeForce RTX 5060 Ti GPU with 16 GB of memory. The differences in configurations, including empty node DEPS links and the number of attention heads, are presented in Table 1. Computational cost was assessed using mean runtime and peak GPU memory consumption. Mean runtime was calculated across seeds 42–44.

Table 1. Evaluated model configuration

Model	***Empty-node DEPS***	***GAT layers***	***Attention heads***
Baseline	N/A	-	-
Syntax-GAT-DEPS-1H	Yes	2	1
Syntax-GAT-DEPS-4H	Yes	2	4
Syntax-GAT-1H	No	2	1
Syntax-GAT-4H	No	2	4

V. RESULTS AND DISCUSSION

1. Overall Performance

The average MUC, B^3, CEAFe, and CoNLL F1 scores obtained across three random seeds for the model configurations are presented in Table 2. Results are reported as mean ± standard deviation.

Table 2. Mean coreference performance ± standard deviation across three random seeds

Model	*MUC F1 (%)*	*B^3 F1 (%)*	*CEAFe F1 (%)*	*CoNLL F1 (%)*	*Gain over Baseline*
Baseline	81.42 ± 0.19	54.58 ± 1.65	59.06 ± 0.95	65.02 ± 0.66	-
Syntax-GAT-DEPS-1H	82.02 ± 0.19	56.40 ± 2.56	59.08 ± 0.60	65.84 ± 1.02 [a]	+0.82
Syntax-GAT-DEPS-4H	82.10 ± 0.20	55.39 ± 2.32	59.94 ± 1.10	65.80 ± 1.12	+0.78
Syntax-GAT-1H	82.26 ± 0.20	57.80 ± 3.78	60.06 ± 0.49	66.71 ± 1.41 [a]	+1.69
Syntax-GAT-4H	81.84 ± 0.65	56.35 ± 0.35	59.66 ± 1.00	65.95 ± 0.64	+0.93

[a.] Statistically significant improvement over the baseline according to a paired one-tailed t-test ($p < 0.05$).

Experimental results reveal that all proposed Syntax-GAT configurations outperform the baseline model. Models supported with syntactic information achieved absolute increases of 0.78-1.69 points in the CoNLL F1 score compared to the baseline model. The Syntax-GAT-1H configuration, which achieved the highest average performance, reached an average CoNLL F1 score of 66.71%. These findings suggest that representations obtained from relation-labeled dependency graphs significantly complement contextual word representations, thereby increasing Turkish coreference resolution performance. The paired one-tailed t-test indicated that the improvements achieved by the Syntax-GAT-DEPS-1H ($p = 0.049$) and the best-performing Syntax-GAT-1H ($p = 0.036$) configurations over the baseline model were statistically significant.

2. Effect of Attention Heads and Empty-Node DEPS

CoNLL F1 results based on seeds are given in Table 3. In models not containing DEPS, the single-headed configuration performed 0.76 points higher than the four-headed configuration, while the difference between models containing DEPS is only 0.04 points.

Table 3. CoNLL F1 results for different random seeds.

Model	*Seed 42*	*Seed 43*	*Seed 44*	*Mean CoNLL F1 (%) ± SD*	*Mean runtime (min)*	*Peak GPU memory (GB)*
Baseline	65.32	65.48	64.26	65.02 ± 0.66	91.55	8.88
Syntax-GAT-DEPS-1H	66.68	66.12	64.71	65.84 ± 1.02	105.51	9.18
Syntax-GAT-DEPS-4H	65.66	66.99	64.76	65.80 ± 1.12	104.08	9.00
Syntax-GAT-1H	67.85	67.14	65.13	66.71 ± 1.41	109.66	9.26
Syntax-GAT-4H	65.85	65.37	66.63	65.95 ± 0.64	108.02	9.17

The computational results indicate that the Syntax-GAT configurations introduce a limited additional cost compared with the baseline model. When models with the same number of attention heads are compared, configurations without DEPS links exhibit longer mean training times than their DEPS-based counterparts. Relative to the baseline, the mean training time increased by approximately 13.7–19.8%, while peak GPU

memory usage increased by only 1.4–4.3%. Increasing the number of attention heads from one to four did not consistently improve average performance, suggesting that distributing information from the same dependency neighborhood across multiple heads may not produce sufficiently complementary patterns. However, Syntax-GAT-4H was the most stable graph-based configuration with a standard deviation of 0.64, indicating that multiple heads may contribute more to reducing seed-related variability than to improving average performance. Similarly, adding DEPS links for empty nodes did not yield further gains; CoNLL F1 decreased by 0.87 points in the single-head model and by 0.15 points in the four-head model compared with their counterparts without DEPS. This suggests that DEPS links may introduce information mixing by transferring less informative connections along with useful syntactic relations into the node representations.

3. Stability and Discussion

When model behavior across different random seed values is examined, the Syntax-GAT-1H configuration, which achieves the highest average performance, also has the highest standard deviation (1.41). Although Syntax-GAT-4H stands out as the most stable configuration, the highest performance and the highest stability did not converge in the same model. The fact that results are based on a development set comprising only two documents and three different seed values constitutes a fundamental limitation on the generalizability of the findings.

VI. CONCLUSION

This study aims to investigate the effect of relation-labeled dependency information on Turkish coreference resolution by integrating contextual representations with a Graph Attention Network architecture. The proposed architecture outperformed the baseline model across all scenarios by explicitly modeling syntactic roles. The most significant quantitative result is that the best configuration achieved an absolute increase of 1.69 points in CoNLL F1 over the baseline model. In general, the structured transfer of dependency relations improves performance, but increasing the number of attention heads and the number of empty node links does not provide additional benefit. The main limitation of the study is that the evaluation was performed on a limited development set. Future work will evaluate the proposed approach on additional datasets and other morphologically rich languages to further examine its generalizability. A more detailed error analysis will also investigate which types of coreference cases benefit most from dependency-based syntactic information and in which cases the model continues to fail.

Abstract

Membrane fouling remains a major challenge in ultrafiltration (UF) pre-treatment for seawater reverse osmosis (RO) desalination, leading to increased energy consumption, excessive chemical usage, and accelerated membrane deterioration. This study presents a physics-informed predictive supervision framework operating at the level of individual membrane modules, in contrast to conventional reactive strategies based on rack-average monitoring. The proposed framework combines a dynamic physicochemical resistance model, numerically solved using a fourth-order Runge–Kutta (RK4) scheme, with a multi-output Temporal Convolutional Network (TCN) trained on a hybrid dataset integrating real industrial measurements and simulation-generated features. The framework was evaluated on a publicly available 150-hour operational benchmark using a chronological train/test split, achieving predictive performance of up to $R^2 = 0.97$ for coagulant dosing. Comparative simulation results indicate potential reductions of up to 36.6% in maintenance interventions, 75.99% in chemical consumption, and 32.16% in energy demand, together with an estimated 60.70% increase in membrane service life. As these findings are based on a simulation-enriched study conducted at a single site, they should be interpreted as indicative upper-bound estimates pending validation under broader experimental conditions.

Keywords: Digital twin; Physics-informed deep learning; Membrane fouling; Dynamic coagulant dosing; Multi-objective optimization

I. INTRODUCTION

Global freshwater scarcity has made seawater desalination, and reverse osmosis (RO) in particular, a cornerstone of water security [1]. The long-term performance of RO plants depends critically on ultrafiltration (UF) pre-treatment, which acts as the primary barrier against particulate matter, colloids, and biological contaminants. As filtration progresses, foulant accumulation induces cake layer formation and pore constriction, hydraulically manifested as an exponential rise in transmembrane pressure (TMP) and specific resistance. Counteracting this degradation requires intensive backwashing and coagulant-based pre-treatment [2], [3], which introduces cascading inefficiencies: mechanical fatigue on membrane fibers and escalating operating expenditures (OPEX) from overdosing. Deterministic resistance-in-series models provide a physically interpretable baseline [4], [5] but struggle with the nonlinear, time-varying nature of fouling [6], [7]. AI-based approaches have substantially expanded the predictive toolkit [8], [9], with recent deep learning and reinforcement learning methods better capturing temporal dynamics [10], [11]. A critical limitation, however, persists: the tacit assumption that parallel UF modules foul uniformly. Existing adaptive strategies [12], [13] compute resistance and trigger backwash

events based on rack-wide averages, thereby masking the heterogeneous fouling trajectories arising from hydrodynamic imbalances. The present work addresses this gap by employing a hybrid physics-informed TCN framework that monitors each module individually, enabling proactive, asynchronous supervisory control.

Recent work reinforces this rack-level bias even as predictive tools have grown more sophisticated. [14] trace the shift from empirical fouling indices to intelligent, data-driven predictors, while [15] embed fouling mechanisms directly into machine-learning architectures to improve interpretability and generalization. [16] demonstrated a real-time deep-learning framework for hybrid NF/RO plants, predicting flux, salt rejection, and energy consumption with R^2 above 0.95, and noted its potential as the computational backbone of full-scale digital twins. However, like the self-adaptive rack-level controllers of [12], [13], these frameworks still reason over aggregate or plant-wide signals: none resolve the module-to-module heterogeneity documented in Figure 1, nor translate individual-module forecasts into an actionable, asynchronous control policy. This is precisely the gap the present framework is designed to close.

II. METHODOLOGY

1. Data Description and Window Selection

Operational data were sourced from the publicly available Dryad repository [17], comprising 422 days of UF system operation as pre-treatment for a seawater RO plant. The dataset records feed pressure, TMP, individual module flow rates, and feed water temperature at high temporal resolution. A contiguous 150-hour window was deliberately selected as the modeling baseline. The original 422-day record contains intermittent logging gaps and fragmented daily sequences; both the RK4 state-space integration and the TCN require unbroken chronological data to preserve the physical integrity of filtration/backwash cycles. The selected 150-hour window is the longest uninterrupted sequence, spanning multiple fouling phases and backwash events that are essential for reconstructing transient behavior. The real sensor signals for individual module throughput are displayed in Figure 1, showing that structural and manifold imbalances generate measurable, module-specific flow deviations even under nominally identical operating conditions—a physical reality that rack-average controllers cannot resolve.

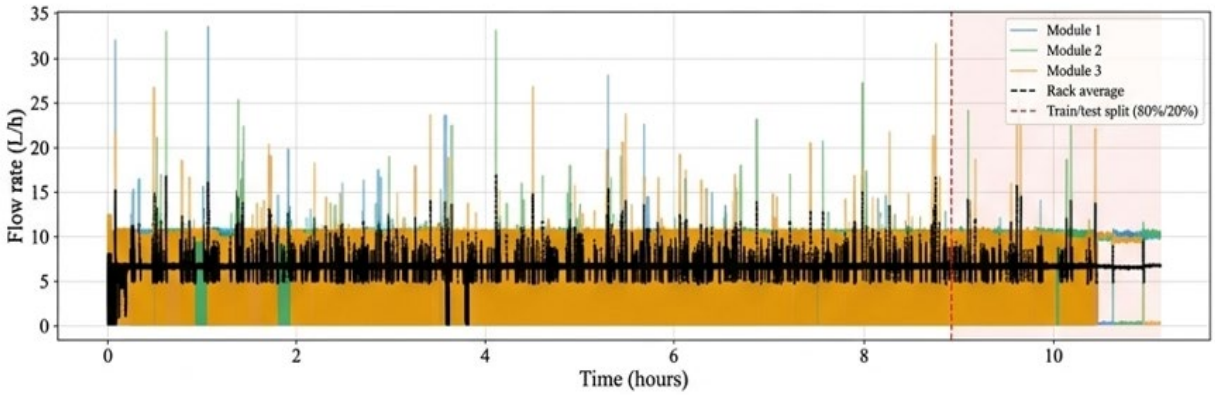

Figure 1. Variation in influent flow rates across identical parallel UF modules, illustrating the hydrodynamic heterogeneity that leads to module-specific fouling trajectories

2. Module Level Mathematical Simulator and Parameter Calibration

A dynamic mathematical simulator was developed to track the individual hydraulic resistance Ri(t) of each parallel module, distinguishing reversible cake-layer resistance Rcake, i, from irreversible fouling resistance Rirr, i, and incorporating a real-time coagulant dosing strategy C(t):

$$\begin{cases} dR_{cake,i}/dt = \beta_{cake} \cdot \eta_i \cdot J_i(t)\cdot(1 + 0.04\cdot C(t)) \\ dR_{irr,i}/dt = \beta_{irr} \cdot \eta_i \cdot J_i(t)\cdot\exp(-0.05\cdot C(t)) \\ R_i(t) = R_m + R_{cake,i}(t) + R_{irr,i}(t) \\ J_i(t) = \Delta P_i(t) / [\mu(t)\cdot R_m^{ref}\cdot R_i(t)] \cdot \delta_i(t) \\ dC(t)/dt = \alpha\cdot(C^*(t) - C(t)) \end{cases} \quad (1)$$

Where ηi is a per-module heterogeneity penalty factor derived from the measured flow deviation of module i relative to the rack average (Figure 1), δi(t) ∈ {0,1} is the binary valve state, and Rmref is the clean-membrane reference resistance. The system is integrated via the fourth-order Runge–Kutta (RK4) method with a fixed time step matched to the sensor sampling rate.

Parameter calibration. The five free parameters (βcake, βirr, ηi, α, and the chemical attenuation constants 0.04/0.05) were calibrated on a dedicated training partition of the 150-hour window (the first 80% of the sequence, approximately 120 hours) by minimizing the mean squared error between simulated and measured TMP trajectories using a grid-search procedure. Model fidelity was then assessed on the held-out chronological test partition (remaining 20%, approximately 30 hours). This chronological split was chosen deliberately to respect the temporal ordering of the data and avoid data leakage. It is acknowledged that, given the single-site, single-window nature of this study, the reported metrics are best interpreted as indicative performance bounds rather than statistically generalized results; cross-validation over multiple independent operational windows and sensitivity analysis over the parameter space constitute important directions for future work.

3. Reference Rack-Average Strategy

To enable a rigorous comparison, the baseline "rack-average" control strategy is defined operationally as follows: a global backwash event is triggered simultaneously across all modules whenever the rack-average hydraulic resistance R(t) = (1/n)Σi=1n Ri(t) exceeds a fixed threshold Rth; the coagulant dose Cref is held constant at the dataset mean dosing level. This corresponds to the standard industrial protocol described in [12], serving as the benchmark against which the proposed asynchronous, module-level strategy is evaluated.

4. Hybrid TCN and Asynchronous Control

The 150-hour dataset was augmented with simulator outputs—module-specific resistances (Ri) and optimal coagulant doses—yielding a hybrid dataset that translates lagging global indicators into precise module-level targets. A multi-output TCN [18] is trained on this enriched dataset to simultaneously forecast Ri and coagulant demand over a 5-minute horizon, using dilated causal convolutions that prevent future information leakage and capture long-range dependencies through residual connections.

The TCN architecture was deliberately favored over recurrent alternatives such as Long Short-Term Memory (LSTM) networks [19]. Unlike LSTMs, which process sequences iteratively and incur substantial computational overhead over long horizons, TCNs exploit dilated causal convolutions that can be trained in parallel, while stacked convolutional layers with residual connections maintain a wide, stable receptive field without the vanishing-gradient issues that can affect deep recurrent models—a property well suited to relating transient, high-frequency hydraulic signals to the slower cumulative dynamics of irreversible fouling.

Concretely, the multi-output TCN comprises four stacked residual blocks with dilation rates $d \in \{1, 2, 4, 8\}$, each containing two causal convolutional layers (32 filters, kernel size 3, L2 weight regularisation of 10^{-4}) followed by batch normalisation, Swish activation, and spatial dropout (rate 0.15); a 1×1 convolution matches channel dimensions on the skip connection where required. The stacked blocks are followed by global average pooling, a dense layer (32 units, Swish activation) with dropout (rate 0.2), and a final linear output layer producing the four target variables (Ri for each module and the coagulant dose) simultaneously. The network takes as input an 11-feature sequence—the three module flow rates, feed temperature, the three module resistances and their first-order time derivatives, and the coagulant dose—over a 90-step input window. It forecasts the same four targets 15 steps (5 minutes) ahead. The coagulant-dose signal was smoothed with a 20-step rolling mean before training to suppress pump-induced measurement noise, and all inputs and targets were independently min–max scaled. The model was trained for up to 30 epochs (batch size 32, 20% validation split) using the Adam optimizer (learning rate 5×10^{-4}) with a Huber loss, with early stopping (patience 8, best weights restored) and a learning-rate reduction on plateau (factor 0.5, patience 4). Hyperparameters (filter count, kernel size, dilation schedule, dropout rates, learning rate) were set empirically based on preliminary experimentation rather than through an automated search; systematic hyperparameter optimization is left for future work.

TCN forecasts drive an asynchronous module-level intervention logic: a targeted backwash alert is issued exclusively for the unit predicted to breach its individual critical resistance threshold within the 5-minute window. At the same time, the global coagulant dose is updated in real time based on evolving heterogeneity in resistance. The model was trained on the first 70% of the enriched sequence and evaluated on the chronologically held-out 30%.

III. RESULTS AND DISCUSSION

1. Backwash Mitigation and Chemical Optimization

By monitoring individual Ri trajectories, the asynchronous framework reduced the total number of backwash events from 328 (reference rack-average strategy, as defined in Section II-3) to 208, eliminating 120 redundant interventions. The evolution of coagulant dosage highlights the critical flaw of global-average reactive controllers: severe dosing volatility driven by lagging aggregate metrics. As shown in Figure 2, the proposed simulator yields a highly stable dosing profile and a projected 75.99% reduction in coagulant consumption over the evaluated 150-hour window. These figures are derived from a simulation-enriched evaluation on a single public dataset; they should be interpreted as scenario-specific estimates rather than guaranteed operational outcomes.

A mathematical wear-estimation submodel was used to project membrane lifespan. Polymer UF membranes degrade through two cumulative mechanisms: (i) mechanical fatigue from cyclic hydraulic stress, quantified as $W_{mec} = \Sigma_k \Delta P_k^2 \cdot \tau_k$, where ΔP_k and τ_k are the pressure amplitude and duration of backwash event k; and (ii) chemical degradation from coagulant overexposure, quantified as $W_{chem} = \int_0^T C(t)\, dt$. A composite wear index $W = w_1 W_{mec} + w_2 W_{chem}$ (with empirical weights w_1 and w_2 taken from the membrane aging literature) is

compared across strategies. By averting 120 backwash cycles and curtailing coagulant exposure by ~76%, the proposed strategy reduces W sufficiently to project an estimated lifespan extension of 60.70% under the studied conditions.

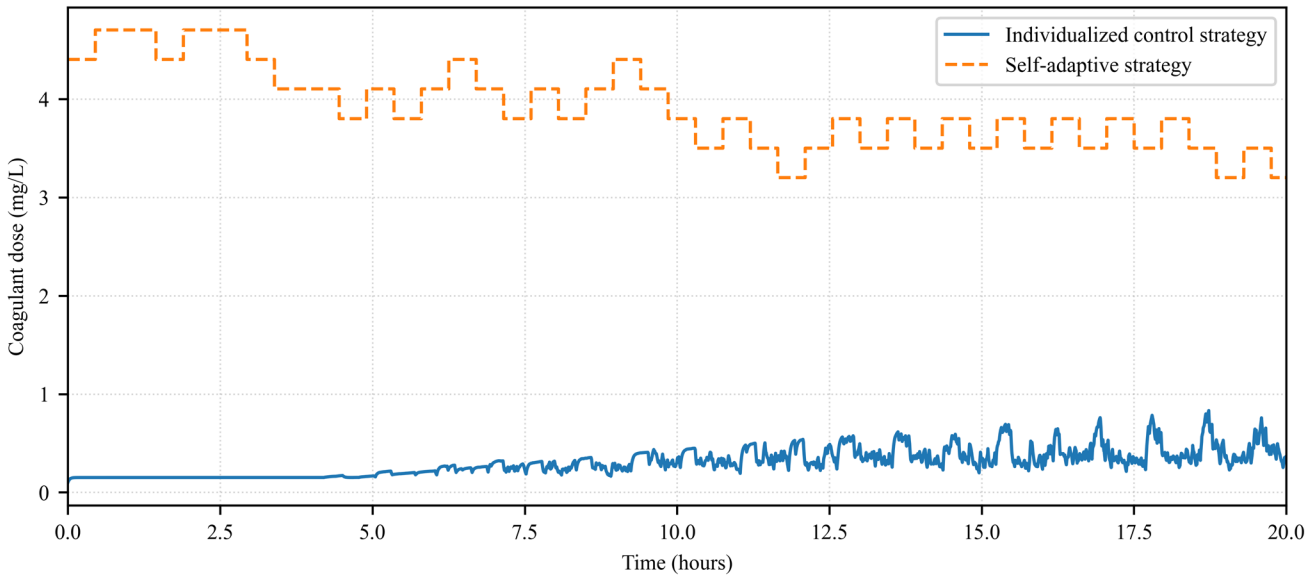

Figure 2. Zoomed comparison of coagulant dosing profiles (first 20 hours shown for clarity): the proposed approach achieves stable, demand-driven dosing versus the volatile reference strategy.

2. Multi-Objective Optimization and Pareto Trade-off

By averting 120 unnecessary backwash cycles, energy consumption dropped from 5.40×106 kWh to 3.66×106 kWh, a 32.16% saving under the simulated conditions. The filtrate purity index, modeled as:

$$\text{Quality Index (\%)} = \max(0,\ 100\times(1 - R_{irr} / R_{irr,crit})) \quad (2)$$

uses Rirr, crit = 0.6, a threshold calibrated on the dataset training partition to correspond to the onset of measurable permeate quality degradation, consistent with the 95% purity requirement reported in the reference industrial protocol [12]. The proposed strategy maintained a stable quality index superior to the rack-average approach throughout the evaluation period, despite a minor ~3.7% reduction in total volumetric production. This defines a clear Pareto trade-off: membrane health is prioritized over brute-force throughput, yielding a 36.59% reduction in immediate maintenance costs while preserving permeate quality above the operational threshold.

3. Predictive Performance of the TCN

The multi-output TCN was evaluated on the chronological held-out test partition for a t+5 min prediction horizon as shown in Figure 3. As reported in Table 1, the model achieves R2 = 0.9745 and RMSE = 0.0372 for coagulant dosing. For module-level resistances, R2 values range from 0.8267 to 0.8908, with all MAE values below 0.08. It is important to note that model evaluation was performed on a held-out chronological segment of a single, simulation-enriched operational trajectory. The reported metrics, therefore, reflect interpolation accuracy within

a continuous simulated regime rather than out-of-sample prediction on fully independent plant measurements; generalization to other sites or operating conditions requires additional validation.

It should also be noted that a systematic comparison against alternative sequence-learning baselines (e.g., LSTM-based predictors) and a formal statistical significance analysis (e.g., confidence intervals via bootstrap resampling across multiple training runs) were not performed in this proof-of-concept, single-window study; both are identified as necessary steps toward a fully validated benchmark, alongside the cross-validation and sensitivity analyses already noted in Section II-2.

Notably, Module 2 exhibits a consistently higher error margin ($R2 = 0.8267$, $MAE = 0.0748$) compared to Modules 1 and 3. This is physically consistent with the greater hydrodynamic deviation of Module 2 from the rack mean: its flow distribution departs more significantly from the uniform assumption embedded in the simulator's nominal parameters, introducing additional stochasticity in its fouling trajectory that the TCN must resolve with less calibration support. In a rack-average model, this module-specific anomaly would be invisible, absorbed into a global mean; the proposed framework, by processing each module individually, ensures a localized response rather than a premature rack-wide backwash.

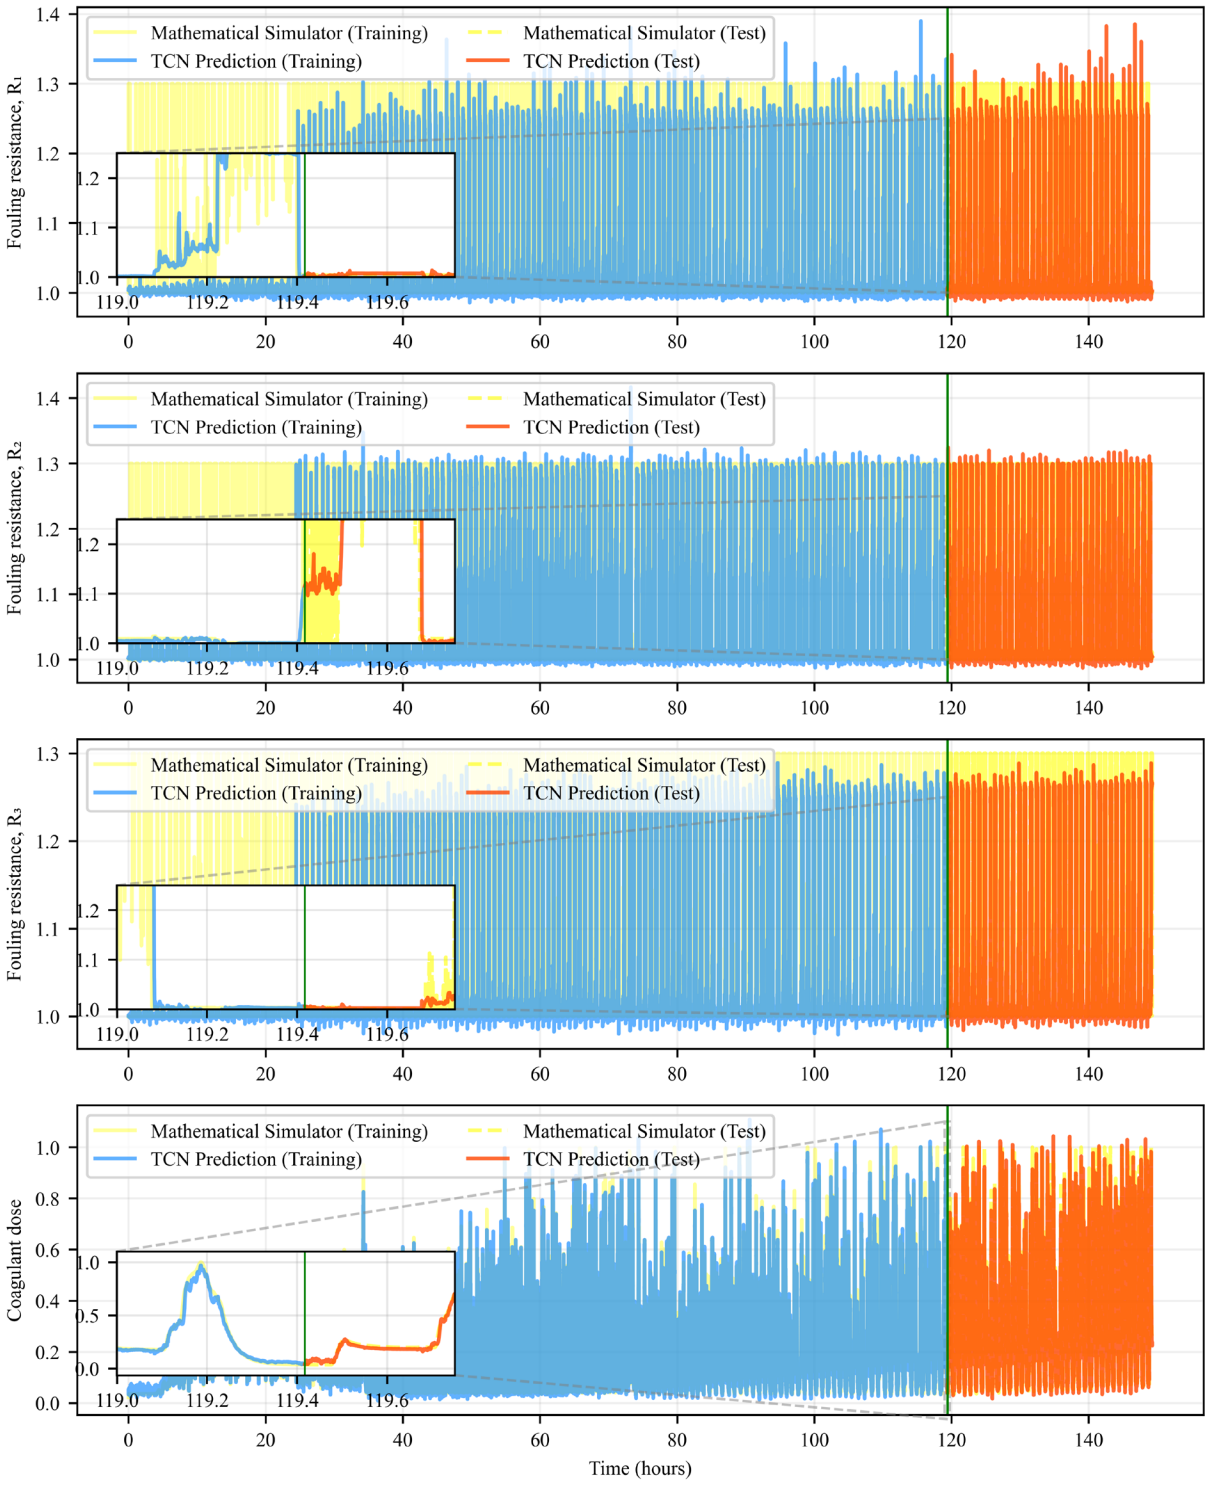

Figure 3. Predictive performance of the multi-output TCN on the chronological held-out test partition: individual module resistance (Ri) and optimal coagulant dose forecasted at a t+5 min horizon.

Table 1. Statistical performance metrics of the multi-output TCN on the held-out chronological test partition (5-minute prediction horizon).

Predicted Variable	**MAE**	**RMSE**	**R^2**
R (Module 1)	0.0559	0.1296	0.8908
R (Module 2)	0.0748	0.1777	0.8267
R (Module 3)	0.0583	0.1289	0.8891
Coagulant Dose	0.0294	0.0372	0.9745

IV. CONCLUSION

This work presents a hybrid physics-informed predictive supervision framework for UF pre-treatment in seawater desalination. By addressing the limitation of rack-average control—the masking of hydrodynamic heterogeneity across parallel modules—the proposed architecture shifts from synchronized reactive maintenance to asynchronous, module-level proactive intervention. A high-fidelity RK4-based mathematical simulator, with parameters calibrated on a 70% chronological training partition, combined with a multi-output TCN, enables 5-minute-ahead forecasting of individual module resistance and optimal chemical demand. Together, these three pillars—physics-based state estimation, module-level resolution, and TCN-driven forecasting—directly address the aggregation bias identified in the literature (Section I), converting hydrodynamic heterogeneity from an overlooked confound into an actionable control signal. Comparative simulation-based analysis against a formally defined rack-average baseline suggests the following potential improvements under the studied conditions:

- (i) an estimated 36.59% reduction in maintenance costs and 60.70% membrane lifespan extension, by eliminating 120 redundant backwash cycles and reducing coagulant overexposure;
- (ii) a 75.99% reduction in coagulant consumption and a 32.16% decrease in energy consumption (saving over 1.7 million kWh);
- (iii) strong predictive fidelity on the held-out test partition ($R^2 = 0.9745$ for dosing; $R^2 \approx = 0.89$ for module resistance), with a minor ~3.7% volumetric production trade-off.

These results are derived from a single-site, simulation-enriched study on a 150-hour window and should be interpreted as indicative upper bounds. Confidence intervals, sensitivity analyses over the model parameter space, and cross-validation over multiple independent operational windows are identified as essential next steps. As a non-invasive, software-driven solution compatible with existing SCADA and PLC environments, this framework constitutes a scalable foundation for plant-wide digital twin deployment and full-scale experimental validation on additional desalination sites.

ACKNOWLEDGEMENT

The authors gratefully acknowledge Yoram Cohen et al. for making their UF pre-treatment dataset publicly available via the Dryad repository. The authors also thank ONEE (Water Branch, Morocco) for background information on industrial-scale UF and RO operations. The first author gratefully acknowledges the Center National pour la Recherche Scientifique et Technique (CNRST, Morocco) for financial support through the PASS doctoral scholarship.

Abstract

Smart home energy systems generate high-frequency Internet of Things (IoT) sensor data that can support short-term, one-step-ahead appliance energy forecasting. However, two methodological risks persist: temporal data leakage, which can inflate performance metrics, and the causal misinterpretation of explainable AI (XAI) outputs. This paper proposes a leakage-aware and explanation-stable machine learning framework and evaluates it on the UCI Appliances Energy Prediction dataset, which contains 19,735 observations at 10-minute intervals. Six model architectures and 13 feature group configurations were evaluated using five-fold TimeSeriesSplit cross-validation on the first 80% of the training data; the final 20% (3,943 rows) was reserved as an untouched prospective holdout. The selected Random Forest model, using 22 temporal and autoregressive features, achieved RMSE = 58.47 Wh and $R^2 = 0.5826$, outperforming the previous-value persistence baseline (RMSE = 66.23 Wh). A 1,000-sample approximate paired-bootstrap audit produced a 95% confidence interval for RMSE reduction of [4.98, 10.65] Wh. SHAP analysis showed that the selected model's predictive structure was dominated by recent appliance-consumption history. In this single-household, one-step-ahead setting, environmental IoT variables added limited incremental value once lag and rolling consumption features were included. Across five seed-specific model-and-sample runs, the top-10 SHAP feature sets achieved an average pairwise Jaccard similarity of 0.9273. A deployment-oriented ablation indicated that smart-meter-only lag and rolling features achieved training-period cross-validation performance close to the selected 22-feature configuration. All findings are framed as model-based associations rather than causal claims, supporting cautious use in energy-awareness dashboards.

Keywords: explainable AI, SHAP, smart home, IoT, short-term energy forecasting, leakage-aware validation, random forest, feature ablation, explanation stability, bootstrap confidence intervals, HEMs.

I. INTRODUCTION

The growth of IoT devices, smart meters, and home-automation systems has increased the availability of high-frequency environmental and energy-consumption data in residential settings. These data streams enable short-term, one-step-ahead appliance energy forecasting for home energy management systems, demand-side response, and consumer energy awareness dashboards [1], [2]. However, two methodological issues continue to limit reliability. Temporal leakage occurs when randomized validation allows future observations to influence model training or selection, producing overly optimistic performance estimates [3], [4]. Causal misinterpretation of XAI outputs is also a concern: SHAP values explain the behavior of the trained model but do not, by themselves, establish physical causal mechanisms [5], [6]. This paper proposes a leakage-aware and explanation-stable framework for short-term appliance energy forecasting, evaluated on the UCI Appliances dataset across 13 feature configurations and six model families. The framework combines leakage-safe autoregressive feature

construction, strict chronological validation, training-only TimeSeriesSplit model selection, operational baseline comparison, bootstrap uncertainty estimation, feature-domain ablation, and SHAP stability auditing. These components reduce the risk of temporally inflated performance estimates and overconfident interpretations of unstable or causally overstated XAI outputs. The study adopts a contextual coherence perspective in which model outputs are treated as context-dependent associations rather than causal mechanisms. Under this perspective, trustworthy forecasting requires consistency across temporal, procedural, operational, statistical, and explanatory contexts. This motivates the emphasis on leakage-aware validation, operational baselines, uncertainty estimation, and explanation-stability auditing, which together assess whether the model behaves coherently under the conditions in which it is trained, selected, evaluated, and interpreted. Four research questions guide the study. RQ1 examines how training only a chronological model selection affects final model choice and holdout interpretation. RQ2 evaluates the contribution of lag and rolling features relative to previous value persistence. RQ3 assesses whether historical consumption, temporal encodings, or environmental IoT variables dominate the model's SHAP interpreted structure. RQ4 examines whether global SHAP feature sets remain stable across repeated seed-specific model and sample runs. The contribution is an audited evaluation protocol for one-step-ahead appliance energy forecasting in settings where recent meter readings are available. The protocol integrates leakage-safe feature engineering, chronological model selection, operational baselines, feature-domain ablation, uncertainty estimation, spike-regime diagnostics, minimal-sensor analysis, and SHAP stability auditing. Tree-based models are evaluated because they perform strongly on medium-sized tabular datasets [7]; the evaluated model families include Random Forest [8], XGBoost [9], and LightGBM [10].

II. RELATED WORK

Short-term residential load forecasting has been widely studied using statistical and machine-learning methods [1], [2]. Tree-based methods remain strong benchmarks for medium-sized tabular datasets [7], while Random Forest [8], XGBoost [9], and LightGBM [10] provide established ensemble architectures. The UCI Appliances dataset established a widely used benchmark based on indoor environmental measurements and external weather data. In the original study, the strongest Gradient Boosting Machine model explained approximately 57% of the variance in the testing set [11]. SHAP and related XAI methods are increasingly used to interpret energy-forecasting models [5], [6], [12–15]. The original SHAP framework provides additive feature attributions for individual predictions [12], while TreeSHAP supports efficient explanation of tree-based models and aggregation from local to global model behavior [13]. Energy-forecasting studies have subsequently used Shapley-based explanations to identify influential model inputs [14], [15]. More generally, analytical conclusions can vary across modeling choices, motivating explicit robustness and stability checks [16]. SHAP values should therefore be interpreted as model-based attributions rather than physical causal effects [5], [6]. This study integrates leakage-aware validation, training-only selection, operational baselines, feature-domain ablation, uncertainty estimation, spike diagnostics, minimal-sensor analysis, and SHAP stability auditing into a single framework.

III. METHODOLOGICAL FRAMEWORK

The framework consists of five stages: data preparation, leakage-safe feature engineering, temporal validation, multi-model feature-group ablation, and SHAP-based explanation stability auditing. The aim is not to introduce a new forecasting algorithm but to evaluate short-term appliance energy forecasting under conditions that more closely reflect prospective smart home deployments. The evaluation structure follows contextual coherence. Temporal coherence is maintained through leakage-safe feature engineering using a one-step shift so that each feature vector at time t uses only information available at t−1. Procedural coherence is ensured through training

only chronological model selection using a 5-fold TimeSeriesSplit [17], which expands the training window and evaluates performance on the immediately following block. Operational coherence is assessed against previous-value persistence, a simple operational benchmark for one-step-ahead forecasting. Statistical coherence was assessed using 1,000 paired bootstrap resamples of the holdout set, with 95% intervals obtained from the 2.5th and 97.5th percentiles. Because holdout observations are temporally dependent, these intervals are treated as an approximate uncertainty audit rather than formal time-series confidence bounds. Explanatory coherence was evaluated using TreeSHAP [12], [13] across five model-and-sample runs with seeds 1, 7, 21, 42, and 99. For each run, TreeSHAP was applied to up to 2,000 randomly sampled holdout observations, and stability was assessed using pairwise Jaccard similarity between the top-10 SHAP feature sets. Because each seed affected both model fitting and SHAP sampling, the audit measures combined model and sample stability. The study uses the UCI Appliances Energy Prediction dataset [11], containing 19,735 observations recorded at 10-minute intervals over approximately 4.5 months in a low-energy house in Belgium. After constructing leakage-safe features, 19,711 usable observations remained. The first 15,768 observations were used for training and TimeSeriesSplit cross-validation, and the final 3,943 observations were reserved as an untouched chronological holdout. The variables rv1 and rv2 were removed because they are random variables without operational meaning. Three additional clarifications prevent common interpretation errors: Visibility is an external weather-station variable, lights measure lighting energy use rather than occupancy, and the dataset contains no direct occupancy sensor. The dataset, therefore, supports controlled evaluation of appliance energy forecasting and feature-domain contribution but cannot directly represent occupancy or individual appliance events. Historical target features were constructed using shift(1) to prevent leakage. The selected 22-feature set comprised 11 temporal features (hour, day of week, weekend, month, minutes since midnight, and their relevant sine/cosine encodings), six appliance lags (1, 2, 3, 6, 12, and 24 steps), and five shifted rolling statistics (means over 3, 6, and 12 steps; standard deviations over 6 and 12 steps). Because the feature set includes a 24-step lag and shifted rolling windows, the first 24 observations were dropped. This design assumes an online, one-step-ahead forecasting scenario in which previously observed smart-meter readings are available before prediction of the next interval. This is operationally realistic for a HEMS but limits the framework to next-interval forecasting using recent consumption history. Strict chronological partitioning was used, with the first 80% of observations allocated to training and cross-validation and the final 20% reserved as a prospective holdout. No future holdout values were used to construct features at an earlier timestamp. Model selection relied exclusively on the mean TimeSeriesSplit RMSE, and the holdout was evaluated only after the selection rule was applied. This design directly addresses RQ1 by preventing retrospective holdout-based model selection. XGBoost achieved the lowest holdout RMSE of 57.74 Wh, but Random Forest was retained as the selected model because the prespecified selection rule relied solely on training-period cross-validation. The leading cross-validation configurations were tightly clustered: Random Forest achieved RMSE = 64.55 Wh, HistGradientBoosting 64.68 Wh, LightGBM 64.74 Wh, and XGBoost 64.86 Wh. These results indicate that the leading architectures performed similarly under the fixed evaluation settings. Six model families were evaluated using fixed hyperparameters: Random Forest, XGBoost, LightGBM, HistGradientBoosting, ExtraTrees, and Ridge regression. The selected Random Forest used 80 trees, max_depth = 14, min_samples_leaf = 2, and max_features = "sqrt". Thirteen feature-group configurations produced 78 model–feature combinations. The baselines were the training mean, a seasonal day/time mean, and previous-value persistence. RMSE was the primary metric, with MAE and R^2 reported as secondary metrics. For the primary explanation, TreeSHAP was applied to 2,000 holdout observations using seed 42. High Jaccard similarity across the repeated runs indicates robustness of the global top-10 feature set, but it does not establish causal validity or complete explanation stability.

IV. EXPERIMENTAL RESULTS

Table 1 reports the holdout performance of the operational baselines, the selected model, and the XGBoost sensitivity result. The selected Random Forest achieved RMSE = 58.47 Wh, MAE = 26.31 Wh, and R^2 = 0.5826, outperforming all three operational baselines. The most important comparator is previous-value persistence, which achieved an RMSE of 66.23 Wh and an R^2 of 0.4645. The selected model, therefore, provides forecasting value beyond a simple lag-1 strategy. Although XGBoost achieved a slightly lower holdout RMSE of 57.74 Wh, it was not selected because model selection was based exclusively on training-period TimeSeriesSplit cross-validation. It is consequently reported as a sensitivity result rather than as the final model. Together with the tightly clustered cross-validation results, its small holdout advantage suggests that leakage-safe lag and rolling features were more influential than minor differences among the leading model families.

Table 1. Holdout performance of baselines and selected models

Model/baseline	**RMSE (Wh)**	**MAE (Wh)**	**R^2**	**Note**
Dummy mean	90.53	52.45	-0.0005	Training mean
Seasonal day/time mean	86.57	47.68	0.0850	Hour/day mean
Previous-value persistence	66.23	26.53	0.4645	Lag-1 baseline
Random Forest, selected	58.47	26.31	0.5826	CV-selected
XGBoost, sensitivity	57.74	25.46	0.5930	Holdout sensitivity

Table 2 reports approximate paired-bootstrap 95% intervals based on 1,000 resamples. The selected Random Forest reduced holdout RMSE from 66.23 Wh to 58.47 Wh, an absolute reduction of 7.76 Wh or 11.72% relative to persistence. The RMSE reduction interval of [4.98, 10.65] Wh remained positive, suggesting that the improvement was not dependent on a fragile point estimate under this approximate row-resampling audit.

Table 2. Bootstrap uncertainty for the selected model and improvement over the persistence baseline

Quantity	**Point Estimate**	**95% CI**
Selected model RMSE Wh	58.47	[53.90, 63.15]
Selected model R^2	0.5826	[0.537, 0.626]
RMSE reduction vs lag-1 Wh	7.76	[4.98, 10.65]
RMSE reduction vs lag-1 %	11.72%	[7.44%, 16.00%]

Published results obtained using the same UCI dataset provide useful context. Candanedo et al. reported a test set RMSE of 66.65 Wh, an MAE of 35.22 Wh, and an R^2 of 0.57 for their Gradient Boosting Machine model [11]. Assadian and Assadian reported RMSE = 59.61 Wh, MAE = 26.62 Wh, and R^2 = 0.66 for a tuned Extra Trees model [18]. The present Random Forest achieved RMSE = 58.47 Wh, MAE = 26.31 Wh, and R^2 = 0.5826. These values indicate competitive, but not directly superior, predictive performance. The studies used different predictors, feature-engineering procedures, tuning strategies, forecasting tasks, and data-partitioning protocols. In particular, the present study evaluates one-step-ahead forecasting using leakage-safe autoregressive features, training-only chronological selection, and an untouched final chronological holdout. The published values should therefore be treated as contextual benchmarks rather than a controlled head-to-head ranking. Feature groups without an autoregressive consumption history produced cross-validation RMSE values above approximately 90 Wh. In contrast, configurations containing lag and rolling history achieved RMSE values of approximately 64.5–66.9 Wh across the evaluated architectures. The selected Random Forest using temporal,

lag, and rolling features achieved the lowest mean cross-validation RMSE of 64.55 ± 4.87 Wh, with MAE = 31.20 ± 4.20 Wh and $R^2 = 0.598 \pm 0.037$. These findings address RQ2. In this one-step-ahead benchmark, recent appliance consumption history was the dominant predictive signal, whereas environmental IoT variables without autoregressive consumption history were insufficient for competitive forecasting. Figure 1 presents the best cross-validated RMSE for each feature group across the 78 model–feature combinations. The complete fold-level cross-validation results are omitted for brevity.

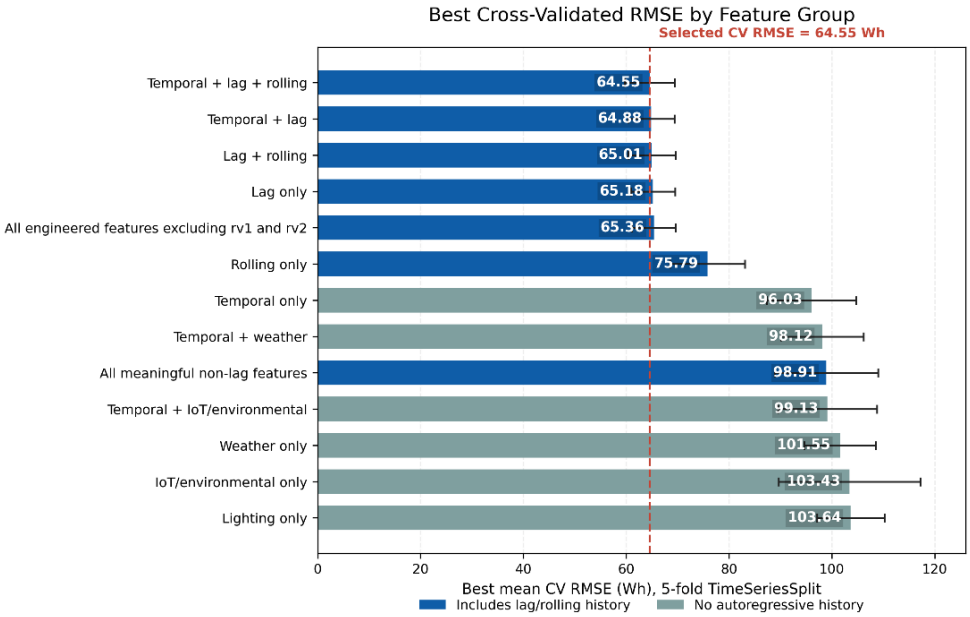

Figure 1. Best training-period CV RMSE by feature group using five-fold TimeSeriesSplit; error bars show fold-level standard deviation.

Table 3 reports holdout error by actual consumption band. The model performed well during low- and moderate-consumption periods, but errors increased sharply above 300 Wh, indicating systematic underprediction during sudden high-load events.

Table 3. Holdout error by actual consumption band

Actual Band	Count	MAE (Wh)	Underprediction	Interpretation
0–100 Wh	3,120	14.50	33.37%	Stable low-use periods
100–300 Wh	652	41.56	40.80%	Moderate routine-use error
>300 Wh	171	183.72	85.38%	Severe spike underestimation

The >300 Wh band was used as a diagnostic high-consumption regime rather than as a model-selection criterion. It represents an upper-tail subset of the holdout observations. For this band, MAE reached 183.72 Wh, and 85.38% of observations were underpredicted, indicating a structural limitation in the available feature set and in the one-step-ahead task design. Sudden high-load events are difficult to anticipate from lag and rolling consumption features alone, particularly in the absence of direct occupancy or appliance-event sensing.

V. EXPLAINABILITY AND STABILITY ANALYSIS

TreeSHAP was applied to the selected Random Forest after confirming that it outperformed both the dummy-mean and previous-value persistence baselines on the holdout set. For the primary explanation, SHAP values were calculated using a random sample of 2,000 holdout observations selected with seed 42. Figure 2 presents the global SHAP bar summary. The five highest-ranked features were all autoregressive consumption-history variables: Appliances_lag_1 with mean absolute SHAP = 21.58 Wh, Appliances_rolling_mean_3 with 10.54 Wh, Appliances_rolling_std_6 with 6.98 Wh, Appliances_rolling_std_12 with 5.14 Wh, and Appliances_rolling_mean_6 with 4.85 Wh. The remaining top-10 features were Appliances_lag_2, hour_cos, Appliances_rolling_mean_12, minutes_since_midnight_sin, and Appliances_lag_3. No environmental IoT variable appeared in the top 10, directly addressing RQ3.

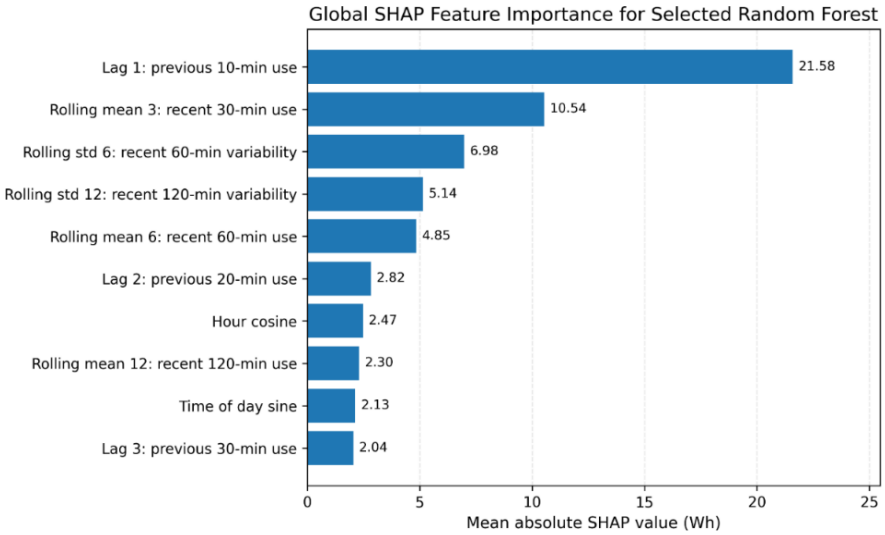

Figure 2. Global SHAP feature importance for the selected Random Forest, showing the dominance of recent appliance-consumption history.

The SHAP ranking is consistent with the feature-group ablation: environmental-only configurations performed substantially worse than configurations containing lag and rolling history, and no environmental IoT variable appeared among the top-10 SHAP features. All SHAP findings are interpreted as model-based associations rather than causal effects. The following rule was applied when translating SHAP outputs into possible dashboard feedback: "Feature X is associated with higher or lower predicted appliance energy use in the trained model. This may reflect household routines or conditions that co-occur with appliance use, but the model does not demonstrate that changing X alone will alter actual energy consumption."

For example, the association between Appliances_lag_1 and predicted energy reflects short-term consumption persistence: appliances operating during the previous 10-minute interval may remain active during the following interval. This is evidence of temporal autocorrelation in the model's predictive behavior, not evidence of a causal intervention pathway. Figure 3 presents pairwise Jaccard similarities among the top-10 SHAP feature sets produced by the five seed-specific model-and-sample runs. Across the ten unique seed pairs, six pairs among seeds 1, 7, 21, and 42 produced identical top-10 feature sets. The four pairs involving seed 99 produced a Jaccard similarity of 0.818, corresponding to one feature difference at the top-10 boundary. The resulting average

pairwise Jaccard similarity was 0.9273. This result addresses RQ4 by demonstrating high stability at the feature-set level across the repeated runs. However, the audit does not isolate model-initialization effects from explanatory-sample variation, nor does it assess rank-order stability, attribution-magnitude stability, or local-explanation stability. The high feature-set overlap supports cautious use of the explanations for model-level energy-awareness feedback. It does not establish real-world causal validity or complete trustworthiness in deployment. Instead, it indicates that the model's broad global explanation pattern remained similar across repeated seed-specific model-and-sample runs, providing a more defensible basis for model-level dashboard summaries than a single-run explanation. User-facing interpretation would still require deployment and user-comprehension testing.

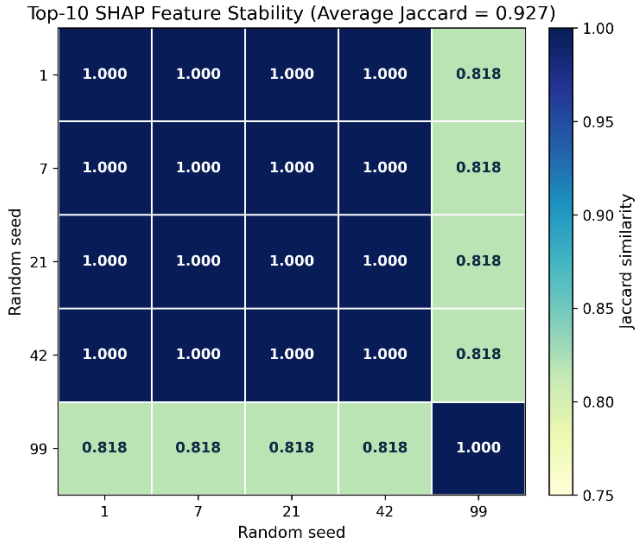

Figure 3. Top-10 SHAP feature-set stability across five seed-specific Random Forest models and sample runs. All pairs not involving seed 99 have identical top-10 feature sets; the four pairs involving seed 99 have Jaccard similarity of 0.818. The average pairwise similarity is 0.9273.

VI. DISCUSSION

Table 4 presents a deployment-oriented ablation based on training-period cross-validation. Each row reports the best model obtained for the corresponding feature group. Random Forest was the best model for the smart-meter-only and smart-meter-plus-time configurations, Ridge was the best model for the environmental-only configuration, and XGBoost was the best model for the full engineered feature set. The table provides preliminary deployment guidance and does not change the training-only selection rule or the reported Random Forest holdout result.

Table 4. Minimal sensor deployment ablation

Deployment setup	Feature group	Features	CV RMSE (Wh)	CV R^2
Smart meter only	Lag + rolling	11	65.01	0.592

Deployment setup	Feature group	Features	CV RMSE (Wh)	CV R^2
Smart meter + time	Temporal + lag + rolling	22	64.55	0.598
Environmental only	IoT/environmental only	19	103.43	-0.029
Full engineered setup	All engineered features	47	65.36	0.588

The smart-meter-only configuration using 11 lag and rolling features achieved a CV RMSE of 65.01 Wh, close to the 22-feature temporal, lag, and rolling configuration, which achieved 64.55 Wh. Environmental-only features performed poorly, with a CV RMSE of 103.43 Wh and a negative R^2. The full 47-feature engineered configuration achieved CV RMSE = 65.36 Wh and did not improve on the selected 22-feature configuration. These results suggest that smart-meter lag and rolling features may provide an efficient basis for low-cost HEMS forecasting. However, the compact feature set must still be evaluated on an untouched holdout or external households. The compact configuration may support lightweight edge deployment. This remains contingent on validating computational requirements, latency, memory usage, handling of missing readings, and operational robustness. For energy-awareness dashboards, SHAP outputs should be framed as non-causal model explanations. Dashboards should also disclose the prediction limitation during high-load spikes above 300 Wh, where the selected model systematically underpredicts demand. Any deployed forecasting model should be evaluated against simple operational baselines such as previous-value persistence. Taken together, the ablation, spike-regime, and explanation-stability findings support the contextual-coherence interpretation. The model behaves coherently when recent consumption history is available, but becomes less reliable during abrupt high-load events not captured by occupancy or appliance-event variables. The stable global SHAP feature set supports reproducible model-level interpretation. At the same time, the minimal-sensor ablation indicates that most of the predictive value comes from smart-meter history rather than from additional environmental sensors. Limitations include the single-household dataset, absence of occupancy or appliance-event sensing, and reliance on an online one-step-ahead setting. SHAP explains model behavior rather than causal mechanisms, and the bootstrap does not fully preserve temporal dependence. Hyperparameters were constrained to ensure reproducibility rather than through exhaustive optimization. Real-world deployment requires appropriate consent, privacy controls, and secure handling of recent meter-reading windows, especially important in single-household datasets.

VII. CONCLUSION

This paper presented a leakage-aware and explanation-stable framework for short-term smart-home appliance energy forecasting. Using strict chronological validation and operational baselines, the selected Random Forest achieved RMSE = 58.47 Wh and R^2 = 0.5826 on an untouched holdout set, improving over previous-value persistence by 7.76 Wh in RMSE. Feature-group ablation and SHAP analyses showed that recent appliance consumption history dominated the prediction in this single-household, one-step-ahead setting. At the same time, environmental IoT variables added limited incremental value once lag and rolling features were included. Spike-regime analysis showed severe underprediction above 300 Wh, highlighting the need for occupancy-aware or appliance-event sensing. SHAP stability analysis supported cautious model-level explanation, provided outputs are treated as associations rather than causal claims. Future work should evaluate the framework across multi-household datasets, different climatic regions, and longer temporal horizons to assess generalisability and robustness.

Abstract
Cost, safety concerns, unpredictability, and access may limit real-world exposure to specific phobias. Virtual reality (VR) provides a controllable and repeatable alternative. This work-in-progress paper presents second-generation VR systems for fear of cats, heights, and flying, and analyzes them as engineering artifacts. A preliminary cross-case comparison examines exposure hierarchy, intensity parameters, interaction and safety logic, and data requirements. Each system implements comprehensive VR event logging, smartwatch integration, temporal synchronization, and backend session histories. At the same time, exposure logic remains phobia-specific: object-based for cats, spatial for heights, and event-sequence for flying. From these cases, we derive a preliminary framework separating common session, logging, synchronization, and backend functions from stimulus-specific exposure logic. A recommendation mechanism is under development, and a formal usability study is planned. No clinical efficacy study was conducted; the contribution is an implemented engineering foundation for later expert review, usability and feasibility evaluation, and clinically supervised research.

Keywords: virtual reality; specific phobias; exposure systems; human-computer interaction; software engineering; interaction design

I. INTRODUCTION

Specific phobias involve persistent fear and avoidance of particular objects or situations. Exposure-based interventions involve structured encounters with feared stimuli, but in vivo exposure may be costly, difficult to organize, or difficult to control safely [1],[2]. VR offers repeatable, configurable exposure in which distance, movement, elevation, openness, sound, timing, and behavior can be controlled and logged. Evidence supports VR exposure, particularly over passive controls, but does not show consistent superiority over active or in-vivo approaches [3-5]; its engineering value therefore also lies in control, repeatability, interaction, and measurement. Designing such systems requires translating exposure principles into software requirements for intensity, progression, control, safety, and logging. These requirements depend on the feared experience: animal exposure centers on a dynamic agent, height exposure on spatial perception and navigation, and flight exposure on a timed multimodal sequence. We compare three student-developed VR prototypes for cats, heights, and flying as object-based, spatial, and event-sequence systems. This is an engineering abstraction, not a clinical taxonomy, and the prototypes are not presented as validated treatments. The study asks how graded exposure can be translated into VR requirements (RQ1), which functions are shared or phobia-specific (RQ2), and which reusable guidelines support progression, control, safety, and behavioral data collection (RQ3). The contribution is a cross-case comparison and preliminary framework linking exposure structure to configurable parameters, interaction and safety logic, and behavioral measures.

II. BACKGROUND AND RELATED WORK

1. Exposure Principles and Current Evidence

Exposure uses structured encounters with feared and avoided stimuli. Meta-analytic evidence shows substantial symptom and approach-behavior improvements [1], while inhibitory-retrieval models emphasize testing threat expectations rather than requiring anxiety to decline continuously [2]. A technological hierarchy should therefore manipulate meaningful threat-related variables rather than merely increase visual realism. VR exposure is a well-developed application area [3]. Outcomes are generally better than those of passive controls, but advantages over active conventional or in vivo interventions are inconsistent [4],[5], cautioning against equating technological sophistication with clinical superiority. Recent studies report benefits across several phobias [6], including heights [7] and flying [8]; evidence for cat phobia is more limited, though it includes a randomized study [9]. Together, they support feasibility while illustrating that different phobias require distinct mechanisms of stimulus control and interaction.

2. Technical Design, User Experience, and Research Gap

VR exposure systems vary in display, tracking, navigation, interaction, stimulus behavior, progression, and user or supervisor control. A review of 70 studies found inconsistent technical reporting, limiting reproducibility and comparison [10]; implementations range from passive 360-degree content to interactive 3D environments with different locomotion and progression schemes. User control and comfort are central HCI concerns. Users may need to pause or terminate exposure without controlling the feared event itself. Usability evaluation remains heterogeneous [11-14], and cybersickness may overlap with anxiety responses; navigation, visual motion, frame stability, and duration should therefore be designed to minimize unrelated discomfort [12]. Programmable environments can record duration, completion, interruptions, position, proximity, and interactions, while wearable biosensors add physiological data [13]. Because logging and technical reporting are not yet standardized [10],[13], there is limited guidance on which software functions can be reused across phobias and which must remain stimulus-specific. This work addresses the engineering-HCI gap.

III. RESEARCH AND DEVELOPMENT METHOD

1. Study Design and Project Context

The study used an artifact-centered qualitative comparison of three functional VR prototypes for cats, heights, and flying, developed as final-year software engineering projects. They were analyzed as engineering artifacts; treatment efficacy and clinical outcomes were outside the scope of this analysis. All prototypes were developed in Unity 6 for Meta Quest 3S and shared six requirements: graded progression, repeatable stages, control over participation, predictable progression, clear stopping or withdrawal, and behavioral event logging, while retaining stimulus-specific exposure logic.

2. Second-Generation Architecture and Multimodal Data Pipeline

Second-generation versions add complete VR event logging and smartwatch integration. Wearable data are timestamped and synchronized with VR events so both streams can be represented on a unified session timeline. Synchronized data is stored on a backend that provides access to the session history. Logging, wearable integration, synchronization, and backend history have been implemented; a recommendation mechanism is under development, and a formal usability study is planned. These functions provide preliminary technical evidence that one data-management pattern can support the three exposure categories without replacing their phobia-specific logic.

3. Translation and Comparative Analysis

For each system, exposure principles were mapped to a hierarchy, controllable parameters, VR interactions, progression, safety rules, and logging. Cat exposure used agent visibility, distance, movement, orientation, and behavior; height exposure used elevation, depth, openness, edge proximity, barriers, and movement; flight exposure used coordinated cabin, taxiing, takeoff, flight, and turbulence events. Each artifact was examined independently and then compared across seven dimensions: exposure structure and unit, controllable parameters, interaction and progression logic, user control, safety, behavioral logging, and primary engineering challenge. Shared features formed the common design core; differences were classified as object-based, spatial, or event-sequence, producing the framework in Section V. The comparison was qualitative and based on implemented artifacts and project documentation; no statistical analysis was appropriate because there was no controlled participant sample or common outcome set. The cat-system developer's five-session use was treated only as non-independent formative feedback, not as evidence of usability or efficacy. Future participant studies require predefined measures, supervision, consent, secure data handling, and ethics approval.

IV. VR EXPOSURE PROTOTYPES

The prototypes share the common requirements and second-generation data functions above, but differ in how exposure intensity is generated. Figure 1 shows representative scenes; the subsections summarize phobia-specific hierarchy, interaction logic, and logged variables.

Figure 1. Representative scenes from the three prototypes: (a) cat phobia, (b) height phobia, and (c) flight phobia.

1. Cat-Phobia Prototype

The cat system progresses from pictures and a distant, passive cat to closer, moving, interactive exposure. Visibility, distance, orientation, motion, and behavior define reproducible stages; the key challenge is balancing engaging agent behavior with predictability. Logs record stage time, completion or interruption, cat distance, approach or withdrawal, and interaction completion, directly reflecting the object-based hierarchy.

2. Height-Phobia Prototype

The height system progresses from protected to increasingly exposed elevated scenes. Intensity combines elevation, visual depth, openness, edge proximity, barriers, ground visibility, and movement, while stable navigation limits motion-related discomfort. Users can stop or step back. Logs record edge distance, time at height, entry into exposed areas, retreat, and level progression, reflecting the spatial structure.

3. Flight-Phobia Prototype

The flight system models flying as a timed sequence of cabin exposure, announcements, taxiing, takeoff, in-flight sounds, and turbulence. Its main challenge is synchronizing visual, auditory, and temporal cues. Users may pause, repeat, reduce intensity, or exit without controlling the aircraft. Logs record stage duration and completion, pauses, repetitions, interruptions, termination point, and responses to takeoff or turbulence.

V. RESULTS: CROSS-CASE ANALYSIS AND PRELIMINARY DESIGN FRAMEWORK

1. Shared and Phobia-Specific Logic

Across systems, the shared design core includes graded progression, repeatable stages, predictable transitions, participation control, stopping mechanisms, and general event logging. These functions are content-independent, whereas the mechanism generating exposure intensity remains stimulus-specific. Object-based exposure varies with a feared agent; spatial exposure depends on the user's position and perception; event-sequence exposure depends on timing across phases. This structure determines hierarchy, parameters, interaction design, safety risks, and meaningful behavioral measures.

Table 1. Cross-case comparison of exposure structures and design requirements.

Dimension	***Cat phobia***	***Height phobia***	***Flight phobia***
Exposure structure	Dynamic object	Spatial environment	Temporal event sequence
Exposure unit	Cat proximity and behavior	Position within an elevated scene	Phase of the simulated flight
Main parameters	Visibility, distance, movement, orientation, behavior	Elevation, depth, openness, edge distance, barriers	Stage, sound, motion cues, turbulence
Primary challenge	Believable but predictable agent behavior	Stable navigation and calibrated spatial intensity	Timing and multimodal synchronization
Implemented VR logging	Distance, approach, withdrawal, interaction completion	Edge distance, exposed-area entry, retreat, duration	Completion, pauses, interruptions, termination point
Engineering category	Object-based	Spatial	Event-sequence

Commonly implemented functions across all systems include synchronized VR/wearable logs, session timestamps, persistent backend storage, and access to session history.

2. Proposed Framework

The comparison informed a five-stage development framework:

- Characterize the feared experience as primarily object-based, spatial, event-sequence, or hybrid.
- Construct an exposure hierarchy with stages representing meaningful increases in challenge or uncertainty.
- Map stages to explicit controllable parameters where possible, supporting reuse, testing, and adaptation.

- Define interaction, progression, and safety rules, including how users enter, repeat, pause, or leave a stage, and distinguishing control over participation from control over the feared event.
- Define common session events and additional behavioral measures that reflect the relevant exposure structure.

The second-generation implementation extends the framework into three layers: a stimulus-specific VR layer for object-based, spatial, or event-sequence logic; a session and synchronization layer for VR events and wearable data; and a backend layer for synchronized records and session histories. A recommendation component is under development (Figure 2).

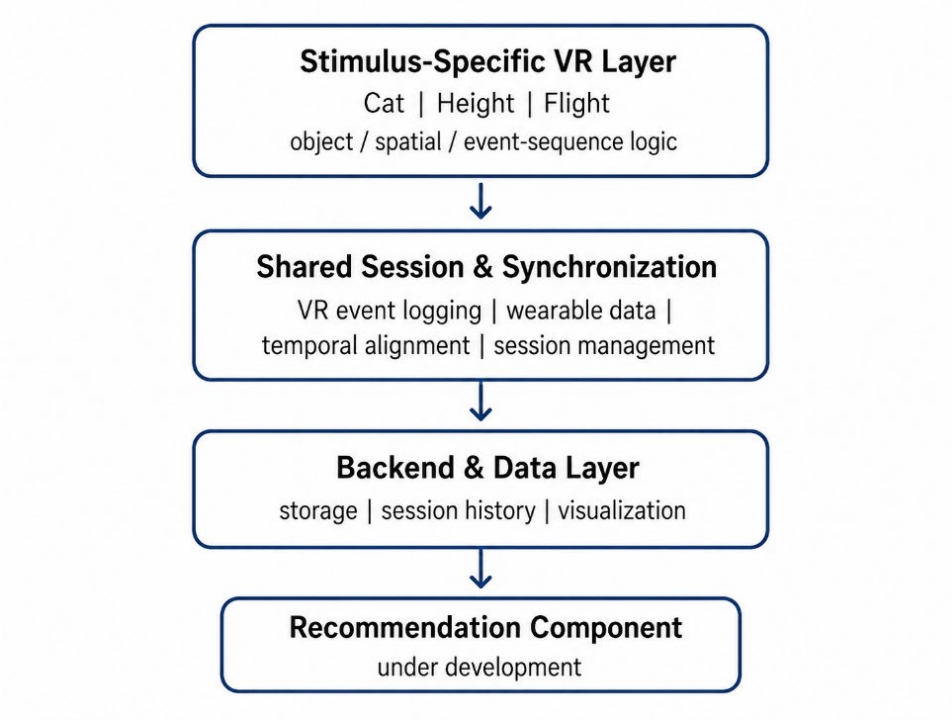

Figure 2. Three-layer architecture of the second-generation VR exposure systems

3. Derived Guidelines and Scope

Three guidelines follow: model exposure stages through parameters and transition rules rather than only separate scenes; calibrate realism to the exposure objective while avoiding unpredictable behavior, unnecessary complexity, and cybersickness; and plan logging with the hierarchy so recorded behavior reflects approach, avoidance, persistence, or interruption. The categories may overlap, and the framework remains an initial engineering model rather than a clinical protocol; decisions about progression require expert review and empirical validation.

VI. DISCUSSION

The results indicate that VR phobia systems differ mainly in the mechanism generating intensity, not simply in visual content. The second-generation implementation separates phobia-specific exposure logic from common

session, synchronization, and backend functions, enabling modular development without forcing different fears into a single exposure structure. This is preliminary technical support, not usability or clinical validation. Parameterizing stages may improve consistency, testing, and later personalization by making changes in distance, openness, edge proximity, sound, or turbulence explicit and reproducible; adaptive progression rules still require empirical validation. Two HCI implications follow. Realism should support recognition and engagement without adding unpredictability or discomfort, because greater immersion does not necessarily improve clinical outcomes [5],[8]. User control should preserve participation and safety without eliminating the feared event; for example, flight exposure can be paused or stopped while the aircraft remains under external control. Behavioral logging is most useful when aligned with exposure structure: common events enable cross-system comparison, while distance, edge proximity, retreat, and interruption capture phobia-specific behavior. Synchronizing these traces with wearable data and preserving session histories provides a basis for future multimodal analysis and recommendation logic. Still, interpretation must be evaluated with usability, self-report, and clinical input.

VII. LIMITATIONS AND FUTURE WORK

The framework is derived from only three heterogeneous student-developed prototypes, which do not represent all specific phobias or hybrid cases and were not evaluated with common technical benchmarks. The qualitative analysis relied on artifacts and documentation; the cat developer's five-session experience was a single, non-independent formative observation. No controlled participant study assessed usability, presence, cybersickness, fear activation, behavioral change, or clinical outcomes. The second-generation logging, wearable integration, synchronization, backend histories, and data interpretation also require systematic evaluation, including synchronization accuracy, missing-data handling, repeated-session reliability, backend usability, and user acceptance. Future work includes a clinical expert review, followed by the planned usability study with predefined measures. The recommendation mechanism remains under development and will require separate evaluation. The architecture should also be tested across additional phobias and hybrid scenarios before any formal clinical efficacy study.

VIII. CONCLUSION

This work identifies object-based, spatial, and event-sequence exposure structures and derives a preliminary framework separating common session and data functions from phobia-specific intensity and interaction logic. Second-generation implementations add synchronized VR/wearable logging, backend storage, and session histories, providing initial technical support for this separation. The contribution remains engineering-oriented work in progress; expert review, usability and feasibility testing, data-pipeline evaluation, and clinical assessment are still required.

Abstract
Interdisciplinary research produces heterogeneous datasets on independently managed platforms, creating semantic barriers to effective integration, reuse, and knowledge discovery. Current ontology-based integrative approaches have shown good performance in structured and domain knowledge environments, but have limitations in integrating qualitative, quantitative, and contextual research knowledge. This study presents the Green Charcoal Ontology (GCO), a FAIR-aligned ontology-driven semantic mediation framework developed using an interdisciplinary Green Charcoal project as an empirical case. The framework incorporates production, market, and geospatial research concepts using a modular OWL 2 DL ontology that links locally developed research vocabularies to existing Semantic Web standards such as SOSA, PROV-O, and GeoSPARQL. The development of the ontology was based on the Design Science Research Methodology and the NeOn approach, and its evaluation was conducted using OWL reasoning, SHACL-based validation, and competency-question-driven SPARQL queries. Results show that cross-domain knowledge retrieval from the integrated knowledge graph is successful, that the data constraints are evaluated, and that logical consistency is achieved across 2674 axioms. In addition to semantic integration, GCO offers a conceptual design for Research Data Management Systems, including common concepts, relationships, provenance structures, and validation mechanisms. The study shows that FAIR-compatible Semantic Interoperability can be achieved through practice-informed ontology engineering while maintaining domain-specific knowledge practices in interdisciplinary and resource-constrained research scenarios.

Keywords: Semantic Interoperability, Ontology Engineering, FAIR Data, principles, Knowledge Graph, Interdisciplinary Research, Research Data Management System

I. INTRODUCTION

The global research landscape is increasingly interdisciplinary, bringing together diverse scientific communities that generate heterogeneous data across institutional repositories, sensor networks, spreadsheets, and relational databases. While this diversity accelerates scientific discovery, it also introduces semantic heterogeneity that hinders data integration, interoperability, and reuse. Beyond a technical issue, semantic heterogeneity reflects differences in disciplinary practices, conceptualizations, and interpretations. Effective interdisciplinary collaboration, therefore, requires shared mechanisms that facilitate communication without enforcing complete conceptual uniformity. The concept of boundary objects explains how shared representations enable collaboration across communities while preserving domain-specific perspectives. Ontology-based semantic models can serve as formal boundary objects by providing machine-interpretable conceptual frameworks that support semantic interoperability and knowledge exchange across disciplines [1]. Nevertheless, achieving semantic interoperability remains a major challenge in interdisciplinary research environments. Unlike syntactic heterogeneity, which arises from differences in data formats and encodings, semantic heterogeneity occurs when the same concepts are represented with different meanings or incompatible conceptual structures [2]. Conventional data integration approaches, such as extract-transform-load (ETL) pipelines, primarily address structural and syntactic inconsistencies but provide limited support for resolving semantic conflicts [3]. Consequently, datasets may be technically integrated while remaining semantically incompatible. Recent studies identify semantic interoperability as a persistent challenge and highlight ontology mapping as an effective mechanism for aligning heterogeneous knowledge representations [4], [5]. Ontologies also function as socio-technical boundary objects that facilitate shared understanding among research communities while preserving disciplinary perspectives [6], [7]. Existing approaches, including hybrid ontology-based integration frameworks [8] and ontology database mapping techniques [9], have advanced semantic integration. However, they primarily target structured or domain-specific environments and provide limited support for interdisciplinary research settings that integrate qualitative, quantitative, and geospatial data while preserving contextual meaning. The FAIR (Findable, Accessible, Interoperable, and Reusable) principles provide internationally accepted guidelines for improving the quality, accessibility, and reusability of research data [10]. However, FAIR compliance extends beyond metadata annotation and open access to include semantic mechanisms that preserve meaning across heterogeneous datasets [11]. Semantic Web standards, including the Resource Description Framework (RDF), RDF Schema (RDFS), and Web Ontology Language (OWL), provide the foundation for machine-actionable knowledge representation and semantic interoperability. Despite these advances, few ontology-driven FAIR frameworks explicitly address semantic mediation across interdisciplinary and resource-constrained research environments, particularly within African research institutions. This challenge is exemplified by the Unlocking the Potential of Green Charcoal to Mitigate Climate Change in Northern Uganda (UPCHAIN) project, an interdisciplinary initiative comprising three complementary work packages. WP1 focuses on green charcoal production and quality assessment; WP3 investigates market dynamics and livelihood impacts; and WP5 analyses raw material availability using Participatory Geographical Information Systems (PGIS). Although these work packages contribute to a common research objective, they employ distinct terminologies, methodologies, metadata structures, and conceptual models. This diversity creates semantic heterogeneity that limits cross-domain data integration and knowledge reuse while providing an ideal empirical setting for developing and validating a unified semantic framework. Although ontology-based integration has demonstrated success in enterprise systems and well-defined knowledge domains, comparatively little attention has been paid to interdisciplinary research environments in which heterogeneous observational, socio-economic, experimental, and geospatial data must be integrated without compromising domain-specific semantics. Existing studies rarely combine ontology engineering, FAIR principles, semantic validation, and competency-question-driven evaluation within a unified semantic interoperability framework. This study addresses this gap by proposing an ontology-driven semantic mediation framework for heterogeneous research data environments using the UPCHAIN project as a real-world case study.

The objectives of this study are to: (i) analyze semantic heterogeneity across interdisciplinary work packages; (ii) develop a FAIR-aligned Green Charcoal ontology; (iii) validate the ontology using OWL reasoning and SHACL constraint checking; and (iv) evaluate semantic interoperability through competency-question-driven

SPARQL queries. The study contributes to the field by first developing a modular ontology that integrates the production, market, and geospatial research domains while reusing established Semantic Web vocabularies, including SOSA, PROV-O, and GeoSPARQL. Second, it proposes an ontology-driven semantic interoperability framework that supports FAIR-compliant integration of heterogeneous interdisciplinary research data. Third, it demonstrates a comprehensive validation workflow combining OWL reasoning, SHACL constraint validation, and competency-question-based SPARQL queries to verify logical consistency and semantic correctness. Finally, it provides a practice-informed case study showing how ontology-driven semantic mediation can improve interoperability and knowledge sharing in interdisciplinary and resource-constrained research environments.

II. RELATED WORK

1. Semantic Interoperability in Interdisciplinary Research

Modern scientific collaborations generate diverse datasets that are stored in independently managed repositories using different data models, metadata standards, measurement conventions, and disciplinary terminologies [12]. This diversity creates significant conceptual fragmentation, particularly in the life sciences, where repositories such as BioPortal contain numerous independently developed ontologies [13], [14]. Similar fragmentation exists in scholarly infrastructures such as the Microsoft Academic Graph [15]. It is even more pronounced in the social sciences and humanities, where concepts are often context-dependent and interpreted differently across disciplines. Interoperability is commonly classified into technical, syntactic, semantic, organizational, and conceptual levels [16]. Although standards such as XML and JSON-LD effectively support data exchange, they cannot guarantee that information retains the same meaning across systems [17]. Consequently, successful collaboration depends on sharing knowledge rather than merely exchanging data [18]. Traditional integration approaches, including relational databases and extract-transform-load (ETL) pipelines, resolve structural inconsistencies but rarely preserve contextual meaning or conceptual relationships among datasets [19]. Semantic technologies address this limitation by representing concepts and their relationships in a machine-interpretable form. Beyond their technical role, ontologies also function as boundary objects, providing shared conceptual models that facilitate collaboration while allowing individual disciplines to retain their own perspectives [20]. Recent advances in Semantic Web technologies have improved knowledge integration across distributed information systems. Nevertheless, most existing frameworks focus on enterprise applications or single-domain repositories. Limited attention has been paid to collaborative environments that integrate independently managed datasets, provenance requirements, governance mechanisms, and FAIR principles into a unified semantic framework. Addressing these challenges requires ontology-driven approaches that support meaningful knowledge integration, cross-domain discovery, and sustainable data reuse. This study responds to this need by developing a FAIR-aligned semantic integration framework for heterogeneous research data.

2. Ontology-Based Data Integration

Ontology-Based Data Integration (OBDI) addresses conceptual inconsistencies by introducing a shared semantic layer that provides a unified view of heterogeneous information sources. Two principal integration paradigms have emerged. Ontology-Based Data Access (OBDA) enables virtual querying of distributed databases through declarative mappings and knowledge graphs. In contrast, materialized integration transforms heterogeneous datasets into a common RDF repository or data warehouse for centralized querying [8], [21], [22]. Both approaches allow users to formulate semantic queries independently of the underlying storage technologies. A typical OBDI architecture comprises a domain ontology, commonly represented in OWL 2 QL. These declarative mappings relate ontology concepts to source schemas, and heterogeneous repositories such as relational, JSON, and graph databases [23], [24]. Depending on the integration strategy, architectures may adopt global, local, or hybrid ontology models. Global ontologies simplify query processing through a unified

conceptual schema, while local ontologies preserve domain autonomy. Hybrid architecture combines these advantages by linking independent domain ontologies through a shared upper-level model, thereby improving modularity, scalability, and semantic consistency across distributed repositories [25]. OBDI has been widely applied in enterprise information systems, healthcare, and industrial applications, demonstrating its effectiveness in semantic querying and knowledge integration. However, its adoption in interdisciplinary research data management remains limited. Existing approaches primarily emphasize data access and query processing, with comparatively little attention given to FAIR-compliant governance, provenance management, modular ontology engineering, and comprehensive semantic validation. These limitations highlight the need for integration frameworks that not only enable semantic access to heterogeneous datasets but also support trustworthy, reusable, and interoperable research data throughout its lifecycle.

3. Ontology Engineering Methodologies and Semantic Web Standards

Ontology engineering methodologies provide systematic guidance for developing interoperable semantic models throughout their lifecycle. Early approaches, including Methontology [26] and Ontology 101 [27], established structured processes covering ontology specification, conceptualization, formalization, implementation, and evaluation. Although these methodologies remain influential, they were primarily designed for standalone ontology development and provide limited support for modular reuse and collaborative development across distributed domains. The NeOn methodology [28] extends these approaches by promoting ontology reuse, modularization, and collaborative engineering, making it particularly suitable for interdisciplinary environments comprising multiple autonomous knowledge domains. Consequently, NeOn provides the methodological foundation for the work-package-oriented ontology developed in this study. Modern ontology engineering is underpinned by the W3C Semantic Web standards, which collectively support interoperable knowledge representation. RDF provides graph-based data modeling [29], OWL enables formal knowledge representation and logical reasoning [30], while SPARQL facilitates semantic querying. Complementary standards, including SKOS, SHACL, PROV-O, SOSA, and GeoSPARQL, support vocabulary management, constraint validation, provenance tracking, sensor observations, and spatial representation, respectively. In addition, declarative mapping languages such as R2RML and RML enable heterogeneous data sources to be transformed into interoperable RDF knowledge graphs, facilitating scalable semantic integration workflows [9]. Recent developments increasingly emphasize modular ontology design and the reuse of established vocabularies to improve maintainability, interoperability, and long-term sustainability. However, many existing implementations focus primarily on ontology construction and knowledge representation, with less emphasis on integrating ontology engineering, semantic validation, provenance management, and FAIR principles within a unified framework for interdisciplinary research. Addressing this limitation requires methodologies that support not only ontology development but also semantic interoperability throughout the research data lifecycle.

4. FAIR Research Data Management

The FAIR principles provide a framework for improving the Findability, Accessibility, Interoperability, and Reusability of research data through persistent identifiers, rich metadata, and machine-actionable standards [10]. Increasingly, FAIR is viewed not merely as a data management guideline but as a socio-technical framework that relies on shared conceptual models to enable meaningful data exchange and reuse across diverse research communities [31], [32]. Its implementation is typically supported by FAIRification workflows that involve data curation, metadata enrichment, semantic annotation, and ontology-based integration. Evaluation frameworks, including the RDA FAIR Data Maturity Model and GO FAIR guidelines, together with assessment tools such as FAIR-Checker [33], FAIRshake, F-UJI, and O'FAIRe, provide measurable indicators of compliance using technologies such as SPARQL and SHACL. More recent developments, including FAIR Digital Objects and FAIR Data Points, further strengthen machine-actionability and support federated data ecosystems [34]. Despite these advances, interoperability remains the least mature FAIR dimension because aligning data meaning across heterogeneous domains is inherently challenging. Most implementations achieve metadata harmonization but

provide limited support for semantic integration across independently developed knowledge models. These limitations are particularly evident in interdisciplinary and resource-constrained research environments, where differences in conceptual models, infrastructure, and technical expertise hinder effective knowledge sharing [35], [36]. Consequently, ontology-driven semantic frameworks remain essential for translating FAIR principles into meaningful, machine-interpretable interoperability that supports cross-domain integration and long-term data reuse.

5. Existing Ontology-Based Research Data Management Systems

Ontology-based research data management (RDM) systems have evolved from standalone ontology development tools to integrated FAIR-enabled knowledge graph platforms. Early systems, including Protégé, SOR, QuOnto, and Oracle Semantic Technologies, established the foundations for ontology development, reasoning, and semantic data management. Community-driven repositories such as the OBO Foundry further promoted ontology reuse, standardization, and collaborative development. More recently, ontology-based data access and management platforms, including Ontop and Mastro, have enabled scalable semantic access to heterogeneous relational databases through declarative mappings, supporting applications in domains such as energy, transportation, and manufacturing [37]. Complementary technologies, including RML, RDFAdaptor, and SHACL-based validation pipelines, further facilitate heterogeneous data transformation and quality assurance [38]. Recent advances have extended these capabilities by integrating FAIR principles with knowledge graphs and research data infrastructures. Platforms such as LDM, NFDI4Earth, PO²/TransformON, and ARGOS support FAIR-compliant data management through semantic annotation, metadata standardization, and lifecycle management, thereby improving data discovery, sharing, and reuse [32], [39]. Collectively, these systems demonstrate substantial progress towards machine-actionable and interoperable research data ecosystems. Despite these advances, several limitations remain. Many existing platforms prioritize data publication and semantic access while providing limited support for integrated ontology engineering, modular knowledge organization, semantic validation through OWL reasoning and SHACL constraints, and competency-question-driven evaluation within a single framework. In addition, relatively few implementations have been evaluated in interdisciplinary research settings characterized by independently managed datasets, diverse conceptual models, and resource-constrained institutional environments. These limitations motivate the development of ontology-driven frameworks that combine FAIR principles, semantic interoperability, governance, and comprehensive validation to support collaborative research data management across multiple domains.

III. METHODOLOGY

1. Research Design

This study adopts the Design Science Research Methodology (DSRM) (Hevner, 2007) as the overarching research framework and the NeOn ontology engineering methodology (Nasir et al., 2024; Suárez-Figueroa et al., 2015) to guide the development of the Green Charcoal Ontology (GCO). DSRM provides the overall process for designing, implementing, demonstrating, evaluating, and communicating the semantic interoperability artifact, while NeOn provides ontology-specific guidance for conceptualization, reuse, modularization, and implementation. Thus, NeOn complements DSRM by operationalizing the ontology engineering activities within the DSRM design and development phase. Following DSRM, the research process comprises problem identification, objective definition, design and development, demonstration, evaluation, and communication. These stages represent a context-specific operationalization of NeOn principles for transforming heterogeneous green charcoal research knowledge into a formal semantic artifact. After development, the GCO was demonstrated and evaluated using UPCHAIN research scenarios through logical consistency checking, constraint validation, and competency questions. The findings and artifacts were subsequently documented and communicated as a contribution toward FAIR-aligned interdisciplinary research data management.

2. Problem Identification

The problem identification phase explored research data management and semantic interoperability issues in the UPCHAIN project. Five focus group discussions (FGDs) with researchers from WP1, WP3, and WP5 were held, and existing work package data structures were explored via entity–relationship (ER) diagrams. The FGDs discussed domain concepts, data generation processes, terminology, and interactions between work packages. Thematic analysis and ER mapping were used to systematically understand the research domain and the need for a semantic interoperability artifact.

3. Objective Definition

The goal of this research is to design and develop an ontology-driven semantic model that facilitates interoperability, integration of heterogeneous Green Charcoal research data, and meaningful reuse across WP1, WP3, and WP5. The study aims to build a common semantic basis by creating a modular OWL 2 DL ontology network to define concepts, relationships, provenance, measurements, and quality constraints in the domain. The developed ontology is tested through reasoning, SHACL validation, and competency questions to assess its ability to support the consistent representation of data and the integration of knowledge across domains.

4. Design and Development

The NeOn ontology engineering methodology was used during this DSRM phase to guide the construction of the GCO. DSRM introduced the overall research framework, but NeOn was responsible for implementing the ontology based on four adapted stages as follows: (1) requirements analysis; (2) conceptualization and design; (3) implementation using OWL 2 DL. This method guaranteed the systematic development of the ontology, starting from stakeholder requirements to a validated semantic artifact.

5. Ontology Engineering

Ontology requirements were established through thematic analysis of five focus group discussions (WP1: two FGDs with seven participants; WP5: two FGDs with six participants; and WP3: one FGD with five participants) and by mapping existing work package data structures using entity–relationship diagrams. The iterative coding analysis identified recurring themes, key domain concepts, relationships, and variations in terminology, while ER mapping guided ontology class identification and integration points. Four dimensions of data heterogeneity: structural (variations in data organization), semantic (divergent interpretations of shared concepts), syntactic (discrepancies in data formats and encoding), and provenance (inconsistencies in data lineage representations), shaped a modular ontology that enhances interoperability while preserving domain-specific integrity. The ontology design incorporated established vocabularies, including SOSA/SSN for observations, PROV-O for provenance, and GeoSPARQL for spatial representation. It was implemented using OWL 2 DL with defined classes, properties, and constraints to support semantic interoperability across heterogeneous research datasets. The resulting ontology harmonizes datasets from WPs into a unified schema, ensuring traceability and facilitating spatial analysis for sustainability assessment.

6. Ontology Design

Ontology Specification

The ontology specification phase defines the ontology's purpose, scope, objectives, intended use, and functional requirements (Nie et al., 2024). It establishes the domain boundaries and translates the identified data

heterogeneity challenges across the work packages into competency questions, stakeholder requirements, and modeling objectives that guide ontology development. The GCO focuses on interdisciplinary research on green charcoal, integrating environmental, agricultural, engineering, and socio-economic knowledge across the value chain, from biomass sourcing to market distribution. Its primary objective is to formulate the competency questions (CQs) developed by the researchers during the ontology requirements analysis phase to define the scope and knowledge-retrieval capabilities of the GCO. They were derived from UPCHAIN research workflows, focus group discussions (FGDs), analysis of existing datasets, and interactions with researchers across work packages, which identified the key knowledge relationships required to integrate production, market, and spatial information. To test the ability of the GCO to facilitate semantic integration across work-packages, two representative CQs were chosen for this study:

- CQ1: What is the complete provenance chain of a green charcoal product, including biomass feedstock species and sourcing location, carbonization process and responsible agents, production sites, quality monitoring records, and final market distribution to end users?
- CQ2: How does green charcoal product quality, together with the sustainability characteristics of biomass feedstock, influence market demand, pricing, and end-user adoption across different market segments in Northern Uganda?

The CQs supported the ontology scope definition process by determining which concepts, properties, relationships, and constraints were necessary. They were then used as assessment criteria to evaluate the ontology's ability to support interdisciplinary knowledge retrieval. Independent domain experts will refine all these during the Research Data Management System implementation.

Ontology Design

The GCO was designed as a modular semantic model to represent and integrate knowledge across WPs, operating as independent modules linked through defined relationships while maintaining domain autonomy. The ontology consists of three interconnected modules: WP1 (Production and Quality Control), WP3 (Markets and Livelihoods), and WP5 (Geospatial and Raw Materials sharing a common semantic foundation, with hierarchical classes representing general concepts (abstract superclasses), domain-specific subclasses, and specialized leaf classes such as GCProductionProcess, GCMarketActor, and BiomassZone class for spatial reasoning in line with GeoSPARQL geo: Feature. Cross-module object properties: suppliesReceipt, resultsInReceipt, locatedInZone, correspondsToReceipt, and tracksSalesOf were defined to connect production, market, and geospatial knowledge, enabling semantic integration while preserving modularity, extensibility, and clear ownership of domain knowledge. Figure 1 illustrates the logical architecture of the Green Charcoal Ontology, showcasing the three domain modules, their internal class hierarchy, and the semantic relationships linking them, with a focus on conceptual organization rather than software implementation.

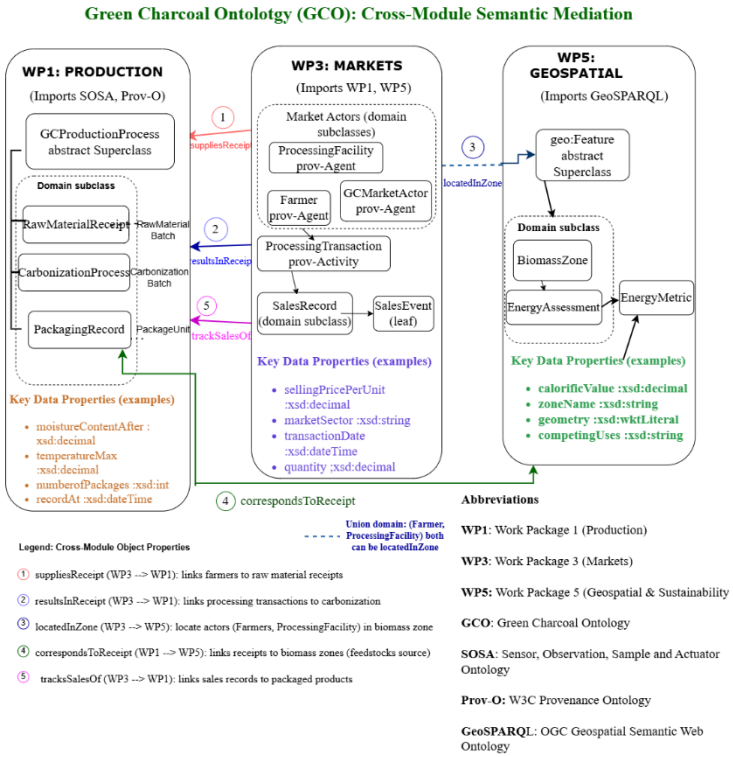

Figure 1. Green Charcoal Ontology (GCO) modular design architecture showing domain modules and cross-module semantic relationships. The logical design specifies the semantic interactions required to integrate interdisciplinary knowledge. Importantly, the union-based domain of locatedInZone allows multiple types of entities, such as farmers and processing facilities, to be associated with a shared spatial location, thereby facilitating spatial inference in production and market activities. Likewise, suppliesReceipt relates market actors to biomass receipts for tracking and reporting purposes; resultsInReceipt associates various production processes with their products; correspondsToReceipt links spatial information about biomass to sourcing information; and tracksSalesOf links market transactions to the produced charcoal products. Together, these semantic relations enable knowledge sharing in the three domains while maintaining the independence of the ontology modules. The ontology design is also based on existing Semantic Web vocabularies to maximize interoperability and reduce duplication of semantic concepts. For observations and sensing activities, SOSA/SSN was selected, PROV-O for the representation of provenance, and GeoSPARQL for spatial entities and spatial relationships. The use of these common vocabularies provides compatibility with existing semantic resources and consistency with FAIR-oriented ontology engineering practices.

7. Ontology Implementation

The GCO was implemented using the W3C Web Ontology Language (OWL) framework, specifically OWL 2 DL, for formal semantic representation, decidable reasoning support, and interoperability with Semantic Web technologies. The ontology was developed in Protégé v5.6.9, which provided the environment for defining ontology classes, object properties, data properties, class hierarchies, and logical axioms. It also supported ontology visualization, ontology imports, consistency checking, and iterative refinement throughout the implementation process. The modules were implemented as separate OWL 2 DL files, serialized in Turtle (TTL), to support portability, reuse, and integration with Semantic Web environments. The modules maintained independent domain ownership while enabling semantic integration through controlled ontology imports and

cross-module object properties. The class hierarchy follows a three-tier structure of superclasses, domain subclasses, and leaf specializations. At the same time, object and datatype properties are defined using XML Schema datatypes *(xsd: decimal, xsd: string, xsd:dateTime)*. Cross-module semantic interactions were implemented through five object properties, the only permitted relationships to span ontology modules. All other object properties remained within their respective modules, preserving modularity and minimizing semantic coupling. Restricting inter-module interaction to these five semantic bridges reduced reasoning complexity, simplified ontology maintenance, and enabled cross-module competency-question evaluation using standard SPARQL queries. Logical constraints identified during ontology design were encoded using OWL 2 DL class restrictions, enabling automatic reasoning over ontology concepts. To complement OWL's open-world semantics, data integrity constraints were implemented separately using SHACL node shapes, enabling validation of instance data against predefined business rules, such as quality thresholds and mandatory property constraints. Specifically, WP3 imports WP1 and WP5 to access shared concepts and to establish relationships among the production, market, and geospatial knowledge domains, while preserving the separation of concerns. Established Semantic Web vocabularies were imported into the GCO. SOSA represents production observations and quality assessments, sensing activities, and measurements, PROV-O captures provenance across production, market, and geospatial processes through Activity, Agent, and Entity to support traceability of research data, and GeoSPARQL supports spatial modeling of BiomassZone for location-based reasoning. These reused vocabularies strengthened alignment with existing semantic standards and supported FAIR representation. Figure 2 (a-c) presents the implemented GCO ontology graph, illustrating the internal structure of the three modules, imported vocabularies, and the semantic connections established between them. WP1 module in Figure 2a shows the production pipeline with eight distinct stages (receipt, milling, mixing, binder preparation, extrusion, drying, carbonization, transport), each generating its own data. Therefore, GCProductionProcess is an abstract superclass (the green-highlighted node in Figure 2a), with each stage as a subclass, and can be queried as a whole or stage-by-stage. The Activity node in Figure 2a shows that each subclass also inherits prov: Activity, since every stage is, in provenance terms, an activity that consumes one entity and produces another. The chain can be traversed using standard PROV-O properties (wasGeneratedBy, wasInformedBy) instead of custom WP1-only properties. Figure 2a also shows the populated data consisting of six CarbonizationProcess and six RawMaterialReceipt individuals, one per production chain.

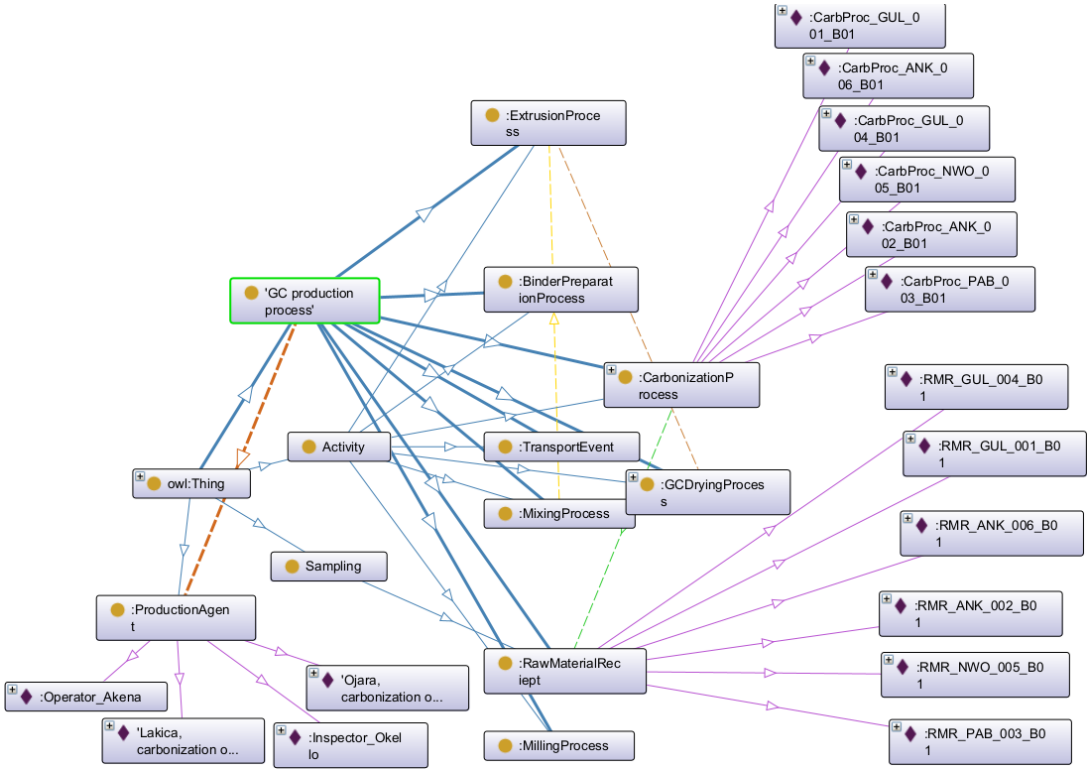

Figure 2a. WP1 Production Process Hierarchy and Populated Carbonization Process and Raw Material Receipt Instances

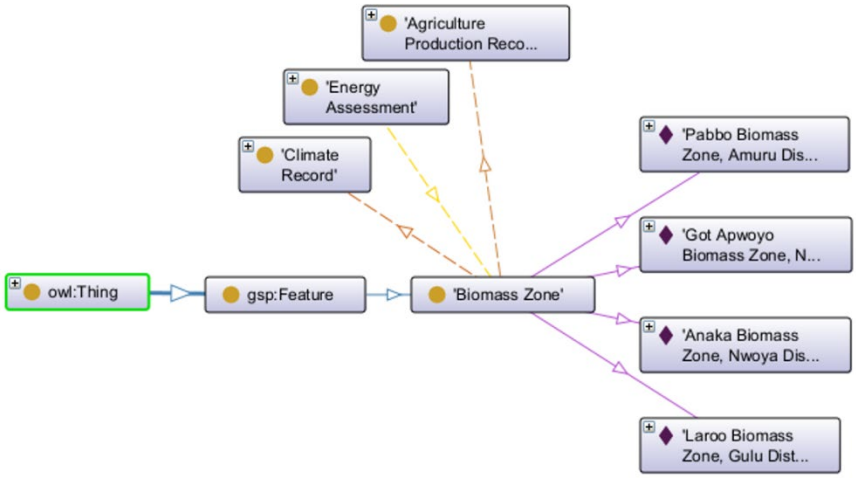

Figure. 2b. WP5 BiomassZone as a subclass of GeoSPARQL geo: Feature, with aggregated climate, production, and energy records

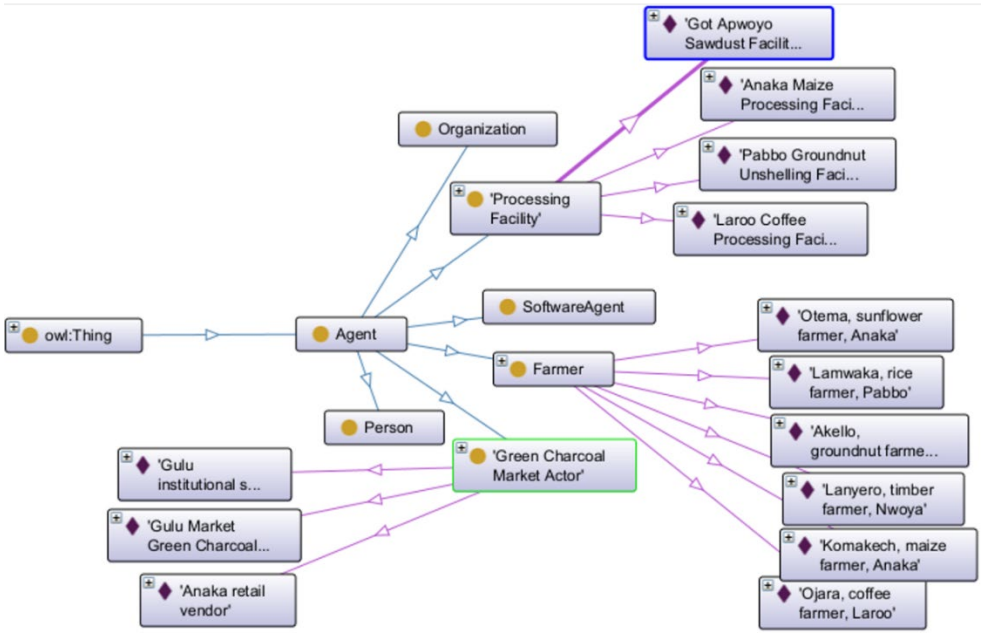

Figure 2c. WP3 Actor Model: Farmer, ProcessingFacility, and GCMarketActor as separate prov: Agent subclass

WP3 (Market and Livelihood) (Figure 2c) was modeled using a role-based agent structure. Farmer, ProcessingFacility, and GCMarketActor were defined as subclasses of prov: Agent to distinguish production, processing, and market roles. ProcessingTransaction was represented as a prov: Activity, while SalesRecord and SustainabilityRecord were modeled as *prov: Entity* instances to capture transaction and sustainability information. MarketSector was implemented as a controlled vocabulary with predefined individuals (Household, School, Restaurant, and Institution) to support consistent querying and reasoning. As the semantic bridge between WP1 and WP5, WP3 implements cross-module properties including suppliesReceipt, resultsInReceipt, locatedInZone, and tracksSalesOf. The module was populated with representative instances of farmers, processing facilities, and market actors for reasoning, validation, and competency-question evaluation. WP5 (Geospatial module) (Figure 2b) is centered on BiomassZone, modeled as a subclass of GeoSPARQL's geo: Feature to support standardized spatial semantics and querying. Environmental observations, represented by *ClimateRecord, AgricultureProductionRecord,* and *EnergyAssessment*, are modeled as subclasses of prov: Entity and linked to biomass zones via the semantic object properties *hasClimateRecord* and *hasProductionRecord*. Cross-module interoperability is achieved through the correspondsToReceipt property, which connects energy assessment records with production data in WP1. Although ENVO was evaluated for environmental representation, it introduced unnecessary semantic complexity and significantly increased reasoning overhead. A lightweight environmental ontology tailored to the study requirements was therefore developed, providing the required functionality while maintaining computational efficiency. The module was populated with four BiomassZone instances and six EnergyAssessment instances used during ontology evaluation.

8. Evaluation

The GCO was evaluated through a DSRM artifact evaluation process, as an experimental validation approach using the HermiT OWL reasoner within Protégé 5.6.9. The complete ontology and its imported modules were successfully loaded in 7.32 s, while ontology classification and inference computation required 1.27 s. The reasoning process pre-computed six categories of inferences, including class hierarchy, object property hierarchy, data property hierarchy, class assertions, object property assertions, and same-individual reasoning, without reporting logical inconsistencies. These results demonstrate that the proposed ontology can be efficiently classified within the proof-of-concept implementation, thereby supporting semantic consistency and interoperability. Given the multidimensional nature of ontology quality, a multi-method evaluation strategy was adopted to assess four key dimensions: logical correctness, data quality, constraint compliance, and functional knowledge retrieval with semantic interoperability. Logical consistency and inference capabilities were evaluated using OWL 2 DL reasoners, specifically HermiT, which supports expressive OWL constructs crucial to the ontology's implementation. Other reasoning engines, such as Pellet, FaCT++, and ELK, were explored, but HermiT was chosen for tasks such as classification and detection of unsatisfiable classes. Data quality was verified using SHACL with pySHACL, in which domain constraints were encoded as SHACL shapes, and RDF instances were assessed against these shapes to identify non-conforming records, particularly those that violated predefined quality requirements. The functional adequacy and knowledge retrieval capabilities were assessed through DL Query within Protégé and SPARQL queries based on competency questions. DL Query was used to verify ontology-level retrieval and inferred knowledge. At the same time, competency questions derived from domain requirements were translated into SPARQL queries to evaluate whether integrated knowledge across WP1, WP3, and WP5 could be retrieved through the defined semantic relationships. These experimental evaluation methods provided evidence that the GCO artifact satisfied its intended objectives by maintaining logical consistency, enforcing domain constraints, and enabling semantic integration and retrieval across interdisciplinary research domains.

9. Communication

This phase disseminates the developed GCO through this publication to researchers, ontology engineers, and practitioners involved in interdisciplinary research data management. The paper presents the ontology specification, design, implementation, and evaluation, demonstrating its ability to integrate heterogeneous Green Charcoal research data through a shared semantic model. By documenting the ontology engineering process and validation results, this publication contributes a reusable ontology artifact that supports semantic interoperability and provides a foundation for similar interdisciplinary research domains.

IV. RESULTS

1. Ontology Structural Integrity

Before evaluating logical consistency, the integrated ontology's structural metrics were meticulously inspected using Protégé 5.6. This step was crucial to confirm that the three work-package modules merged faultlessly without namespace conflicts or declaration errors. The merged ontology comprises 2,674 axioms, including 979 logical axioms, 73 classes, 91 object properties, 103 data properties, and 89 individuals. The absence of conflicting declarations and unintended equivalence relationships indicates that the imported modules were successfully integrated into a unified ontology network. This structural integrity is essential to ensuring the ontology functions effectively across various research domains, as it maintains semantic coherence and facilitates interoperability among diverse datasets. To further validate the ontology's logical consistency, it was processed using the HermiT reasoner, which completed the evaluation in 1373 milliseconds (ms). This rapid processing time demonstrates the efficiency of the ontology's design and the effectiveness of HermiT in handling

complex reasoning tasks. The successful classification of the merged ontology without structural conflicts or unsatisfiable classes reinforces the reliability of the GCO as a robust semantic model for interdisciplinary research.

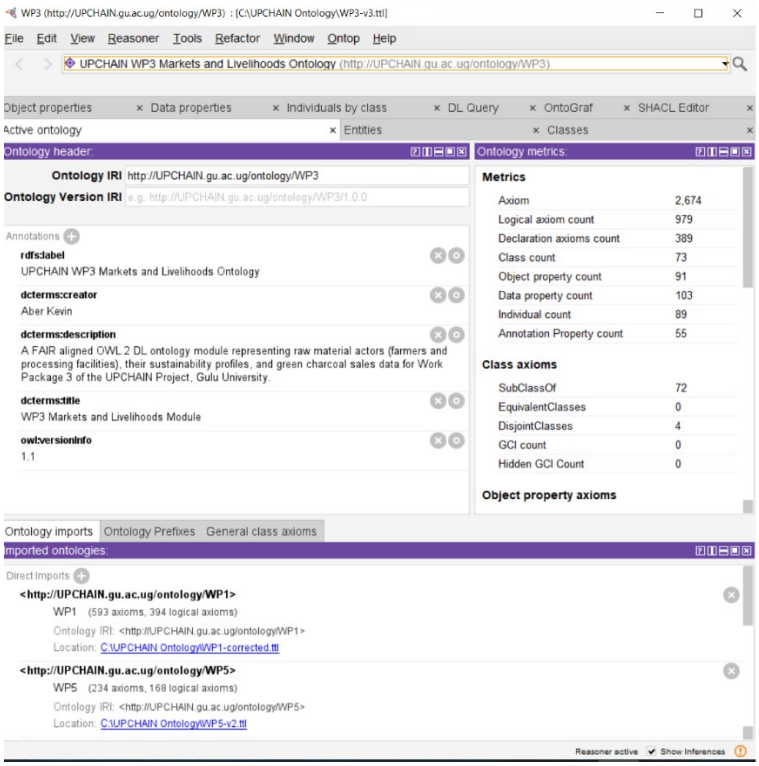

Figure 3. Ontology metrics of the merged WP3 ontology module importing WP1 and WP5.

2. SHACL Constraint Validation

While OWL reasoning effectively verifies the ontology's semantic consistency, it does not enforce instance-level quality constraints due to the open-world assumption inherent in OWL. To address this limitation, SHACL validation was employed using pySHACL to assess the compliance of populated RDF instances against specific domain constraints. In this evaluation, six CarbonizationProcess individuals were scrutinized against the defined SHACL shapes. The validation results indicated a "Conforms: False" status, revealing two instances: CarbProc_ANK_006_B01 (16.9%) and CarbProc_PAB_003_B01 (18.5%) that exceeded the established moisture-content threshold of 15%, as in Figure 4a. This finding is significant because it highlights potential quality issues in the data that could affect downstream applications and decision-making in the green charcoal production sector. To further validate the consistency of the encoded quality rules, the moisture constraint was independently assessed using a DL Query executing in 132 ms, as shown in Figure 4b. The query expression: *{CarbonizationProcess} and (moistureContentAfter some } xsd:decimal[<=15.0])* returned four of the six CarbonizationProcess individuals: *CarbProc_ANK_002_B01, CarbProc_GUL_001_B01, CarbProc_GUL_004_B01, and CarbProc_NWO_005_B01*. Notably, these results correspond precisely to the complement of the two instances identified by SHACL validation, reinforcing the reliability of the quality constraints. The agreement between the findings from OWL-based reasoning and SHACL validation provides convergent evidence that the quality constraints were accurately represented at both the semantic and data validation levels. This dual validation approach not only enhances the ontology's robustness but also ensures it

effectively captures and enforces critical quality parameters necessary to maintain data integrity in interdisciplinary research contexts. The identification of non-conforming instances serves as a crucial feedback mechanism for refining the ontology and improving data quality management practices.

3. Competency Question and Cross-Domain Retrieval Evaluation

The functional capability of the Green Charcoal Ontology (GCO) was rigorously assessed through competency questions derived from a comprehensive analysis of domain requirements. These questions were translated into SPARQL queries and executed against a populated knowledge graph containing 1,343 triples from Work Packages 1, 3, and 5, as illustrated in Figure 5 (a & b). CQ1 aimed to determine whether the ontology could effectively trace the complete chain of a batch from feedstock to market. The results, depicted in Figure 5a, revealed six unique entries, each detailing specific associations among feedstock, production agents, moisture readings, and market sectors. The absence of repetitions in the provenance chains indicates that the ontology successfully preserves per-batch provenance. This finding confirms that the GCO accurately links production entities to market actors while preserving distinct details, thereby meeting the structural coverage criteria essential for effective data management.

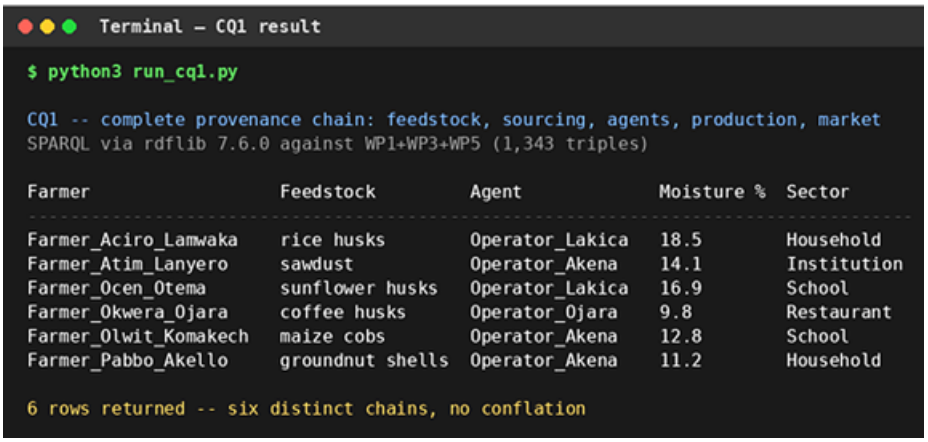

Figure 3. CQ1 Result: Six Distinct Provenance chains, one per farmer, each with a different feedstock, agent, and market sector

CQ2 focused on evaluating the economic relationship between batch quality and market outcomes as represented in the ontology. The results highlighted in Figure 5b demonstrated a clear trend: as moisture content increased, the calorific value decreased, leading to declines in both selling price and quantity sold. Notably, the two batches labeled as "Rejected," with moisture contents of 16.9% and 18.5%, recorded the lowest selling prices and quantities. These batches were also identified as SHACL violations, which were excluded from the DL query results. This consistency reinforces the ontology's capability to identify out-of-specification batches across multiple evaluation layers, ensuring that quality control measures are effectively integrated into the data management process.

Figure 4. CQ2 Result: Selling Price and Quantity sold fall as quality falls, rejected batches sit at the lowest

Throughout the evaluation, the two batches, CarbProc_ANK_006_B01 and CarbProc_PAB_003_B01, were consistently flagged as non-conforming quality instances through various validation methods, including SHACL constraint validation, OWL 2 DL class-expression reasoning, and SPARQL-based competency queries. Furthermore, the merged ontology was successfully classified, with no structural conflicts or unsatisfiable classes detected by the reasoner. The convergence of results from these complementary evaluation approaches provides robust evidence of the ontology's validity. Each method examines distinct quality dimensions: structural

coherence, logical entailment, data-constraint compliance, and functional knowledge retrieval, demonstrating that the GCO is a logically consistent and interoperable semantic model for interdisciplinary green charcoal research. Through this modular ontology design and reusing established Semantic Web vocabularies, the GCO operationalizes FAIR principles, significantly enhancing the findability, accessibility, interoperability, and reuse of heterogeneous research knowledge. This comprehensive evaluation underscores the ontology's potential to facilitate effective data integration and management in complex research environments, ultimately supporting informed decision-making in the green charcoal sector.

V. DISCUSSION

This study highlights the significance of ontology-driven semantic mediation in enhancing interdisciplinary research integration, particularly through the Green Charcoal Ontology (GCO). The findings underscore that effective semantic interoperability transcends technical data exchange, focusing instead on coordinating meaning across diverse knowledge practices. The GCO's successful integration of production, market, and geospatial concepts illustrates that achieving interoperability does not require replacing existing data infrastructures or enforcing complete conceptual agreement across disciplines. Instead, it establishes a shared semantic layer that connects independently managed datasets while preserving the autonomy of domain-specific practices. The GCO functions as a formal semantic boundary object, facilitating collaboration among research communities while allowing each domain to retain its unique interpretations and practices. This perspective aligns with Star and Griesemer's [20] concept of boundary objects, emphasizing that ontology development is not merely a computational modeling task but a process of negotiating shared meaning across different knowledge systems. This is particularly crucial in sustainability research, where integrating scientific measurements, spatial observations, stakeholder experiences, and socio-economic knowledge is essential to addressing complex research questions. A key implication of this study concerns the representation of knowledge from qualitative and contextual research. Unlike many ontology-based integration approaches developed around structured quantitative datasets with relatively stable schemas, UPCHAIN involves knowledge generated through field practices, stakeholder interactions, and domain-specific interpretations. Such knowledge cannot always be captured through direct schema transformation. The development of GCO therefore required practice-informed concept identification, competency questions, vocabulary alignment, and iterative modeling to capture contextual meanings while maintaining machine interpretability [40–42]. This demonstrates the importance of grounding ontology engineering in the practices through which knowledge is produced. This practice-informed approach supports Carlile's view that interdisciplinary collaboration depends on exchanging and transforming knowledge, rather than merely transferring data [43]. The study further contributes to discussions on global versus modular ontology architectures. While universal ontologies aim to achieve broad conceptual consensus, complete alignment across interdisciplinary research communities is difficult because disciplinary assumptions, research objectives, and local contexts shape concepts. Conversely, highly specialized ontologies may provide detailed representation but limited interoperability beyond their original domain. The modular hybrid architecture adopted in GCO addresses this tension by maintaining work-package-specific concepts while establishing semantic bridges through shared concepts and reused Semantic Web vocabularies. This demonstrates that interoperability does not require identical conceptual models but mechanisms that enable meaningful alignment between heterogeneous perspectives [25]. Beyond semantic integration, the GCO serves as the semantic blueprint for the Research Data Management System (RDMS). It defines core entities, relationships, provenance structures, and validation constraints that guide system implementation while remaining independent of specific technologies. Unlike conventional integration approaches that primarily rely on structural mappings or relational joins, the ontology explicitly represents domain meaning and enables reasoning, provenance tracking, and future system extensions. The combined use of OWL reasoning, SHACL validation, and competency-question evaluation provides a layered quality assurance approach that assesses logical consistency, data conformity, and practical usability [44]. This reinforces the view that FAIR implementation requires more than metadata availability; it requires machine-interpretable representations of concepts, relationships, and provenance [10], [11], particularly in research environments where heterogeneous

systems must continue to operate independently [45]. The practical impact of the ontology extends to multiple stakeholder groups, including researchers, data managers, GIS specialists, field researchers, and future data users. Before GCO, datasets generated by different work packages required substantial manual interpretation and reconciliation before cross-domain analysis could be performed. The ontology enables researchers to query relationships between biomass resources, production characteristics, spatial distributions, and livelihood outcomes within a shared semantic environment. Thus, its contribution is not only the formal representation of domain concepts but also the creation of an infrastructure that supports interdisciplinary knowledge discovery and data reuse. By reusing established Semantic Web vocabularies, including SOSA, PROV-O, and GeoSPARQL, locally developed research concepts align with international standards while preserving contextual and cultural knowledge relevant to the project. This makes the framework transferable to similar interdisciplinary and resource-constrained research environments. This approach is particularly relevant for resource-constrained research environments where replacing existing infrastructures may be impractical. By introducing a semantic layer over existing systems, ontology-driven mediation provides an incremental pathway toward FAIR-aligned research ecosystems. This is valuable in African research contexts, where fragmented infrastructure, limited technical capacity, and isolated data repositories remain barriers to effective reuse of research data [35], [36]. The study demonstrates that semantic interoperability can be progressively achieved without disrupting established data collection practices. Several limitations remain. The evaluation was conducted as part of a single interdisciplinary research project, and wider adoption across institutions and domains requires further validation. In addition, ontology reuse required balancing semantic richness, reasoning performance, and maintainability. Future work will investigate broader stakeholder validation, larger-scale datasets, automated FAIR assessment, and integration within federated research infrastructures. Nevertheless, the findings demonstrate that practice-informed, modular ontology engineering provides a practical and scalable approach for enabling FAIR-aligned semantic interoperability while preserving the contextual meanings embedded within interdisciplinary research practices.

VI. CONCLUSION

This study presented the Green Charcoal Ontology (GCO), a FAIR-aligned, ontology-driven semantic mediation framework to improve interoperability across heterogeneous interdisciplinary research data environments. Using the UPCHAIN project as an empirical case, the framework integrates production, market, and geospatial knowledge through a practice-informed ontology that aligns local research concepts with established Semantic Web standards, including SOSA, PROV-O, and GeoSPARQL. The evaluation demonstrated that GCO supports logical consistency, data quality validation, and cross-domain knowledge discovery through OWL reasoning, SHACL validation, and competency-question-based SPARQL queries. Beyond enabling semantic integration, the GCO provides a conceptual blueprint for the Research Data Management System (RDMS) by defining shared concepts, relationships, provenance structures, and validation mechanisms required for interoperable research workflows. The findings highlight that achieving FAIR interoperability requires more than standardized metadata; it requires explicit representation of meaning, context, and relationships across research domains, positioning ontology development as both a technical and practice-grounded process. This work demonstrates how semantic models can support collaboration among diverse research communities while preserving domain-specific knowledge practices. Future work will investigate broader stakeholder validation, deployment across additional research domains, automated FAIR assessment, and integration within federated research data infrastructures. The proposed approach provides a practical foundation for advancing semantic interoperability and the development of reusable research data ecosystems, particularly in interdisciplinary and resource-constrained environments.

ACKNOWLEDGEMENT

The authors gratefully acknowledge the UPCHAIN project team for their valuable contributions throughout this research. We also thank the youth group in Pabbo for their participation in the field experiments and data collection that informed the development of the ontology. This work was financially supported by the Ministry of Foreign Affairs of Denmark.

Abstract
The rapid growth of distributed energy resources in modern grid topologies brings significant operational challenges, including transformer overloads and voltage constraint violations caused by unexpected generation and consumption across the grid. Resolving these incidents requires curtailment allocation algorithms that coordinate the available flexibility of DERs according to prioritized criteria. This paper presents a formal comparative analysis of four curtailment allocation algorithms from an active network management perspective. Equal-percentage curtailment enhanced by a water-filling mechanism, capacity-ranked minimum DER-count greedy curtailment, merit-order curtailment, and grid-aware curtailment methodologies have been compared within this DER management framework. A benchmark scenario involving nine PV-based DERs was constructed using IEEE 123-bus QSTS feeder data from the Open Energy Data Initiative to reveal differences among these four strategies. According to the results, no single strategy dominates across all other methodologies. The most suitable choice for different situations depends on whether the system operator prioritizes fairness, operational simplicity, or economic efficiency, as well as on contract types. Rather than proposing a universally optimal allocation method, this study provides a transparent framework for selecting a curtailment strategy based on the operator's priorities and available grid information.

Keywords: greedy algorithms, distributed energy resources, DER curtailment, active network management, network constraint optimization, smart grid

I. INTRODUCTION

The global energy transition in grid networks has progressed rapidly in recent years. This growth mainly stems from the increasing number of distributed energy resources across all grid layers, including low-, medium-, and high-voltage layers. Electric vehicle chargers, roof photovoltaic systems, and heat pumps are becoming more widespread day by day. With this change, the conventional grid topology is evolving, shifting the unidirectional power-flow characteristic from generator-side equipment to consumer-side equipment [1]. As DER penetration in grid networks increases, operators at grid operations centers face increasingly challenging situations in maintaining grid stability while allocating these DERs within their operational boundaries. Reverse power flow, transformer overload, and congestion among feeders are the most frequent effects of the increasing number of DERs [2]. Conventional grid management methodologies, such as open-close switches, are inadequate for this kind of new-generation grid network enriched with distributed energy resources. At this very point, the active network management paradigm stepped onto the stage with the aim of solving these types of problems. Instead of changing the network topology as seen in traditional approaches, this approach benefits from real-time monitoring and resource control over grid systems, while managing these distributed energy systems within their operational limits based on congestion [1]. In this manner, grid assets are continuously monitored for their measurement values, and control operations are determined in control rooms using software systems. These

operations are decided, calculated, and sent to grid systems to relieve the congestion in grid networks [3]. Recent research has offered a congestion management perspective that includes direct DER control, local flexibility markets, and flexible tariffs, all of which introduce different operational requirements and trade-offs [4],[5]. The power of active network management rises from the ability to modulate DER output. This modulation applies to both generation and consumption units. This requires both awareness of device capacities and evaluation of each device's topological position within the grid network and its influence at the grid level [6],[7],[8]. When a grid network violation is detected, the operator needs to determine which DERs to curtail and how much to curtail them. This curtailment allocation problem can be addressed using various algorithmic approaches that address different criteria, such as operational objectives, optimality criteria, and correctness factors. The present paper focuses on the design and evaluation of curtailment allocation strategies for heterogeneous DER pools. Specifically, four different greedy algorithms, which differ in their optimization objectives, data requirements, and behavioral properties, are used for the curtailment allocation problem. Compared with network-constrained power flow methodologies, which require detailed network models and may impose significant computational and data management requirements, the evaluated approaches rely on sorting and simple iterative calculations [5],[9]. Thanks to sorting-based implementations, analyzed algorithms can operate with O n log n), O (n), or O (n) sağ parantez time complexity, where n represents the number of DERs connected to the grid. Grid operators may choose different strategies for congestion cases, such as prioritizing fairness across DERs, minimizing the number of affected equipment, optimizing operational cost efficiency, and applying the operation that provides the greatest relief at a specific location on the grid. These strategies have different consequences for DER owner experience, system economics, and grid operations. Recent fairness-focused studies show that fairness, economic benefits, and network effectiveness may lead to different allocation outcomes and may not be optimized simultaneously [10],[11]. The analysis presented in this work aims to provide a structurally and practically grounded comparison among these strategies to inform decisions on the design and configuration of smart grid management platforms. Related to this, the main contribution of this work is not the introduction of a new superior algorithm, but the comparison of four perspectives: proportional fairness, minimum DER activation, economic priority, and electrical effectiveness.

II. RELATED WORK

Over the past two decades, energy grids have evolved to include more distributed energy resources, and the challenges of this process have begun to rise. To prevent congestion in grid networks, curtailment of DERs is treated as the last resort by early active network management systems; only generation-side curtailments were applied as a solution, since they are seen as more acceptable from a cost perspective [1],[12]. Later adoptions were directed toward the consumption-side flexibility and voltage regulation operations, which provide more comprehensive efficiency and fairness in real-time network management [13]. More recent research classifies distribution-level congestion management into direct control mechanisms, local flexibility markets, and tariff-based approaches. The applicability of these mechanisms is highly dependent on network conditions, local regulations, available information, and client-side objectives [4]. According to the current active network management literature, curtailment allocation strategies can be evaluated from two different perspectives: optimization and computational differences. Proportional curtailment, in which each DER connected to the grid contributes the share of the curtailment amount based on its proportional availability, due to its simplicity and fairness [14]. However, this solution should be supported by a water-filling mechanism to ensure feasibility by iteratively redistributing the remaining curtailment amount among the DERs that still have availability to curtail. Recent fairness-oriented research has shown that equal, proportional, and dynamic allocation approaches can yield different curtailment distributions even when they satisfy the same network constraints [10]. Fairness-based methodologies can prevent situations in which the system repeatedly curtails a specific DER owner. However, regarding fairness-based strategies, this approach may involve trade-offs that result in higher total

system curtailment while compromising economic efficiency [11]. Another possible operational approach is to minimize the number of DERs involved during curtailment operation. In this study, this objective is represented by a capacity-ranked minimum DER count greedy methodology that curtails higher-capacity DERs first. This approach can reduce the number of control commands affecting grid assets and, accordingly, contractual interactions. However, it does not take into account the fairness and cost-effectiveness of each DER, so it is treated as an operational-simplicity heuristic rather than an optimal congestion-management strategy. The merit order curtailment approach adopts the perspective of curtailing the cheapest resources first, once available, and provides a cost-optimal solution for congestion cases [15]. When partial curtailment is allowed according to clients' contract types, the allocation problem begins to resemble a fractional resource allocation problem rather than the classical knapsack problem [16]. Ordering DERs based solely on their curtailment costs is cost-optimal only when all curtailed units provide the same amount of violation relief. In cases where electrical sensitivities differ, a cost-to-relief metric may be required. In that sense, more complex market-based approaches incorporate congestion pricing, demand-response preferences, and client-based constraints into their methodologies [17]. While these strategies provide a comprehensive representation of economic behavior, they should be informed by additional market, contractual, and operational data, unlike a simple merit order mechanism. Grid-aware curtailment is a solution in which curtailment decisions are made based on the weighted electrical influence of each DER on the grid network. This approach is considered in the context of optimal power flow decomposition and distributed grid control operations within the grid network [18], [19]. To benefit from this approach in real-time solutions, power transfer distribution factors and voltage sensitivity coefficient values need to be prepared offline for efficient calculations, provided network topologies remain the same over long-term executions [6]. Recent voltage sensitivity-based control approaches use active and reactive power sensitivity matrices to identify location-aware effects of DERs and to inform voltage management decisions [7]. Sensitivity coefficients have also been applied to flexibility management, involving both node-voltage and line-loading constraints [8]. In recent studies, comprehensive alternating-current optimal power flow-based distribution systems have begun to emerge, and their flexibility platforms are designed to evaluate network constraints, flexibility offers, and operational schedules simultaneously [5]. These formulations may yield more feasible and optimized decisions based on network and economic criteria, but they heavily rely on detailed grid models and extensive input data on grid assets. In situations lacking such data, model-free reinforcement learning methods have also been proposed to learn fair DER curtailment strategies [20]. Such approaches reduce overall dependence on additional data but require training iterations to provide meaningful operational predictability. Existing studies provide advanced solutions for individual objectives such as fairness, market efficiency, network feasibility, and model-free perspectives; however, this study simultaneously compares four operational principles: proportional fairness, minimum DER activation, merit order cost priority, and sensitivity-based grid effectiveness. It is described how grid operators' preferred allocation strategy changes depending on the objective and the available data on grid networks.

III. EXPERIMENTAL STUDY & ANALYSIS

1. System Model

Within the scope of this study, the distribution network monitored by an active network management framework is considered. With that, the operator can monitor real-time telemetry data from a grid network with n flexible distributed energy resources connected. Each DER also has set of operational parameters such as its current output a_i minimum opratioal limits min_i and maximm ratd apacity max_i. Full notation use throughout the paper is given in Table 1. The allocation problem is evaluated for a single operational perspective, where the curtailment decision is made. The corresponding active network management framework performs the identification of single eligible DERs and calculation of the required relief. This study focuses specifically on

the subsequent allocation of requirements among the eligible DERs. For grid-aware curtailment, sensitivity coefficients are assumed to remain valid during the allocation interval and to be recalculated upon physical changes in network topology or operating conditions.

2. Violation Detection and Curtailment Trigger

Thanks to the active network management framework, once a constraint violation is detected for a specific network element, the grid operator can trigger a curtailment event. These violations may be line or transformer overload that corresponds to the network.

Table 1. Variables and variable descriptions used in the current study

Variable Name	**Description**
n	Number of flexible DER assets
a_i	Current analog value of DER i
min_i	Minimum allowed operating value of DER i
max_i	Maximum rated value of DER i
k_i	Curtailability factor of DER i, $k_i \in (0,1]$
h_i	Available curtailment amount, $h_i = a_i - min_i$
q_i	Maximum realizable curtailment, $q_i = k_i \cdot a_i - min_i$
c_i	Curtailment cost of DER i
s_i	Electrical sensitivity coefficient of DER i with respect to the violated element, $s_i \in (0,1]$
C_{req}	Total curtailment amount
x_i	Curtailment amount assigned to DER i, $0 \leq x_i \leq q_i$
I_{req}	Required weighted electrical relief for the violated network element in the grid-aware formulation

element exceeds its rated capacity, or overvoltage events in network elements that exceed the upper bounds defined by grid constraints. In such cases, the grid operator computes the required aggregate curtailment amount, Calt req, and then provides it as input to curtailment allocation algorithms. Calculation of the active network management framework and kept identical for all aggregate-based curtailment algorithms. This separation allows us to compare only allocation decisions produced by the algorithms under the same detected violation. For the grid-aware curtailment algorithm, the operator provides the required impact value I alt req, which is derived from the magnitude of the detected violation. Resunokta s alt i, büyük veya eşittir I alt req , son toplama, where the left-hand side represents cumulative weighted electrical relief provided for violated network equipment.

3. Curtailment Allocation Problem

Upon detection of a violation incident and the required curtailment amount, the Calt req is calculated by the operator. The curtailment allocation problem is addressed by determining a vector of curtailment assignments x eşittir (x alt 1,x alt 2 ,…, x alt n)which satisfies the following feasibility constraints.

$$\sum_{i=1}^{n} x_i \geq C_{req}, \quad 0 \leq x_i \leq q_i, \quad \forall i \in \{1,\ldots,n\} \tag{1}$$

First constraint within the (1) ensures that total curtailment is sufficient, so that it can solve the violation, and the second constraint ensures each DER is curtailed inside its physical and contractual boundaries.

In the grid-aware algorithm, aggregate curtailment is replaced by a location-specific feasibility condition.

$$\sum_{i=1}^{n} x_i \cdot s_i \geq I_{req}, \quad 0 \leq x_i \leq q_i, \quad \forall i \in \{1,\ldots,n\} \tag{2}$$

Regarding to (2), aggregate-curtilment instance is feasible when $\sum_{i=1}^{n} q_i \geq C_{req}$ while, grid-aware instance is feasible when $\sum_{i=1}^{n} q_i \cdot s_i \geq I_{req}$. If corresponding condition is not satisfied, that means, available DER flexibility is insufficient to resolve the violation and algorithm reports the allocation problem as infeasible.

Along with the feasibility, different types of secondary objectives may apply depending on priorities of grid operator based on contract types such as providing fair curtailment distribution among DERs, minimizing the number of curtailed DERs by reducing communication overhead to the grid, minimizing the total cost of curtailment applied to the grid, and prioritizing DERs whose electrical locations enable the most effective relief to the violated network element. The following allocation obctives represent these operational priorities: proportion utilization distribution atoplama, and available DERs, minimization of $\sum_{i=1}^{n} c_i \cdot x_i$ and minimization of $\sum_{i=1}^{n} x_i$ subject to location-specific relief toplama, subject (2), respectively.

4. Algorithmic Details

This paper analyzes four different curtailment algorithms: equal-percentage curtailment, capacity-based greedy curtailment that minimizes the number of affected DERs, merit-order (cost-based) curtailment, and grid-aware curtailment.

5. Algorithm Selection

Four strategies were predetermined to represent different grid operator objectives and to provide deterministic allocation rules under DER-level constraints. Equal percentage curtailment represents proportional burden sharing; minimum DER count curtailment aims to reduce the number of controlled assets; merit order curtailment prioritizes economic efficiency; and grid-aware curtailment targets DERs according to their electrical effectiveness while relieving violations on grid networks. Strategies also differ in their data requirements. Equal percentage and minimum DER count strategies use DER curtailment limits while merit order and grid-aware solutions require unit cost and electrical sensitivity data, respectively. Considering these, four curtailment methodologies provide a basis for examining how grid operator priorities and data availability affect curtailment strategy selection.

6. Equal Percentage Curtailment

Algorithm gets set of DERs (n) and required curtailment amount C_{req} as an input and outputs per-DER curtailment alocation x_i such that $\sum_{i=1}^{n} x_i = C_{req}$ whenever aggregate available flexibility is sufficient.

Each DER gets a curtailment share based on its availability, h alt i=a alt i eksi alt simge taban , min , son taban , alt i, considering their operational limits, alt simge taban , m i. n , son taban , alt i, and alt simge taban , m a. x , son taban , alt i. As a result of the water-filling approach, each DER fulfilling its available curtailment share in the current iteration is removed from the next iteration. This process terminates when $C_{req}$is are fully met, or all DERs are saturated. The equal percentage curtailment procedure is expressed in Table 2.

7. Minimum DER Count Capacity-Based Greedy Curtailment

Set of DERs n and required curtailment amount C_{req} is provided as input and per-DER curtailment allocation x_i, using fewest possible DERs expected as output.

All DERs are sorted according to their realizable curtailment values q_i in descending order then, algorithm greedily assigns full curtailment to each DER until C_{req} is fully met. Sorting by q_i values first, ensures number of DERs participated to the solution is minimal. Allocation methodology is expressed in Table 3.

Since the last selected DER can be applied partial curtailment, the minimum number of required DERs corresponds to the smallest integer k where sum of the k number of largest q_i value meets or exceeds C_{req}.

Table 2. Equal percentage curtailment pseudo code

   if Remaining ≤ 0, break
   x_i ← min(q_i, Remaining)
   Remaining ← Remaining − x_i
end for
if Remaining > 0, report infeasible
return x
```

8. Merit Order (Cost-Weighted) Curtailment

Algorithm expects set of DERs n, curtailment costs of each DER c_i and required curtailment amount C_{req} value as inputs and gives per DER curtailment allocation x_i, minimizing total curtailment cost $\sum_{i=1}^{n} c_i \cdot x_i$ as an output.

All DERs are sorted according to their curtailment costs c_i in ascending order then, algorithm greedily assign full curtailment to each DER until C_{req} is fully met. Since partial curtailment is allowed with this methodology, this procedure follows continuous fractional allocation rule. Basically, this approach minimizes the direct curtailment cost for the aggregate target, assuming that each curtailed unit provides an equivalent amount of violation relief. Merit order curtailment algorithm is given in Table 4.

Sorting DERs only regarding to their c_i values are not enough for minimizing location specific relief costs under varying electrical sensitivities. Therefore, present merit order algorithm is kept separate from grid-aware formulation as it is evaluated against the aggregate C_{req} target.

9. Grid Aware Curtailment

Set of DERs n, electrical sensitivity coefficient for each DER s_i and required violation relief value I_{req} are given to the algorithm as an input and per DER curtailment allocation x_i such that $\sum_{i=1}^{n} s_i \cdot x_i \geq I_{req}$, while minimizing the total allocated curtailment $\sum_{i=1}^{n} x_i$.

Each DER is also assigned their sensitivity coefficient, representing its $x_i$contribution to relieving the specific network violation. First DERs are sorted according to their $s_i$values in descending order and greedily curtailed up to their $q_i$values until cumulative weighted impact is greater than required violation relief. Unlike previous methods , this algorithm directly aims at localized violation relief rather than meeting only the C alt requirement, which makes it a congestion location aware approach. The grid-aware curtailment methodology is presented in Table 5.

Sorting by s_i prioritizes the DERs providing the greatest violation relief per curtailed unit. According to the single-constraint linear sensitivity formulation, this methodology minimizes the total physical curtailment required to satisfy I_{req}.

end for
if RemainingImpact > 0, report infeasible
return x
```

10. Computational Requirements and Theoretical Scalability

Since active network management platforms provides control over grid networks, curtailment allocation problem must be solved in real time as well. Let (n) denote the number of eligible DERs installed to grid. Minimum DER count, merit order and grid-aware algorithms each require one sorting operation followed by a linear allocation cycle, resulting in $O(n\log_n)$ time complexity and O(n) storage. With that, etheequal percentage algorithm has O (n^2) worst-case complexity when the active DER set is scanned again, right after each saturation event sorting-based implementation using saturation breakpoints can reduce this complexity to $O(n\log_n)$.

For gridaw, the curtailment methodology: O sol parantez n alt simge taban, log, son taban, alt ogy, $O(n\log_n)$ values describe only the allocation phase. Calculation and periodic update of sensitivity coefficients constitute a separate process with its own computational requirements, depending on the network model and the selected sensitivity calculation method. Therefore, sensitivity retrieval may represent a greater practical burden in computational and data management than subsequent greedy allocation.

11. Data Preparation

To create a representative scenario for comparing these algorithms, a source-based, semi-synthetic benchmark was constructed from the IEEE 123-bus qsts (quasi-static time series) feeder released through the Open Energy Data Initiative (OEDI) [21, 22]. Source-based model provides nine active PV (photovoltaic) systems, their bus and phase connections, 50 kW (kilowatt) base nameplates, and quarter-hour PV profiles. Table 6 maps domain parameters to their corresponding origin classes and construction rules.

Then, each 50-kW PV source is scaled by a factor to create a controlled, high PV operating condition. Within the voltage regulator controls held as fixed, the initial voltage at Bus 83 phase 1 was 1.061 pu (per-unit), exceeding the 1.050 pu limit. Required aggregated curtailment, which is Calt req, is determined by applying binary search to the common proportional reduction in PV output until the voltage limit has been reached [21],[22]. Meanwhile, the grid-aware target I alt req sensitivity-weighted kW-equivalent was derived from local finite-difference voltage sensitivities [8],[21],[22].

Based on direct and derived references to the sources, the nine DER benchmarks given in Table 7 are used to compare the behavior of the four curtailment algorithms. Values of h_i and q_i were calculated from $h_i = a_i - min_i$ and $q = k_i a_i - min_i$, respectively. Since the current use case does not contain any contractual information, the curtailability value k_alt, which represents the maximum allowed curtailment percentage for a specific DER, is set to 1.

Within this DER set, the topology, PV identities, base nameplates, and profile values are directly taken from the public model. Alt i, s alt i, C alt req, I alt req, and post allocation voltages are derived from power flow calculations. Since the data does not include any contractual details, all values are set to 1, meaning all DERs can be fully curtailed if needed.

Table 6.DER benchmark parameters, their referenced values, and data origins

Distributed Energy Resource Property	**Referenced value**	**Data origin**
DER pool	Nine active PV systems at buses, 7, 29,49,55,63,68,80,87,113 [21],[22]	Direct source
a_i	145.961-149.866 kW [21],[22]	Direct source
min_i	0 kW for every PV [21],[22]	Source derived
max_i	150 kW [21],[22]	Source derived
k_i	1.0	-
s_i	0.049-1.000 [8]	Source derived
c_i	80-1000 GBP/MWh [23]	Direct source
C_{req}	530.447 kW [21],[22]	Source derived
I_{req}	194.432 kW [8], [21],[22]	Source derived

Table 7. OEDI-based DER inputs used for algorithm executions

	Distributed Energy Resource Property

Distributed Energy Resource Name	a_i(kW)	min_i(kW)	max_i(kW)	k_i	h_i(kW)	q_i(kW)	c_i (GBP/MWh)	s_i
DER-07	149.583	0	150	1.00	149.583	149.583	320	0.0493
DER-29	145.961	0	150	1.00	145.961	145.961	90	0.0943
DER-49	145.961	0	150	1.00	145.961	145.961	650	0.0948
DER-55	149.283	0	150	1.00	149.283	149.283	150	0.1504

DER-68	149.548	0	150	1.00	149.548	149.548	1,000	1.0000
DER-80	145.847	0	150	1.00	145.847	145.847	80	0.2816
DER-87	145.847	0	150	1.00	145.847	145.847	250	0.2466
DER-113	149.866	0	150	1.00	149.866	149.866	500	0.9642

12. Execution Analysis

Each algorithm mentioned in the algorithmic details section has been executed on the source-based DER set in Table 7, which forms an identical input base. Resulting curtailment allocations from four methodologies were applied to the IEEE 123-bus feeder data in OpenDSS to assess how these curtailments affect grid behavior.

Total curtailment cost metric is calculated as toplam alt limit i eşittir 1 üst limit n of, c alt i,, nokta x alt i , son toplama/ 1000 in GBP/h, algorithmic feasibility stands for satisfaction of the requirements and targets, and violation resolved determined by post allocations on bus 83 right after power flow replay on OpenDSS.

According to the execution results observed with four different curtailment algorithms in Table 8, the selection of the appropriate methodology depends heavily on operational objectives. Power flow analysis after curtailment allocations indicates that meeting the aggregate curtailment target does not always eliminate voltage violations.

Table 8. Results of algorithm executions in terms of evaluation criteria

Evaluation Criteria	Algorithm Type			
	Equal percentage	**Minimum DER count**	**Merit order**	**Grid aware**
Curtailment allocation target (kW)	C_{req} = 530.448	C_{req} = 530.448	C_{req} = 530.448	I_{req} = 194.432
Number of DERs curtailed	9	4	5	2
Total curtailment (kW)	530.448	530.448	530.448	196.099
Total curtailment cost (GBP/h)	206.39	284.57	69.54	172.82
Post-allocation at Bus 83 phase 1 (pu)	1.050	1.041	1.055	1.049

Local 1.05 pu violation resolved.	Yes	Yes	No	Yes
Algorithmic feasibility	Yes	Yes	Yes	Yes
Congestion-location aware	No	No	No	Yes
Primary objective	Proportional fairness	Minimum activated DER count	Minimum direct cost	Minimum kW for localized relief
Additional data required	None	None	c_i per DER	s_i per DER

When all DERs have identical contractual constraints, and no additional data are available, such as curtailment costs and electrical sensitivities, an equal-percentage curtailment strategy is appropriate, since it is the only methodology that applies curtailment proportionally while satisfying the fairness principle. This method curtailed all nine DERs by equally distributing curtailments by %39.91 of their available capacity and reduced bus 83 phase 1 to 1.050 pu.

Scenarios that the grid operator decides the minimum number of DERs contributes to the curtailment process, and again, no additional data is available, as in the equal percentage scenario, then the minimum DER count capacity based greedy curtailment algorithm steps forward. Thanks to this methodology, communication overhead during the application of curtailment to the field equipment was kept minimal. In the benchmark set, the curtailed set was reduced from nine to four, and it is seen that the selection of DER-68 and DER-113, which are electrically effective based on their s alt ivalues, reduced bus 83 to 1.041 pu. This result indicates that the minimum DER count strategy is not location-aware and does not provide localized relief, since the DERs with the largest q alt values are also sensitive assets.

During curtailment operations, if cost efficiency is the operator's top priority, the merit order curtailment algorithm is used, as its primary objective is to keep the cost of the curtailment process to a minimum. With *values set to 1, the algorithm curtailed five DERs and produced the lowest total curtailment cost of 69.54* GBP. Post-allocation voltage remained at 1.055 pu, exceeding the 1.05 pu limit, since the allocation order does not consider DERs' voltage sensitivities with respect to the violated bus. Also, the curtailment cost of each DER should be determined within the grid to benefit from this method.

When a violation is observed on a specific line or on overloaded equipment on the grid, the grid-aware curtailment algorithm is the only option aimed at localized overload relief. With k_i values set to 1, the algorithm selected DER-68 and DER-113, which required 196.099 kW of total curtailment and reduced us 83 to 1.049 pu. The total curtailment value of this method must not be directly compared with other approaches, since it satisfies I alt req rather than C alt req while meeting the .050 pu voltage limit. Also, this methodology requires precomputed sensitivity values for each DER within the fleet.

Minimum DER count, merit order, and grid-aware allocation strategies require one sorting operation followed by a linear pass; therefore, they all have O (n log n) time complexity. Naïve iterative water filling implementation of equal percentage cut-off has $O(n^2)$ worst-case complexity w,h wwhereas ssortingthe DDERS aaccording to theirsaturation thresholds reduces tthe complexityto Oo OOO complexity to OOO complexity to OOO complexitytoO$(n\log_n)$.

IV. CONCLUSION & FUTURE WORK

This study compared four deterministic DER curtailment allocation strategies representing distinct operational objectives: proportional burden sharing, minimum DER activation, operational cost minimization, and location-specific violation relief. These methodologies were evaluated using a source-based semi-synthetic benchmark derived from the IEEE 123-bus QSTS feeder and nine PV profiles available in the Open Energy Data Initiative. The resulting allocations were observed in OpenDSS, examining both the algorithmic feasibility of each strategy and its actual effects on the grid. Experimental analysis indicates that no single algorithm outperforms the others when considering all objectives included in this study. The choice of methodology depends on the grid operator's operational priorities. Data availability, such as curtailment cost or electrical sensitivity data for each DER, also affects which algorithm to choose when calculating curtailment. The most immediate next step is to apply all four curtailment algorithms to real operational DER datasets and reproduce the same comparative analysis on data retrieved from actual grid networks.

Increasing algorithm diversity also represents a promising direction for future research. New methodologies, such as LP-based optimal power flow formulations and hybrid greedy optimization approaches, may also prove useful for congestion resolution in various aspects.

Abstract
We present a per-pixel classification system for marine surface monitoring in Sentinel-2 multispectral imagery. The method rests on two contributions. First, *pixel2vects*, a feature-engineering process that converts an unstructured multispectral hypercube into a structured dataset by precomputing a 68-dimensional vector per pixel 11 raw spectral bands, 12 physics-based spectral indices, and 45 spatial descriptors (multiscale, texture, and band-context). This makes local spatial context explicit and the sparse-annotation problem of remote sensing is turned into a dense tabular one. Second, TRITON (**Token Representation of Imagery for Transformer Orchestration Networks**), a 3.35M-parameter modular Transformer that treats each of the five heterogeneous feature groups as an independent token and models their interaction through self-attention. To handle the severe class imbalance in the MADOS benchmark (a 405× ratio across 15 classes), TRITON is trained with a Label-Distribution-Aware Margin (LDAM) loss combined with a prototype-memory auxiliary loss. On the MADOS test set, our best single-seed model reaches 76.43% macro-F_1, surpassing the published state of the art, MariNeXt (76.0%), without patch-level CNNs, pretraining, or copy-paste augmentation. This represents a more efficient solution for marine pollution detection in both training and inference.

Keywords: marine pollutant detection, oil spill, Sentinel-2, Transformer, class imbalance, per-pixel classification, MADOS.

I. INTRODUCTION

Detecting marine pollutants—oil spills, floating debris, sea snot, and related surface phenomena—from satellite imagery is a prerequisite for large-scale, continuous ocean monitoring. Sentinel-2 offers a favorable combination of spatial resolution (10–20 m), spectral coverage (11 usable bands between 440 nm and 2200 nm), and a 5-day global revisit cycle. The MADOS dataset proposed in [1] formalizes the problem as a 15-class per-pixel classification over 174 scenes, partitioned at the scene level to prevent spatial leakage between splits. Recent works on the MADOS dataset have largely relaxed one of its two hard constraints—either the labeling requirement, through self-supervised transfer to other sensors [2], or the class structure itself, by collapsing the 15 classes into a debris-versus-background decision that makes the severe imbalance of MADOS more tractable [3]. We keep both constraints and instead change the pixel representation. A central difficulty with remote-sensing datasets is sparse annotation: of the 2803 MADOS patches (240 × 240 pixels), only 1,481,155 (0.91%) pixels are labeled; the rest are marked as unlabeled. Approaches that take in the multispectral image, directly translate this sparsity into heavy CNN or segmentation architectures with large number of parameters and high training and inference cost. This work takes a per-pixel view instead, hypothesizing that the spectral signature of a pixel, along with its local spatial context, contains most of the information needed to classify it, which is under-exploited by scene-level models. We therefore precompute, for every pixel, a fixed-length vector that encodes both spectral and spatial evidence (Section IV) and classify each vector independently using a compact Transformer (Section V). The formulation has practical

advantages: predictions are independent of scene size, computation can be trivially parallelized, the sparse-annotation problem becomes a dense tabular one with millions of labeled examples, and every input feature has an explicit physical definition. The contributions of this work are: pixel2vects, a 68-feature per-pixel representation for Sentinel-2 marine scenes, organized into five physically meaningful groups (bands, indices, multiscale, texture, band-context), whose spatial component accounts for the largest single performance gain we observe (≈+11 pts macro-$F1$). TRITON, a 3.35M-parameter modular Transformer that tokenizes feature groups rather than individual features, projecting each group into a shared embedding space and modeling inter-group interaction with self-attention. An imbalance-handling recipe balanced sampling with an LDAM margin loss and a prototype-memory auxiliary term together with an ablation showing which additional mechanisms (Deferred Re-Weighting, post-hoc logit adjustment, cross-loss ensemble) are counterproductive once balanced sampling is in use. State-of-the-art results on MADOS together with a reproducible multi-seed evaluation protocol.

II. RELATED WORK

Kikaki et al. [1] introduced MADOS dataset and evaluated a spectrum of baselines. Among per-pixel methods, Random Forest [4] over spectral features reaches 56.6% macro-$F1$, and RF++—the same classifier augmented with hand-crafted spatial features—reaches 64.4%. Among scene-level segmentation methods, U-Net [5] obtains 63.8%, SegNeXt [6] 60.6%, and MariNeXt, a SegNeXt-based pipeline with multi-scale features, Very Simple Copy-Paste (VSCP) augmentation, and geometric test-time augmentation, holds the published state of the art at 76.0%. The 7.8-pt gap between RF and RF++ is direct evidence that explicit spatial descriptors carry substantial information in this domain; our pixel2vects representation extends this observation. Recent work in this area has moved in three directions. Dalsasso et al. [2] attack the labeling bottleneck rather than the model, transferring debris detection from Sentinel-2 to daily 3-m PlanetScope acquisitions through self-supervised cross-sensor pre-training—trading spectral richness for revisit frequency. Bouchelaghem et al. [3] merge MARIDA and MADOS and collapse the label space to debris versus background, reporting that models trained on MADOS transfer to MARIDA with a relative $F1$ loss of only 1.25% (0.901 → 0.890), which suggests that the geographic diversity of the benchmark matters more for generalization than its annotation density. Giannopoulos et al. [7] used ConvNeXt screening stage with a domain-adapted Segment Anything Model for oil spills in Sentinel-1 SAR and—directly relevant to our design—find it necessary to append GLCM texture measures to the backscatter input, an independent instance of hand-crafted spatial descriptors improving a modern deep model. None of the three retains the 15-class per-pixel formulation this work addresses. Focal loss [8] re-weights the per-example gradient by prediction difficulty. LDAM [9] instead enforces a per-class margin $\Delta y \propto n{-}1/4$ on the decision boundary, optionally combined with Deferred Re-Weighting (DRW), a two-phase schedule that introduces inverse-frequency class weights late in training. Logit adjustment [10] corrects model outputs post hoc using the training label prior. A blunter alternative is to remove the imbalance by construction, collapsing the label space into a binary decision [3]; we retain all 15 classes and treat the imbalance as a loss-geometry problem. These mechanisms are typically evaluated in isolation; Section VI examines their behavior in combination with balanced re-sampling. Vaswani et al. [11], introduced a multi-head self-attention Transformer (originally for language processing) over a token sequence, while FT-Transformer [12] adapts it to tabular data by mapping each scalar feature to a token and reading out through a CLS (classification) token. In remote sensing the prevailing per-pixel Transformer design instead attends over a spectral–spatial neighborhood: Wu et al. [13] classify hyperspectral pixels by combining a convolutional front-end with cross-window attention over the patch surrounding each pixel, so spatial context enters the model as attended raw values. TRITON adopts the token-plus-CLS scheme but tokenizes at the granularity of physically defined feature groups (Section V), which shortens the sequence from 69 to 6 tokens and respects the heterogeneous numeric regimes of the groups; spatial context enters as precomputed

descriptors rather than as an attended neighborhood, which is what keeps the sequence short and each input interpretable.

III. DATASET

MADOS [1] comprises 174 Sentinel-2 scenes acquired between 2015 and 2022, annotated by domain experts into 15 marine surface classes: Marine Debris, Dense Sargassum, Sparse Floating Algae, Natural Organic Material, Ship, Oil Spill, Marine Water, Sediment-Laden Water, Foam, Turbid Water, Shallow Water, Waves & Wakes, Oil Platform, Jellyfish, and Sea Snot. The split is performed at the scene level (≈70/15/15), so no geographic region contributes pixels to more than one partition. We use all 11 non-atmospheric bands (B1–B8A, B11, B12; 440–2200 nm) resampled to 10 m, with ACOLITE Rayleigh-corrected reflectance (ρrc) following the MADOS preprocessing protocol. After feature extraction (Section IV), our working dataset contains 1,078,367 training, 203,652 validation, and 199,136 test pixels. Two properties of the benchmark shape everything that follows. First, annotation is sparse: of the 2,803 patches (240×240 pixels), only 0.91% of pixels carry a label. Second, the training distribution is severely long-tailed—Marine Water contributes on the order of 105 pixels against 1,165 for Natural Organic Material and 1,339 for Jellyfish. Because macro-$F1$ weights every class equally, performance on the rare classes dominates the metric, which is what drives the loss design of Section V and the ablations of Section VI.

IV. PIXEL2VECTS: PER-PIXEL FEATURE REPRESENTATION

A Sentinel-2 multispectral image is defined as $I \in \mathrm{R}H\times W\times 11$. The pixel2vects process, maps every pixel into a 68-dimensional feature vector

$$\mathbf{f} = [\mathbf{b}, \mathbf{i}, \mathbf{m}, \mathbf{t}, \mathbf{c}], \tag{1}$$

that is, it concatenates five module vectors—bands, indices, multiscale, texture and band-context. The grouping is not cosmetic: it defines the token structure of TRITON (Section V) and the granularity at which normalization statistics are computed, each group being independently z-score normalized with training-set statistics. Bands (11): Raw ρrc reflectance at the 11 non-atmospheric Sentinel-2 MSI bands: coastal aerosol (B1, 443 nm) at 60 m; blue, green, red and NIR (B2–B4, B8; 490, 560, 665, 842 nm) at 10 m; and the three red-edge bands (B5–B7; 705, 740, 783 nm), the narrow NIR band (B8A, 865 nm) and the two SWIR bands (B11, 1610 nm; B12, 2190 nm) at 20 m. The two atmospheric bands, B9 (water vapor) and B10 (cirrus), carry no surface signal and are discarded. Indices (12): Physics-based band combinations that amplify class-discriminative contrast, each following its standard published definition. They cover floating vegetation (NDVI, EVI, FAI), floating debris (FDI, NRD), open and turbid water (NDWI, MNDWI, AWEI, SI), moisture and surface films (NDMI), and sediment or bare substrate (BSI, NDSII). Six belong to the normalized-difference family $(bi - bj)/(bi + bj)$, while FAI and FDI are baseline-subtraction indices measuring the NIR excess of a pixel over a red–SWIR linear baseline—the standard signature of floating material.

Multiscale (20): Computed on the gray scale composite $I_{gray} = (B2 + B3 + B4)/3$ at five scales $\sigma \in \{1, 2, 4, 8, 16\}$ pixels (i.e., 10-160 m): the Gaussian-smoothed intensity G_σ, the Sobel gradient magnitude $M_\sigma = \sqrt{(S_\sigma^x)^2 + \left(S_\sigma^y\right)^2}$, and the two eigenvalues $(\lambda_\sigma^1 + \lambda_\sigma^2)$ of the local Hessian of G_σ, 5 + 5 + 10 = 20 features. The eigenvalue pair characterizes local geometry—blob-like structures ($\lambda 1 \approx \lambda 2 < 0$) versus elongated ridges ($|\lambda 1| \gg |\lambda 2|$)—which helps separate slick patches from ship wakes. Texture (13): Six

GLCM/Haralick descriptors (contrast, homogeneity, dissimilarity, ASM, energy, correlation) from the per-pixel Grey-Level Co-occurrence Matrix over a 13 × 13 window with 16 gray levels, accumulated over four directions (0◦, 45◦, 90◦, 135◦) [14]; standard and uniform Local Binary Patterns at $P = 8$, $R = 1$, each normalized to [0, 1] (2) [15]; the Laplacian of Gaussian $\nabla 2G\sigma$ at $\sigma \in \{2, 4\}$ (2) [16]; and the local standard deviation over windows $w \in \{5, 11, 21\}$, computed via $Var[X] = E[X^2] - E[X]^2$ (3). Band-context (12): Local descriptors over the bands most informative for floating-material detection (B4, B8, B11) and NDVI: the 5 × 5 local mean and standard deviation of each of B4, B8 and B11 (6) and of NDVI (2); the local gradient direction at $\sigma = 1$ encoded as $(cos\theta, sin\theta)$ to avoid the $\pm\pi$ discontinuity (2); and the two cross-band local mean differences Δ_{B8-B4} and Δ_{B8-B11} (2). The 45 spatial descriptors of the last three groups are computed once per patch with vectorized operations and stored in HDF5, so the per-pixel classifier receives spatial context as a precomputed input.

V. TRITON

TRITON follows the encoder-Transformer design of Vaswani et al. [11]. The 68-feature vector is partitioned into its five module vectors of dimension $d$bands = 11, $d$idx = 12, $d$ms = 20, $d$tex = 13, $d$bctx = 12. Because these groups occupy heterogeneous numeric and physical regimes (reflectances ≈0.01–0.3, GLCM contrast in [0, 10], LBP codes in [0, 255]), TRITON projects each group independently before letting them interact through self-attention. Figure 1 summarizes the model.

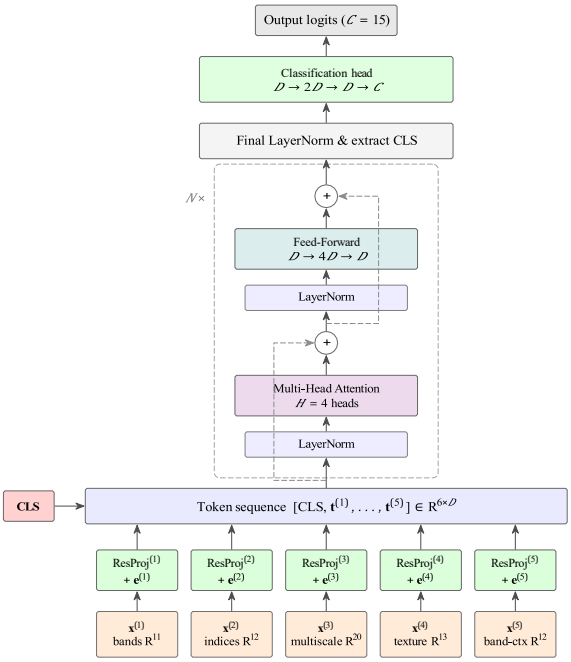

Figure 1. Architecture of TRITON. Each per-pixel input is split into five heterogeneous feature groups x(m) (68 features total); each group is independently projected to a shared D-dimensional space by a ResidualProjection block and augmented with a learnable module-type embedding e(m) . With a prepended learnable CLS token, the resulting 6-token sequence is processed by $N = 3$ pre-norm Transformer encoder layers with residual connections, and the final CLS embedding is mapped to $C = 15$ class logits by a three-layer head.

From vectors to tokens: Each module vector x(m) ∈ Rdm is mapped to a token of shared dimension $d$model = 256 through a residual projection:

$$\mathbf{z}^{(m)} = \mathrm{LN}_{\mathrm{out}}(\,\mathrm{MLP}^{(m)}(\mathrm{LN}_{\mathrm{in}}(\mathbf{x}^{(m)})\,) + \mathbf{W}^{(m)}_{\mathrm{skip}}\,\mathrm{LN}_{\mathrm{in}}(\mathbf{x}(m)), \tag{2}$$

with MLP(m) (h) = W2 Dropout0.20(GELU(W1h + b1)) + b2 and FFN hidden width 2 $d$model. The linear skip path and the output LayerNorm stabilize optimization across groups with disparate input statistics.

A learnable module-type embedding e(m) ∈ R$d$model —the analogue of positional encodings for an unordered set of typed tokens—is added to each token, and a learnable class token is prepended, giving the 6-token sequence T (0) = [$t$cls, t (1) , . . . , t (5)] with t (m) = z(m) + e(m).

Encoder and classification head: The sequence passes through L = 3 pre-norm Transformer encoder layers (h = 4 attention heads, head dimension 64, FFN ratio r = 4 so $d$ff = 1024, attention dropout 0.05, FFN dropout 0.10), each applying multi-head self-attention and a feed-forward block with residual connections around both, followed by a final LayerNorm. The class-token output hcls aggregates information from all module tokens and feeds a 3-layer head (256 → 512 → 256 → 15, GELU, dropout 0.20) producing class logits ℓ ∈ R15; at inference yˆ = arg max$c$ ℓc. The complete model has 3,352,215 parameters.

Loss function: The training objective combines a margin loss on the classifier logits with a prototype loss on the embedding geometry:

$$\mathrm{L} = \mathrm{L}_{\mathrm{LDAM}}(\ell,\ y) + \lambda_{\mathrm{proto}} \cdot \mathrm{L}_{\mathrm{proto}}(\ell_{\mathrm{proto}},\ y), \tag{3}$$

with λ_{proto} = 0.3.

LDAM: To address class imbalance [9], a per-class margin is subtracted from the true-class logit during training:

$$\Delta_c = \min\left(\frac{C}{n_c^{1/4}},\ \Delta_{\max}\right) \qquad \tilde{\ell}_y = \ell_y - \Delta_y, \tag{4}$$

(other logits unchanged), and standard cross-entropy is applied to ℓ˜. Rare classes are thus required to be classified with a wider safety margin. We use C = 0.5, Δmax = 0.5, and disable label smoothing (which interacts destructively with the margin geometry).

Prototype memory: An exponential-moving-average bank maintains one unit-norm centroid $\mathbf{p}_c$ per class in CLS space, updated each batch from the normalized class-mean embedding with momentum α = 0.999. Auxiliary logits are cosine similarities scaled by temperature τ = 0.07,

$$\ell_{\text{proto, }\square} = \frac{1}{\square} \cdot \frac{\langle \mathbf{h}^{\text{cls}}, \mathbf{p}_{\square} \rangle}{\| \mathbf{h}^{\text{cls}} \|}, \tag{5}$$

and the auxiliary cross-entropy encourages compact, well-separated class clusters on the unit sphere—targeting spectrally confusable pairs such as Oil Spill / Marine Water. The two terms act on complementary spaces: LDAM shapes the decision boundary in logit space, the prototype loss structures the embedding geometry.

VI. EXPERIMENTS

All experiments use the MADOS scene-level splits; macro-$F1$ on the test set is the primary metric, with mIoU and overall accuracy (OA) as secondary metrics. TRITON is trained with WeightedRandomSampler (exponent β = 0.7, sampling probability $\propto n-\beta$), the LDAM + prototype loss of Section V, Gaussian input noise (σ = 0.02) on bands and indices, band dropout (p = 0.15), mixup (α = 0.1) applied jointly to all five groups, gradient clipping at norm 1.0, AdamW (lr 3 × 10−4, weight decay 10−4) and OneCycleLR with 10% warm-up; one run takes 35–80 minutes on a single NVIDIA GPU. Every epoch's checkpoint is scored on validation macro-$F1$, the top-5 are retained and their logits averaged at evaluation, and test-time augmentation (TTA) averages logits over 8 forward passes with independent Gaussian noise (σ = 0.02) on the spectral features.

1. Results on MADOS

Table 1. MADOS test-set results. Best result per metric in bold. All values in %.

Method	Macro-F_1	mIoU	OA
RF [1]	56.6	43.9	67.1
RF++ [1]	64.4	52.4	83.8
U-Net [5]	63.8	51.0	82.9
SegNeXt [6]	60.6	49.2	86.6
MariNeXt (pub. SOTA)	76.0	64.3	**89.1**
TRITON – best single (seed 123)	**76.43**	**66.55**	88.69
TRITON – 3-seed mean ± std	75.72±0.68	—	—
TRITON – 15-ckpt ens. × TTA-8	76.18	66.38	88.73

As shown in Table 1, TRITON exceeds the published state of the art in macro-$F1$ (+0.43 best single, +0.18 in

the 15-checkpoint ensemble—hereafter "ensemble") and mIoU (+2.25 / +2.08), with OA 0.4 pts lower—the expected consequence of reallocating decision margin from frequent to rare classes under a metric that values the latter. Table 2 breaks the deployed system (15-checkpoint ensemble × TTA-8) down over the 199,136 annotated test pixels. Oil Spill, the class of primary applied interest, is the strongest pollutant class at 81.8% $F1$, and its error is asymmetric in the operationally favorable direction: 89.2% recall against 75.5% precision, i.e., the system misses one in nine true slick pixels while over-flagging at a rate an analyst can triage. Nine of the fifteen classes exceed 85% $F1$ and Sediment-Laden Water is effectively solved (99.7%).

Three classes carry the macro-average penalty. Natural Organic Material collapses to 6.8% $F1$, but with 31 test pixels any estimate is statistically meaningless—a data-scarcity problem (1,165 training pixels) rather than a modeling failure. Waves & Wakes (44.6%) and Jellyfish (45.4%) are genuinely hard: both keep reasonable precision (65.4% and 81.9%) but Recall metric below 34%, so the models are conservative on them rather than confused. Relative to the best single model the ensemble redistributes rather than adds accuracy: Oil Spill improves from 75.2 to 81.8% $F1$ while Jellyfish (78.0 → 45.4) and Waves & Wakes (65.7 → 44.6) give back the margin LDAM had recovered on individual seeds, since averaging logits over 15 checkpoints pulls the rare-class boundaries back toward the frequent classes they border. The two systems reach nearly the same macro-$F1$ (76.43 vs. 76.18%) by opposite routes: the ensemble here buys independence from seed choice, not tail performance.

Table 2. Per-class results of the deployed system (15-checkpoint ensemble × TTA-8). Support in pixels; all other values in %.

Class	Support	Prec.	Rec.	F_1	IoU
Marine Debris	836	72.1	83.4	77.3	63.0
Dense Sargassum	472	94.6	85.4	89.8	81.4
Sparse Floating Algae	982	89.5	90.9	90.2	82.2
Natural Organic Mat.	31	7.1	6.5	6.8	3.5
Ship	2,048	78.6	72.3	75.3	60.4
Oil Spill	38,488	75.5	89.2	81.8	69.2
Marine Water	103,394	94.5	87.8	91.0	83.5
Sediment-Laden Water	25,038	99.4	100.0	99.7	99.4
Foam	223	78.6	98.7	87.5	77.7
Turbid Water	8,557	76.9	96.1	85.4	74.5
Shallow Water	10,621	87.1	83.9	85.4	74.6
Waves & Wakes	3,324	65.4	33.9	44.6	28.7
Oil Platform	2,614	83.1	93.4	87.9	78.5
Jellyfish	274	81.9	31.4	45.4	29.4
Sea Snot	2,234	97.8	91.6	94.6	89.7
Macro avg	199,136	78.8	76.3	**76.18**	**66.38**
Overall accuracy					88.73

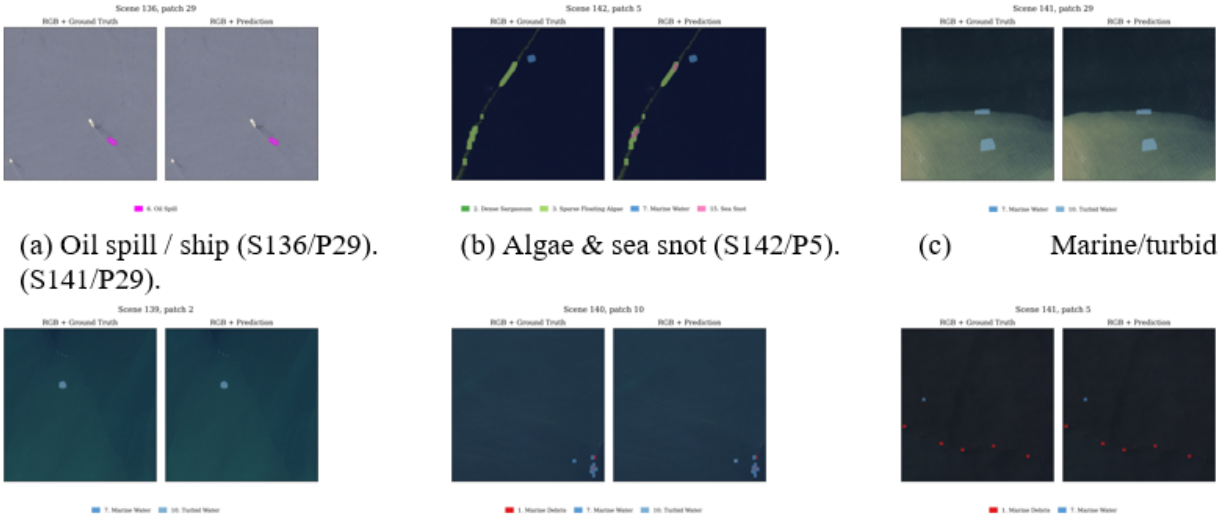

Table 3. Row-normalized confusion matrix of the deployed system, in % of the row support (rows: ground truth; columns: predictions, by the class index of the first column; bold diagonal: recall). "·" is nonzero but below 0.5%, blank is exactly zero.

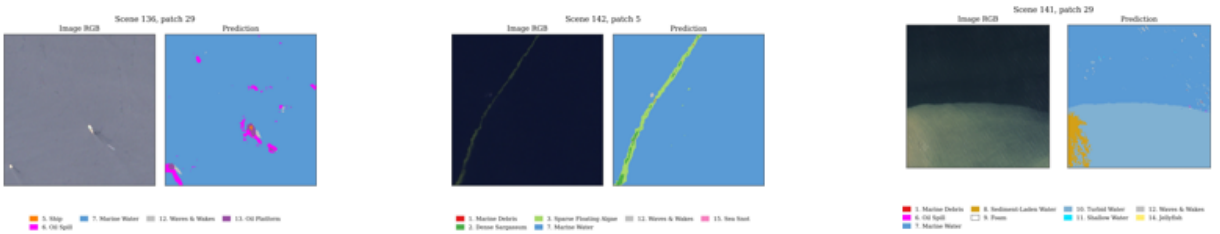
		Predicted class													
#	True class	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14

0	Marine Debris	**83**		2	·	12			1		·				·	·	·	2				
1	Dense Sargassum		**85**	12																		2
2	Sparse Floating Algae		2	**91**				4							2	·						1
3	Natural Organic Mat.	55		13	**6**	23										3						
4	Ship	1			·	**72**		4	·		·	·	·			1	20					·
5	Oil Spill	·		·		·		**89**	10			·	·			1	·					
6	Marine Water	·		·		·	9		**88**		·	1	1			·						·
7	Sediment-Laden Water									**100**												
8	Foam										**99**					1						
9	Turbid Water								3	1	**96**					·						
10	Shallow Water			·		1			6		·	9	**84**			·						
11	Waves & Wakes	4				4	32		15		1	1	8			**34**	1			·	·	
12	Oil Platform					6	1									·	**93**		·			
13	Jellyfish	5					2	57										3	**31**	1		
14	Sea Snot	3			·	1	·	·	1		3						·				**92**	

Table 3 shows that the errors are structured, not diffuse. Most of the off-diagonal mass falls in a single dark-surface cluster spanning Oil Spill, Waves & Wakes, Jellyfish and Marine Water: 32% of Waves & Wakes pixels and 57% of Jellyfish pixels are predicted as Oil Spill, and together with the 9% of Marine Water assigned to Oil Spill they account for essentially all of that class's precision loss, while the reverse leak is smaller and one-directional (10% of Oil Spill becomes Marine Water). Two further entries are equally interpretable: 20% of Ship becomes Oil Platform—both are bright man-made structures on water, distinguished mainly by motion, which a single acquisition cannot show—and 12% of Dense Sargassum becomes Sparse Floating Algae, a density threshold on the same material rather than a different material. The residual mass follows the same logic among adjacent water states (Shallow Water: 9% → Turbid, 6% → Marine). Errors therefore track physical similarity between surface types rather than random noise, and none place a pollutant class inside an unrelated category.



The same behavior is visible directly in the predicted maps. Figure 2 shows six representative test patches spanning the pollutant-relevant classes of the benchmark. For each patch the left panel overlays the sparse expert annotation on the RGB composite and the right panel overlays the TRITON prediction on the same composite; only annotated pixels are colored, so the two are directly comparable. The prediction tracks the ground truth closely: the Oil Spill trailing the ship in Figure 2a is recovered with its correct extent and position, the floating-vegetation trail in Figure 2b is likewise captured, and the Marine / Turbid water boundary (Figures 2c and 2d) is delineated cleanly despite the two classes being spectrally similar. The small Marine Debris targets in Figures 2e and 2f—each a handful of pixels—are localized correctly, consistent with the per-pixel formulation's ability to classify isolated targets independently of scene context. The most visible failure is

(a) Oil spill / ship (S136/P29). (b) Algae & sea snot (S142/P5). (c) Marine/turbid (S141/P29).

(d) Turbid patch (S139/P2). (e) Debris cluster (S140/P10). (f) Debris targets (S141/P5).

Figure 2. Qualitative results on six MADOS test patches. Per patch, the left panel is the RGB composite with the ground-truth annotation overlaid and the right panel the same composite with the TRITON prediction; only expert-annotated pixels are colored. Scenes are identified as S{scene}/P{patch} following the MADOS naming.

(a) Oil spill / ship (S136/P29). (b) Algae & sea snot (S142/P5). (c) Marine/turbid (S141/P29).

Figure 3. Dense per-pixel prediction maps for three of the patches of Figure 2. For each patch, the left panel is the RGB composite and the right panel is the full TRITON class map over every pixel (not only the annotated ones). The legend lists all classes appearing in the map. in Figure 2b, where a Sparse Floating Algae streak is partially predicted as Sea Snot: the floating-material confusion of Table 3, a genuine spectral overlap rather than a localization error.

Because MADOS annotation is sparse, Figure 2 only reveals behavior on labeled pixels; Figure 3 shows the full per-pixel prediction maps for the same patches. Despite classifying each pixel independently, TRITON produces spatially coherent regions—contiguous water bodies, connected vegetation trails and compact debris clusters—rather than salt-and-pepper noise, and its predictions on unlabeled pixels (e.g., the extended Oil Spill and Sea Snot regions around the annotated targets) remain consistent with the surrounding surface context.

This is the clearest visual evidence that the precomputed spatial descriptors, not scene-level context, carry the information the model needs.

2. Ablations

Representation. Comparing spectral-only per-pixel Transformers on the 11 raw bands against TRITON on the full 68-feature representation isolates the contribution of pixel2vects (Table 4, top). Spectral-only architectures plateau near 61%, below the RF++ spatial baseline (64.4%); varying architecture and schedule across designs moved test macro-$F1$ within a ≈10-pt band, all of it below that baseline. Adding the 57 spatial and index features raises TRITON to 72.35% (+11.5 pts), the largest single gain in the study attributable to the representation, not to architectural novelty. Tripling the parameters (9.26M) raises validation $F1$ by 3.5 pts but leaves test $F1$ unchanged while doubling the validation–test gap: capacity is not the bottleneck on this dataset.

Loss geometry: With the representation fixed, replacing Focal loss by the LDAM margin loss of Section V improves macro-$F1$ by +3.58 pts, with a clear optimum at $C = 0.5$ (at the end of Table 4). The gain decomposes almost entirely into the rare classes (Focal → LDAM, per-class $F1$): Jellyfish 32.9 → 80.0 (+47.1), Foam 39.4 → 78.3 (+38.9), Waves & Wakes

Table 4. Ablations on the representation (top) and on the loss geometry with the representation fixed (bottom). Test macro-F_1 in %.

Configuration	Params	Test F_1
Spectral Transformer (11 bands, wavelength PE)	1.97M	58.76
FT-Transformer (11 bands, per-feature tokens)	2.72M	60.87
TRITON (68 features, group tokens)	3.35M	**72.35**
TRITON (68 feat., D=384, L=4)	9.26M	72.51
Focal (γ = 1.5)	3.35M	72.35
LDAM (C = 0.3)	3.35M	75.46
LDAM (C = 0.5)	3.35M	**75.93**
LDAM (C = 0.7)	3.35M	75.48

49.9 → 65.7 (+15.8), Marine Debris 58.4 → 71.5 (+13.1), Sparse Floating Algae 78.6 → 88.6 (+10.0), while no frequent class loses more than 3.5 pts. This asymmetry—double-digit gains on rare classes against low single-digit losses on frequent ones—is the signature of a margin reallocation, and it is what macro-$F1$ rewards. Imbalance mechanisms do not compose: Three individually reasonable mechanisms degrade performance once balanced sampling and LDAM margins are in place. Deferred Re-Weighting (inverse-frequency class weights from epoch 50) cost

≈11 pts of validation macro-$F1$ at the switching epoch and ended at 75.62%, below plain LDAM: it interacts destructively with a sampler that already deforms the class distribution. Post-hoc logit adjustment, $\ell y \leftarrow \ell y - \tau \log \pi y$, assumes training under the prior natural label, and then degrades monotonically—72.35% ($\tau = 0$) →

66.09% (τ = 0.2) → 35.17% (τ = 1)—because the sampler has partially uniformized that prior label. Cross-loss ensemble of Focal and LDAM checkpoints yields 75.74%, below LDAM alone: the Focal models' near-zero confidence on Foam and Jellyfish dilutes precisely what LDAM repaired (Jellyfish 80% → 57% within the ensemble). Re-sampling, re-weighting, margin shaping and posterior correction all act on the same class prior, so their effects compound rather than add; one intervention point should be chosen and the rest held neutral.

Seed variance and ensemble: Across three seeds (Table 5) the spread is 1.62 pts, which exceeds the margin separating our best model from MariNeXt (+0.43 pts), so single-seed comparison would be statistically fragile. Validation rank also fails to predict test rank—the best-validation seed 42 is not the best-test seed 123—consistent with the ≈10-pt val–test gap induced by geographically disjoint splits, a gap invariant to loss, model size and seed. Pooling the top-5 checkpoints of all three seeds (15 checkpoints) with TTA-8 gives 76.18% macro-$F1$ with no dependence on a fortunate seed; TTA alone contributes

+0.15 pts within the ensemble, its largest per-class effect being +4.5 pts on Jellyfish. A scripted 10-seed protocol that trains, bundles and evaluates each configuration without manual intervention is in place to convert the headline number into a distribution.

Table 5. Seed variance (LDAM $\mathcal{C}$ = 0.5, TTA-8). All metrics in %.

Seed	Val □$_1$	Test □$_1$	mIoU	OA
0	86.60	74.81	64.98	88.92
42	86.76	75.93	65.72	87.84
123	86.31	**76.43**	**66.55**	88.69
mean ± std		75.72±0.68	—	—

3. Computational Efficiency

Table 6 places the accuracy results in the context of what they cost. TRITON reaches state-of-the-art macro-F_1 on a single Titan-class GPU rather than two workstation cards, with 3.35M parameters and a 335 MB peak VRAM footprint at inference. A single model sustains 184,033 px/s (22.1 ms per 4,096-pixel batch), so one 240 × 240 MADOS patch (57,600 pixels) is classified in ≈0.3 s. The deployed configuration performs 15 × 8 = 120 passes per pixel and drops to 1,534 px/s; as shown above, that 120× cost buys independence from seed choice rather than accuracy, so the single-seed model is preferable whenever latency matters.

The cost TRITON does not eliminate is displaced to the CPU. The 45 spatial descriptors take 809 ms per patch on a single core (37.8 min for the 2,803 MADOS patches) and increase the stored dataset size from 127 to 278 MB. The step is embarrassingly parallel and computed once per scene—under 5 min on 8 cores—but it is a genuine precondition, and unlike MariNeXt's end-to-end pipeline, it must be reimplemented and revalidated before transfer to another sensor. The trade is deployment-dependent:

Table 6. Computational cost of TRITON (measured on our hardware) against MariNeXt (as reported by its authors [1] and in the accompanying deployment report [17]). "n/r" = not reported.

Aspect	TRITON (ours)	MariNeXt

Paradigm	per-pixel (68 feat. + Transf.)	dense seg. (SegNeXt + VSCP)
GPU	1× TITAN RTX, 24 GB	2× RTX A5000, 24 GB ea.
Parameters	**3.35 M**	n/r
Batch size	4,096 px	n/r
Throughput (1 model)	0.18 M px/s	n/r
Throughput (deployed)	1.5 k px/s	n/r
Inference latency	22.1 ms / batch	n/r
Peak GPU memory	**335 MB**	n/r (≤ 24 GB)
Preprocessing	45 spatial feat., 809 ms/patch	VSCP + geometric TTA
Feature storage	+151 MB (127 → 278 MB)	n/a (end-to-end)
Macro-F_1	**76.18** (ens.) / 76.43 (best)	76.0
mIoU	**66.38**	64.3
Overall accuracy	88.73	**89.1**

TRITON is preferable where GPU count or memory binds, a dense end-to-end model where preprocessing must stay inside a single GPU graph.

VII. DISCUSSION AND CONCLUSIONS

Representation dominating the outcome: Comparing the classification metrics between TRITON (76.43%),) and the spectral-only Transformer (60.87%), there is a difference of ≈15.6 points in favor of TRITON. From this difference, ≈11.5 points are attributable to the pixel2vects features, and the remaining 3.6 points corresponds to seed selection and ensemble. This improves the RF and RF++ observations of the MADOS results [1]: explicitly, computed spatial descriptors carry most of the contextual information this classification task needs, in a form that keeps every model input physically interpretable. Margins, not gradients, repaired the long tail: Focal loss, despite per-class weighting and difficulty modulation, left the four rarest classes between 1.5% and 49.9% $F1$, where LDAM's margin mechanism recovered 38–47 points with no architectural change. Focal loss and LDAM are often treated as interchangeable imbalance remedies; on this benchmark they are not. Capacity, data and limitation: The 9.26M-parameter variant improved validation but not the test performance, and the ≈10-point val–test gap was invariant to every intervention: with geographically disjoint splits and 103-pixel rare classes, generalization is constrained by data, not by model expressiveness. Three limitations follow from our design choices: per-pixel predictions carry no explicit spatial coherence, so post-processing (e.g., morphological filtering or a CRF) is a natural extension not explored here; the spatial descriptors use fixed scales and window sizes inherited from the literature, their joint optimization was not attempted, and their extraction imposes a CPU stage (Section 3) that a dense end-to-end model does not need; and Natural Organic Material remains effectively unsolved, with no path to improvement short of additional labeled data.

By analyzing our results, our proposed pixel2vecs representation (68 features) that makes spectral, multiscale, textural and local-context evidence explicit, allows TRITON to match and even slightly exceed (76.43% vs. 76.0% macro-*F*1 and 66.55 vs. 64.3% mIoU for our best single model) a more complex state-of-the-art segmentation pipelines in the literature. Our system runs on one graphic card using only 335MB (out of 24GB) of memory for the inference footprint, instead of two as in [1]. LDAM margin loss proved to be the only imbalance mechanism worth adding to our architecture. What still remains a challenge, is the dataset imbalance with some classes represented by few classified pixels, rather the model itself. Natural Organic Material (31 test pixels) and the dark-surface confusions among Oil Spill, Waves & Wakes and Jellyfish persisted across every configuration we tried, and the ≈10-point validation–test gap induced by geographically disjoint splits was invariant to loss, capacity and seed. For operational monitoring the outcome is a system whose errors are physically interpretable.

Abstract
Tuftsin-Phosphorylcholine (TPC) is a potent immunomodulatory ligand known to suppress pathological immune responses, yet its precise molecular targets at the cell membrane remain partially characterized. To accelerate target discovery, we present a dual silico framework that integrates physics-based simulation with statistical learning. The first method uses Molecular Dynamics (MD) and flexible docking to compute explicit binding affinities between TPC and candidate active centers, based on empirical force fields and classical physical interactions. The second method employs a reverse Quantitative Structure-Activity Relationship (QSAR) approach, combined with machine learning, to identify the essential topological and electronic features of active centers that are characteristic of strong TPC binding. This dual computational pipeline establishes a predictive platform to rapidly map the precise mechanism by which TPC prevents immune attacks, laying the groundwork for targeted, steroid-free alternative therapies for managing autoimmunity.

Keywords: computer-aided target identification, tuftsin-phosphorylcholine, reverse QSAR, molecular dynamics simulations, empirical potential energy, classical force fields, ligand-receptor docking, machine learning algorithms, active center topology, allosteric inhibition cavities, electrostatic pockets, immunomodulatory ligands, autoimmune attack suppression.

I. SCIENTIFIC BACKGROUND AND STATE OF THE ART

Globular proteins catalyze viral or bacterial multiplication. Such a protein has the same site called an active center. Proteins function using this active center. The active center is the "hands" of the protein. If we want to inhibit the multiplication of a virus or a bacterium, we need to find a small molecule (called a ligand) that can strongly bind to the active center and thus stop (inhibit) the function of the protein. Such a small molecule will be a drug against viruses or bacteria. Chemists usually search for such molecules by synthesis and by investigating their inhibitory function in vitro. Obviously, such a wet-lab job is slow and expensive. However,

there is a way to do it much faster and more cheaply. It is creating drugs using a computer. Indeed, if we know the structure of the protein and the location of its active center, we can calculate (based on known physical laws of molecular interaction) the strength of attraction between the ligand and the active center of the protein using a computer (Figure 1 in [1-4]).

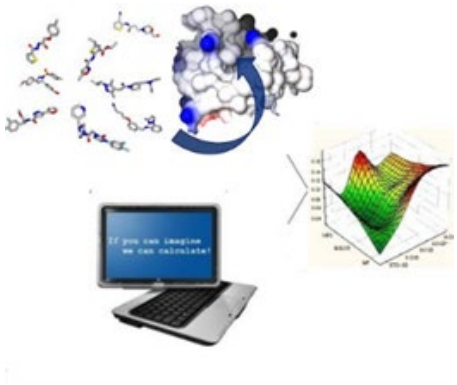

Figure 1. Computer-aided drug design.

In [4], we can find this first method by using Molecular Dynamics (MD) with Classical Potentials: "The central idea behind MD simulations is to study the time-dependent behavior of microscopic systems. This is obtained by solving the second-order differential equations represented by Newton's second law:

$$f_i(t) = m_i a_i(t) = -\frac{\partial V(x(t))}{\partial x_i(t)} \tag{1}$$

.re $f_i(t)$ is the net force acting on the iThe atom of the system at a given point in time $t, a_i(t)$ is the corresponding acceleration, and m_i is the mass. In Eq. (1), the instantaneous configuration of the system is represented by the vector. $x(t)$, which describes the position of the N interacting atoms in Cartesian space.

$$(x = \{x_1, y_1, z_1, x_2, y_2, z_2, \dots, x_N, y_N, z_N\}) \tag{2}$$

Usually, in computational drug discovery, we adopt a classical mechanics description of the forces. Notably, this approximation holds for massive particles such as nuclei, whereas electron motion must be averaged out. To achieve this, an empirical potential energy function is introduced ($V(x)$ in Eq. (1)), and the model arising from this simplified representation is referred to as the force field (FF), or molecular mechanics (MM):

$$V = A + B + C + D + E, \tag{3}$$

where each term describes a specific physical component of the atomic interactions:

- Stretching of chemical bonds:

$$A = \sum_i^{bonds} \quad \frac{k_{l,i}}{2}\left(l_i - l_{0,i}\right)^2 \tag{4}$$

- Bending of valence angles:

$$B = \sum_i^{angles} \quad \frac{k_{\alpha,i}}{2}\left(\alpha_i - \alpha_{0,i}\right)^2 \tag{5}$$

- Torsional rotation around bonds:

$$C = \sum_i^{torsions} \quad \left\{\sum_k^M \quad \frac{V_{ik}}{2}\left[1 + cos\left(n_{ik} \cdot \theta_{ik} - \theta_{0,ik}\right)\right]\right\} \tag{6}$$

- Van der Waals interactions (Lennard-Jones potential):

$$D = \sum_{i,j}^{pairs} \quad \varepsilon_{ij}\left[\left(\frac{r_{0,ij}}{r_{ij}}\right)^{12} - \left(\frac{r_{0,ij}}{r_{ij}}\right)^{6}\right] \tag{7}$$

- Electrostatic Coulomb forces:

$$E = \sum_{i,j}^{pairs} \quad \frac{q_i q_j}{4\pi\varepsilon_0 \varepsilon_r r_{ij}} \tag{8}$$

In Eq. (3), the first three terms represent intramolecular interactions of the atoms. They describe variations in potential energy as functions of bond stretching, bending, and torsion between atoms directly involved in bonding. Summations represent them over bond lengths (l), angles (α), and dihedral angles (θ), respectively. The stretching and bending contributions share the same functional form, as harmonic potentials describe them using reference values. l_0 and α_0 and force constants k_l and k_α, respectively. However, because of their intrinsic periodicity, torsional terms are naturally defined by a cosine series of M terms for each dihedral angle. Thus, n_{ik} is a parameter describing the multiplicity for the kThe term of the series, $\theta_{0,ik}$, i_k is the corresponding phase angle, and V_{ik} is the energy barrier. Taken as a whole, this group of contributions is usually referred to as the "bonded" terms of the FF."

The modern theory of differential equations in biology is described in [5-7].

In drug design, we have to reach stable equilibria; only in the case of stable equilibria is the process of creating a medicine physically achievable. This stable equilibrium is at the global energy minimum, as given by Eq. (3).

Mathematical methods for optimal search (global minimum) are described in the papers [8-11].

In [4]: "Although FFs can reduce the computational burden, Eq. (1) can still be analytically solved for only a few atoms. For biological macromolecule simulations, numerical methods must be used to split the integration of the equations of motion into discrete time intervals, called time-steps, δt. In doing so, forces are assumed to be constants during each integration step. However, as reported in Eq. (1), the forces depend on atomic positions that change over time. Thus, a small δtguarantees reliable forces over time. In practice, with appropriate workarounds, a time step of 1 or 2 fs can be safely considered as a good compromise between calculation accuracy and efficiency. This is commonly achieved, for example, with the SHAKE and related algorithms. Here, the equations of motion are solved while still satisfying the geometric constraint for the fastest degrees of freedom (i.e., the stretching and bending of bonds involving hydrogen atoms). Other strategies envision, for example, repartitioning the mass of heavy atoms onto the neighboring hydrogen atoms, allowing for a time-step increase of up to 4 As an example of an integrator, the velocity-Verlet is a simple and widely used algorithm in MD codes. Within such an integrator, the positions at time $(t + \delta t)$ are calculated by current positions, velocities ($v(t)$), and accelerations according to

$$x_i(t + \delta t) = x_i(t) + v_i(t)\delta t + \frac{1}{2}a_i(t)\delta t^2 \tag{9}$$

Accelerations are, in turn, calculated by the forces acting on each atom, that is, by taking the first derivative of the potential energy with respect to positions with opposite sign as shown in Eq. (1). Then, velocities are propagated as follows:

$$v_i(t + \delta t) = v_i(t) + \frac{1}{2}[a_i(t) + a_i(t + \delta t)]\delta t \tag{10}$$

As seen in Eq. (10), the second term on the right-hand side corresponds to the arithmetic mean of the accelerations taken at time t and $(t + \delta t)$. Moreover, to calculate accelerations at the next step, positions must be updated *before* advancing velocities. In fact, to be used safely in an MD simulation, any numerical integrator

must satisfy some practical and theoretical requirements. They must follow the analytical trajectory as closely as possible and preserve the physical properties of the equations of motion, with total energy as a constant of motion, given by the sum of the potential and kinetic energy. $\big(K(p)\big)$:

$$H(x,p) = V(x) + K(p) \tag{11}$$

Here, $H(,p)$ is the classical Hamiltonian of the system that depends on the coordinates and momenta of the particles and returns the total energy (E) of the system. From these considerations, it should be clear that as long as the integrator works properly, MD naturally follows the motion of a microscopic isolated system, where neither matter nor energy is exchanged with the surroundings."

The second method is the Quantitative Structure-Activity Relationship ($QSAR$). Indeed, if there are many known pairs of "active centers" - "ligands" - with strong attraction, then it is possible (using machine learning) to find which features of the pairs are characteristic of such strong attraction. (Figure 2, in [12-15])

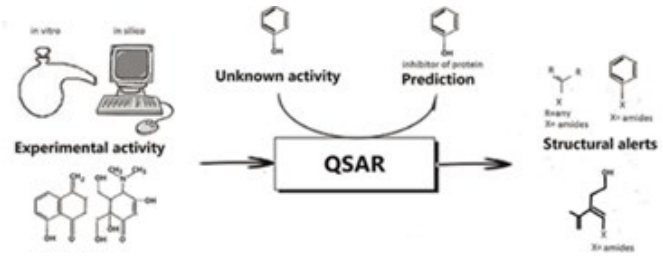

Figure 2. QSAR (*Quantitative Structure-Activity Relationship*)

In [14], we can find the history and development of $QSAR$: "The concept of a quantitative structure-activity relation. Until now, various $QSAR$Approaches have been developed gradually and have served as valuable predictive tools, particularly in the design of pharmaceuticals and agrochemicals. The first equation $QSAR$ was published by Crum-Brown and Fraser in 1868 (Brown et al. 1868), which is considered the first formulation of a quantitative structure activity relationship: the physiological activity" Φ was expressed as a function of the chemical structure C.

$$\Phi = f(C) \tag{12}$$

Studies were further extended by Richert et al. (1983), who reported that the toxicity of organic compounds is inversely related to their water solubility; in other words, differences in biological activities are due to changes in chemical and, especially, physicochemical properties.

$$\Delta\Phi = f(\Delta C) \tag{13}$$

The first well-defined $QSAR$ was developed and reported by Fujita and Ban (1970). Recently, various techniques have been introduced, and various software is available based on different algorithms in marketing."

II. RESEARCH OBJECTIVES AND SPECIFIC AIMS

We will leverage our expertise in computer programming, computer-aided molecular design, and QSAR to identify the specific active centers on the surfaces of immune cells that are blocked by TPC [16].

The primary objectives and the practical value of uncovering this mechanism are:

- Deciphering the Mode of Action: Uncovering exactly which active centers TPC blocks will explain *why* it successfully aborts immune attacks across multiple autoimmune models (lupus, arthritis, colitis, multiple sclerosis).
- Predicting Side Effects: Mapping all matching active centers on cell membranes will help identify off-target binding to non-intended proteins, ensuring drug safety.
- Rational Optimization: Revealing the precise geometry of the active center will enable chemists to modify the TPC molecule to make it more potent and selective (targeted design).
- Personalized Medicine: Disclosing specific target receptors will allow clinicians to match TPC therapy specifically to patients who overexpress these particular cell-surface proteins.

Our computational tools will establish an analytical platform to map how small immunomodulatory molecules suppress incorrect immune attacks and regulate human defense pathways.

III. DETAILED DESCRIPTION OF THE PROPOSED RESEARCH

1. Working hypothesis

We hypothesize that the interaction between the known drug TPC and its unknown targets on the surface of immune cells can be effectively modeled using physical and statistical algorithms. This will enable us to map the mechanisms of immune attack suppression significantly faster and cheaper than traditional in vitro proteomics. This predictive framework aligns with recent breakthroughs that combine neural networks and physical simulations in molecular structural biology, such as AlphaFold-3 [17] and Graph Neural Networks (GNNs) [18].

2. Research design and methods

Given the structure of TPC, we will calculate its binding affinity across thousands of documented active centers of human immune proteins using a computer. Reverse QSAR will use machine learning to identify structural and electronic features shared by proteins that strongly interact with TPC.

3. Analysis of potential active center locations on the cell membrane

Based on the foundational experimental data reported by Blank & Shoenfeld (2024), we identify the following critical zones for conducting a global energy minimum search:

- Allosteric inhibition cavities of innate immune receptors (e.g., TLR4): It is experimentally established that the phosphorylcholine (PC) component of TPC blocks the TLR4 signaling pathway, preventing the onset of an immune attack. Computational screening will focus on the inner hydrophobic cavity of the MD-2 co-receptor protein and allosteric side pockets at the TLR4/MD-2 interface. Binding of TPC to these zones is expected to induce a conformational shift that blocks the signal.
- Deep electrostatic pockets of navigational receptors (e.g., Neuropilin-1): Structural data indicate that the tuftsin domain of TPC binds to the Neuropilin-1 receptor, shifting the cell from an attacking state to a protective phenotype. Modeling includes calculating the insertion parameters of the TPC C-terminal arginine (R) into the deep, negatively charged cavity of the receptor, forming a hydrogen bond with the D320 residue of Neuropilin-1.

- Allosteric and boundary zones of presentation platforms (MHC / HLA Class I and II): Since TPC is too small to fit the classical peptide-binding groove of MHC, the software will scan the terminal barrier pockets of the MHC II groove (P1 and P9 pockets) for electrostatic shielding properties. Additionally, the outer loops of the MHC-TCR interface will be assessed, where TPC might act as a "molecular shield" to arrest the immune attack driven by T-lymphocytes.

4. Preliminary results and team competencies

- PI Dr. Oleg Kupervasser (Israel) possesses extensive expertise in chemical physics (Ph.D. from the Weizmann Institute) and postdoctoral experience in QSAR and 3D protein structures (University of Haifa). He developed software to locate loops and locks in protein configurations and to calculate the effects of surrounding solutions on protein-ligand interactions (the patented DISOLV program). This background is perfectly aligned with modeling how TPC fits into the active centers of immune receptors.
- Co-PI — Prof. Yehuda Shoenfeld (Israel) is a world-renowned authority on autoimmune diseases and the founder of the Zabludowicz Center for Autoimmune Diseases (the largest center of its kind in Israel). His unparalleled expertise in immune system pathophysiology ensures the project's fundamental biological relevance.

IV. SIGNIFICANCE, IMPORTANCE, INNOVATION, AND POTENTIAL BENEFITS OF THE PROPOSED RESEARCH

The current status quo is the search for new drugs in vitro, drawing on prior experience without clear algorithms. We want to develop a universal, clear algorithm written in silico (i.e., in computer programs).

The current status quo in pharmacology relies on tracking drug mechanisms through prolonged *in vitro* screening. We propose a universal, clear, in silico algorithm to discover active centers that are blocked by a drug. The fundamental scientific breakthrough of this project is as follows:

If the hypothesis is validated *in silico*, this project will reveal a completely new class of small-molecule inhibitors and allosteric modulators of MHC (HLA) class I and II proteins. This will challenge the established dogma in classical immunology, stating that large presentation platforms of adaptive immunity are inaccessible to precise small-molecule intervention. We will shift from empirical observation of TPC effects to precise physical mapping of its hidden biophysical targets, discovering new allosteric pockets on the surface of key human immune receptors.

V. APPLICABILITY

Expected results and long-term therapeutic impact: The deployment of this software platform will provide a cost-effective, rapid method for identifying active centers in immune cells that TPC blocks. Defining the exact topographic coordinates ("cavities") on the MHC surface where TPC binding conformationally shuts down autoantigen presentation will lay the groundwork for developing potential alternatives to conventional steroid therapies. Unlike non-specific corticosteroids (such as dexamethasone or methylprednisolone), which cause severe systemic side effects and globally suppress the entire immune system, selective small-molecule TPC-based inhibitors are hypothesized to target the initiation step of the pathological immune response, potentially minimizing systemic adverse effects.

This will enable the effective treatment of severe autoimmune conditions while preserving the patient's general infectious safety and overall health. Risks and Mitigation: The previously identified risk of being unable to validate *in silico* findings without direct access to a wet laboratory is now completely mitigated. Prof. Yehuda Shoenfeld and his research group will provide full laboratory validation of the computational modeling results.

VI. COOPERATION VECTORS BETWEEN THE RESEARCH GROUPS

- In Israel (Computational PI — Dr. Oleg Kupervasser): Responsible for leading the development of mathematical algorithms and software for target searching, leveraging extensive experience in QSAR and molecular mechanics.
- In Israel (Biological Co-PI — Prof. Yehuda Shoenfeld): Responsible for the scientific supervision of the medical and biological validation phases. Prof. Shoenfeld will lead laboratory testing of modeling results (in vitro binding assays and cellular assays on macrophages and T-cells) to experimentally confirm the highly specific binding of TPC to the computationally predicted active centers.
- Mathematical Group (Co-PI — Dr. M. Bershadsky (Israel), Vadim Povolotskii (Israel), Mariia Lishnevskii (Israel)): Responsible for delivering mathematical optimization for tracking TPC-receptor interactions via molecular dynamics and implementing global optimization algorithms to reduce computational overhead.

VII. WORK PLAN AND GANTT CHART

Table 1. 3-Year Parallel Joint Research Roadmap Gantt Chart

#	Task Description	Year 1	Year 2	Year 3
1	Months 1–12 (Year 1): Computational group formulates the mathematical core, combining physical integrators and statistical QSAR learning rules for machine learning. Simultaneously, Prof. Shoenfeld's biology laboratory performs parallel *in vitro* testing of the baseline TPC molecule to provide experimental constants for method calibration.			
2	Months 13–24 (Year 2): The computational group optimizes the software of the universal method based on the combination of physical force fields and neural network recognition (inspired by the Nobel Prize in Chemistry 2024) and designs new candidates			

#	Task Description	Year 1	Year 2	Year 3
	ligands. The biology laboratory maintains parallel cell cultures and prepares validation platforms.			
3	Months 25–36 (Year 3): Computational group performs final scoring of the universal method. Biology laboratory executes parallel *in vitro* comparative assays (TPC vs new candidate ligands) to experimentally confirm the accuracy and predictive power of the developed universal method.

Abstract
This paper presents the design, fabrication, and experimental characterization of a lightweight asymmetric double-cone antenna optimized for wideband operation. The proposed antenna incorporates a miniaturized reflector diameter, optimized conductor thickness, and an adjustable feed gap to achieve significant weight reduction while preserving broadband performance. The structure was modeled and optimized using CST Studio Suite, followed by prototype fabrication and measurement using a vector network analyzer (VNA). Key performance metrics, including the reflection coefficient (S_{11}), voltage standing wave ratio (VSWR), and input impedance, were evaluated for various feed-gap configurations, with a 2 mm gap providing the best overall performance. The fabricated antenna demonstrates a measured operating bandwidth of approximately 4–14 GHz, with minimum reflection coefficients of −46.95 dB at 6.84 GHz and −35.57 dB at 9.45 GHz. Stable VSWR characteristics are maintained across the operating band. A comparison between simulated and measured results confirms the validity of the proposed design. Furthermore, benchmarking against a commercially available wideband antenna from a leading global manufacturer highlights the improved impedance-matching performance achieved by the proposed structure. The results verify that the optimized asymmetric configuration effectively reduces weight without compromising electromagnetic performance, making it suitable for wideband communication systems and uncrewed aerial vehicle (UAV) applications.

Keywords: Biconical antenna, asymmetric design, compact antenna, wideband, impedance matching, UAV applications.

I. INTRODUCTION

Biconical antennas, consisting of two conical conductors connected at a common apex, are widely employed due to their broad impedance bandwidth, omnidirectional radiation characteristics, and simple geometric structure. These features make them suitable for numerous applications traditionally served by half-wave dipole

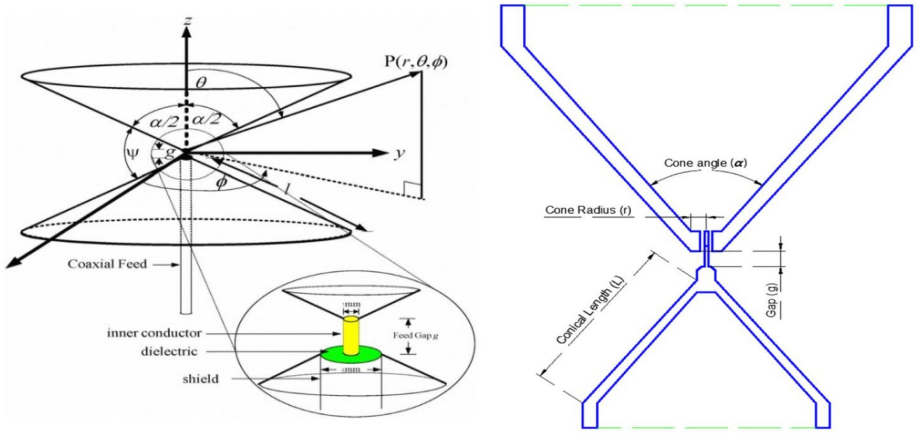
antennas, including electromagnetic compatibility (EMC) testing, broadband communication systems, and uncrewed aerial vehicles (UAVs) [1–3].

Despite these advantages, conventional biconical antenna designs face several challenges. These include relatively large physical dimensions, limited control over the main beam direction in the E-plane, and significant size and weight constraints, which are particularly critical in UAV-based systems [4]. Extending the operational range of UAV communication systems typically requires increasing the transmitted power at both the UAV and the ground station. This can be achieved using directional antennas, antenna arrays, or tracking antenna systems that focus radiation toward the UAV. However, such approaches are often complex and costly, introducing additional challenges. For example, highly directional antennas necessitate careful mitigation of both co-channel and cross-channel interference. In contrast, antenna arrays significantly increase system complexity, which is undesirable for lightweight and compact UAV platforms [4]. To address the size and weight limitations of biconical antennas in UAV applications, the authors in [2] proposed a miniaturized biconical antenna loaded with metallic disks and cylindrical elements. This configuration expands the impedance bandwidth from 200 to 965 MHz while maintaining stable radiation patterns and gain,achieving a reduction in antenna height of 288.4 mm and diameter of 175mm. In [3], an irregular biconical antenna composed of two dissimilar cones connected by an annular ring was introduced to achieve a nearly constant beam direction over the operating bandwidth. The E-plane beam direction can be controlled by adjusting the annular ring dimensions and the slope ratio between the cones. However, once installed on a UAV, beam reconfiguration becomes impractical, as it relies on fixed geometric parameters. Furthermore, the limited bandwidth reported in [3] was later extended in [5] through an asymmetric miniaturized biconical antenna operating over the 3.1–10.6 GHz frequency range. Similarly, a dual-band (2.45 GHz and 5.80 GHz. A circularly polarized biconical antenna incorporating parasitic parallelepiped elements was proposed in [6] to enhance bandwidth and overall performance. Additional modifications to the classical biconical structure, including the integration of rings and cylindrical elements, were presented in [7], resulting in an ultra-wideband operation spanning from 1.5 GHz to 41 GHz. Integrating the antenna into the drone airframe provides an effective solution to structural and spatial constraints while reducing overall system weight. Since payload capacity is a critical design parameter in uncrewed aerial vehicles (UAVs), minimizing antenna weight without degrading electromagnetic performance is essential. In this work, a lightweight asymmetric bicone antenna is proposed and optimized using CST Studio Suite, followed by fabrication and experimental validation. The proposed design achieves approximately a 33% reduction in weight compared to a conventional bicone antenna, while maintaining comparable impedance bandwidth and radiation characteristics to those of a commercially available counterpart from a leading global manufacturer.

II. ANTENNA DESIGN

The mathematical model of a biconical antenna provides a comprehensive framework for describing its electromagnetic behavior through key parameters and governing equations. This model is fundamental for analyzing antenna performance and for optimizing the design to meet specific application requirements.

1. Biconical Antenna Geometry



The proposed integrated and miniaturized conical dipole antenna employs an asymmetric configuration to enhance performance over a wide frequency range. The antenna consists of two conical sections that are positioned with a small gap between their apices. The first cone, located closer to the feed source or mounting structure, has a larger diameter, while the second cone, positioned farther from the source, has a smaller diameter. This asymmetric geometry is deliberately selected to improve impedance matching, bandwidth, and radiation characteristics.

Several geometric parameters govern the antenna's performance:

- The cone angle (α) primarily influences the antenna directivity and gain.
- The cone radius (r) affects the beamwidth and radiation resistance.
- The gap between the cones (g) plays a critical role in determining antenna gain and operational bandwidth.
- The cone length (L) controls the resonant frequency of the antenna.

As illustrated in Fig. 1, these parameters are treated as design variables and are systematically optimized to achieve the desired performance. The optimized antenna structure provides broadband operation with a realized gain ranging from approximately 2 to 6 dB. Furthermore, the return loss (S_{11}) is maintained below -10 dB across the operating frequency band, while the voltage standing wave ratio (VSWR) remains between 1 and 2 [8].

Figure 1(b) presents the final configuration of the proposed biconical antenna, which is derived from the classical structure shown in Figure 1(a). The modified design incorporates truncated cones, outer rings, a coaxial feed line, and cylindrical elements to enhance bandwidth and impedance matching, as illustrated in Figure 1(b) [5].

(a) (b)

Figure 1. The structure of the biconical antenna. (a) Geometry configuration, (b) Cross-section view

2. Input Impedance

For an infinite biconical antenna operating in free space, the characteristic impedance can be expressed as [9]

$$Z_o = 120ln\left(cot\left(\alpha/2\right)\right) \quad (1)$$

Since the characteristic impedance in (1) is independent of the radial distance r. It also represents the input impedance at the feed terminals of an infinite biconical structure. Moreover, because (1) corresponds to a purely resistive impedance, it can be further simplified for small cone angles. Under this assumption, the input impedance can be approximated as

$$Z_{in} \approx 120ln\left(4/\alpha\right) \quad (2)$$

During the optimization process, a 50-Ω coaxial feed line was connected to the antenna model. This configuration was adopted to account for the feeding mechanism accurately and to minimize the influence of cable effects on the antenna's impedance matching and overall performance.

3. Skin Depth Characteristic

Since the biconical antenna can be modeled as a transmission line, the thickness of the conductive material significantly affects its electrical performance. In this work, antenna weight is reduced by decreasing the thickness of the conductive sheets in the antenna structure. However, the minimum feasible thickness is limited by the skin depth. (δ) of the conductor.
For good conductors, the skin depth δcan be expressed as [10]

$$\delta = {1}/{\sqrt{\pi\delta\mu\sigma}} \tag{3}$$

where $f$as the operating frequency, $\sigma$is the electrical conductivity of the material, and $\mu = \mu_r\mu_0$is the magnetic permeability of the conductor. Here, $\mu_o = 4\pi \times 10^7\ H/m$ denotes the permeability of free space, and $\mu_r$is the relative permeability of the material.
It should be noted that (3) is valid only for good conductors, where conduction currents dominate over displacement currents. Table 1 summarizes the calculated skin depth values (δ) for the conductive materials employed in the fabricated antenna prototype.

Table 1. Maximum skin depth $\delta$of copper and aluminum biconical antennas at $f = 100$MHz.

	Copper	***Aluminum***
μ_r	0.9999912	1.00000037
σ	5.8×10^7	3.5×10^7
δ	7 μm	8.5 μm

Based on the skin depth (δ) values listed in Table 1, electromagnetic waves are effectively reflected from the antenna surface when the conductor thickness is significantly greater than δ. As reported in [11], within the operating frequency range of 1–13 GHz, The thickness of the conductive material has a negligible effect on the performance of a biconical antenna, provided that this condition is satisfied.

4. Size Re-Adjustment

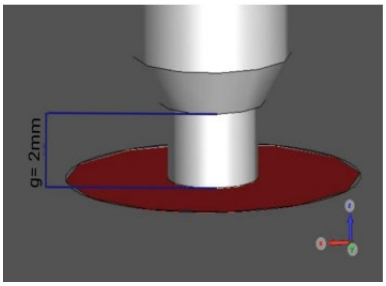
Previous studies [12–14] have demonstrated a strong relationship between the physical dimensions of a biconical antenna and its radiation characteristics, particularly the E-plane radiation pattern. Systematic size-reduction targeting parameters such as cone length, flare angle, and material thickness has been widely adopted as an effective approach to antenna miniaturization and weight reduction. In this work, the antenna's weight was reduced by modifying its overall dimensions, including the reflector diameter and the conductor thickness. These adjustments inherently alter the critical dimensional ratios that define the antenna's asymmetric configuration. As noted in [12], changes to the upper section of the antenna—effectively altering the equivalent cap size and cone geometry—directly influence the downward tilt of the E-plane radiation pattern. Consequently, any dimensional reduction intended to reduce weight must be accompanied by a careful re-optimization of the antenna geometry to preserve the desired beam direction and overall radiation performance. The optimized antenna configuration was obtained using CST Studio Suite. Figure 2 shows the fabricated prototype based on this design. Its electromagnetic performance was subsequently validated through a series of experimental measurements, the results of which are presented and analyzed in this section III.

Figure 2. Fabricated an asymmetric biconical antenna after mechanical assembly.

III. RESULTS AND DISCUSSIONS

The proposed asymmetric biconical antenna was analyzed via simulations in CST Studio Suite and experimentally characterized with a Vector Network Analyzer (VNA). Key performance parameters, including the reflection coefficient (S_{11}Voltage standing wave ratio (VSWR), input impedance, and Smith chart were extracted to verify impedance matching across the targeted frequency band. In addition, the influence of varying the feed gap between the two conical elements on antenna performance was investigated. Simulated and measured results of the modified antenna were compared with those of the original copper and aluminum prototypes to assess performance variations. The antenna was characterized over the frequency range 0.8–18 GHz, including the targeted operating frequency of 1.2 GHz. For benchmarking purposes, identical measurement procedures were conducted on a commercially available dual-cone antenna from a global manufacturer. Furthermore, two gap lengths, 2 mm and 8 mm, were investigated to evaluate their influence on the antenna's performance. The feed gap (Gap) The distance between the two conical sections is a critical parameter affecting broadband performance. In this study, the performance of the manufactured antenna was evaluated for two gap lengths. The impact of the gap on impedance matching, resonant frequency, and operational bandwidth was assessed by analyzing S11 and SWR curves. Due to manufacturing constraints for the 2 mm gap, an iron adjustment piece was used to achieve the required spacing, whereas a copper piece was used for the 8 mm gap. It should be noted that these material selections were dictated solely by mechanical considerations for precise gap implementation, rather than by a comparison of metallic properties. Aluminum was unavailable at this stage for these adjustments.

Figure 3 illustrates the geometric configuration of the antenna for a 2 $mm\ gap, showing\ the\ position\ of\ the\ iron\ adjustment\ piece\ relative\ to\ the\ feed, while\ the\ 8\ mmThe$ gap configuration employs a copper piece. This visualization highlights the effect of short feed distances on impedance matching near the resonant frequency. This analysis aims to identify the optimal gap that provides the best combination of impedance matching and frequency stability for the fabricated antenna.



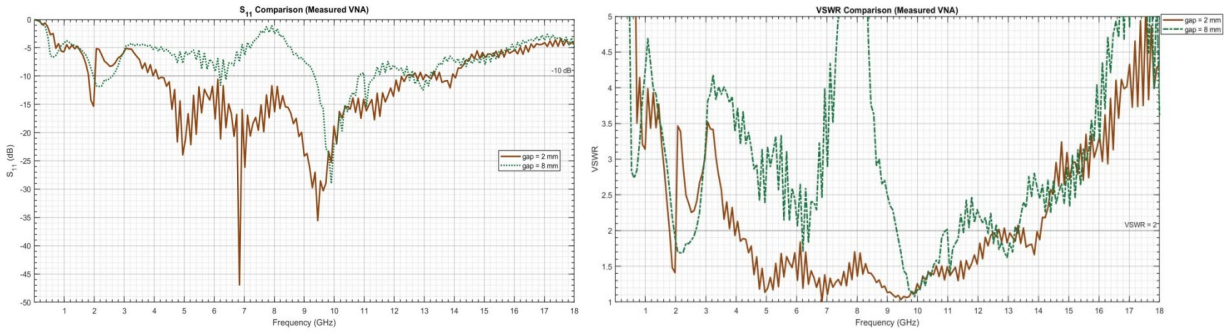


Figure 3. Feed gap of 2 mm implemented using an iron adjustment piece.

After conducting experimental measurements on the fabricated antenna with both gap lengths, the antenna performance was evaluated based on the measured reflection coefficient (S_{11}), bandwidth, and VSWR. Figure 4 presents the measured. $S_{11}$and VSWR curves over the frequency range of 0.8–18 GHz for the 2 mm and 8 mm gap configurations. The key observations are summarized below.

- From Figure 4(a), for the 2 mm feed gap, the lowest S_{11}values occur at 6.84 GHz and 9.45 GHz, with corresponding magnitudes of −46.95 dB and −35.57 dB, respectively. In contrast, for the 8 mm gap, S_{11}exhibits multiple fluctuations around the −10 dB level, with the minimum value of −28.85 dB observed at 9.9 GHz. This indicates that the 2 $mmThe\ The\ The\ equation\ gapThe$ gap provides consistently lower reflection coefficients across most of the measured frequency range.
- Applying the $S_{11} \leq -10\ dB$ criterion, the operational bandwidth for the 2 mm gap is approximately 4–14 GHz, resulting in a bandwidth of 10 GHz. Conversely, for the 8 mm gap, the fluctuating S_{11}Response makes it difficult to define a clear, continuous operational band that meets this matching criterion.
- Figure 4(b) presents the VSWR curves, which closely correspond to the behavior of S_{11}. For the 2 mm gap, ideal VSWR values near 1 are observed at 6.84 GHz and 9.45 GHz, indicating improved power transfer and reduced reflection at these frequencies. For the 8 mm gap, impedance matching is primarily effective near the resonant frequency of 9.9 GHz, while VSWR values increase outside this region, indicating higher reflected power across the remaining frequency band. Overall, the 2 mm gap exhibits a more stable and significantly lower VSWR over a wide frequency range compared to the 8 mm gap, confirming its superior impedance matching performance.

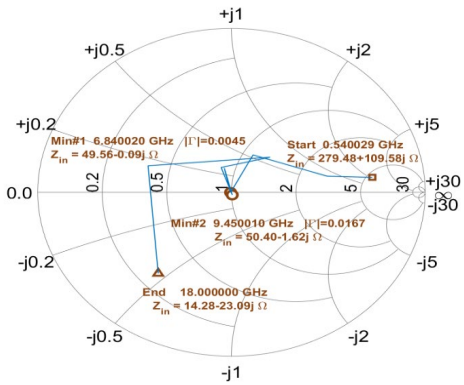
(a) S_{11} Measurements (b) VSWR Measurements

Figure 4. Measurements of $S_{11}$and VSWR for the fabricated antenna with 2 and 8 mm feed gaps.

To further evaluate impedance matching, the antenna's input impedance was plotted on a Smith chart using a Vector Network Analyzer. It should be noted that the trajectory on the measured Smith chart may appear unclear due to the large number of frequency points and minor ripples caused by measurement noise. Consequently, the optimal matching points were identified programmatically using MATLAB and treated as reference values.

Figure 5 shows the Smith chart for the fabricated antenna with m , e,p. Based on this analysis, the two best-matching points were found at 6.84 GHz and 9.45 $GHz$with corresponding input iimpedances of cap Z sub in equals 50.4 minus j 1.62 cap omega and cap Z sub in equals 49.56 minus j 0.09 cap omega respectively The proximity of these values to 50 Ω, combined with minimal imaginary components, confirms excellent impedance matching, consistent with tthe 11th cap S sub 11thVSWR measurements.

For the 8 mm gap, the Smith chart was not presented due to increased ripple and a less clear trajectory in the measurement data. Instead, the numerical values of Z_{in} The reference frequencies were used to assess matching performance.



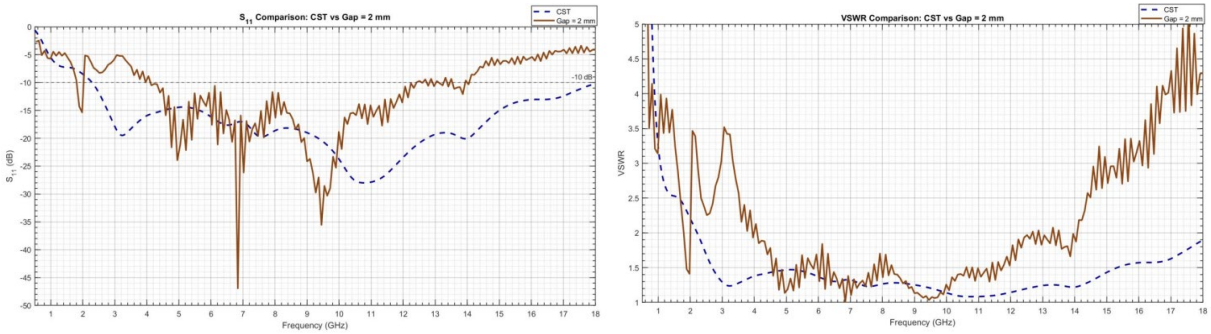


Figure 5. Smith chart of the fabricated antenna with a 2 mm feed gap.

1. Acronyms: Comparison Between Simulation and Practical Measurements

Based on the optimal practical tuning of the fabricated antenna with a 2 mm feed gap, the simulated results obtained using CST Studio Suite were compared with the antenna's measured performance. This comparison was performed using the reflection coefficient (S_{11}), VSWR curves, and the input impedance (Z_{in}) at specific frequencies. Figure 6(a) presents both the simulated and measured. S_{11}curves on a single plot to highlight the differences between the CST predictions and the practical measurements. The CST simulation curve exhibits a smooth response, whereas the measured data show distinct ripples due to fabrication tolerances, connector effects, and measurement noise. Additionally, slight shifts are observed in the positions of the main reflection dips. The practical measurements show deeper, multiple dips compared to the simulation, reflecting subtle real-world variations not captured by the idealized CST model. Similarly, the VSWR curves from the CST simulation and the practical measurements were compared on a single plot, as shown in Figure 6(b). This comparison corroborates the reflection behavior observed in the S_{11}Results and highlights the differences in fluctuation between the practical measurements and the simulation. The simulated curve exhibits a smoother response, while

the measured VSWR shows small ripples and variations due to fabrication tolerances, connector effects, and measurement noise, consistent with the behavior observed in the S_{11}Comparison.

Regarding the operational bandwidth, the CST simulation predicts a wider frequency span of approximately 2.3–18 GHz, whereas the practical measurements indicate an effective bandwidth of roughly 4–14 GHz. This discrepancy is primarily attributed to fabrication tolerances, connector effects, and minor variations in material properties, which slightly limit the measured performance compared to the idealized simulation model.

(a) (b)

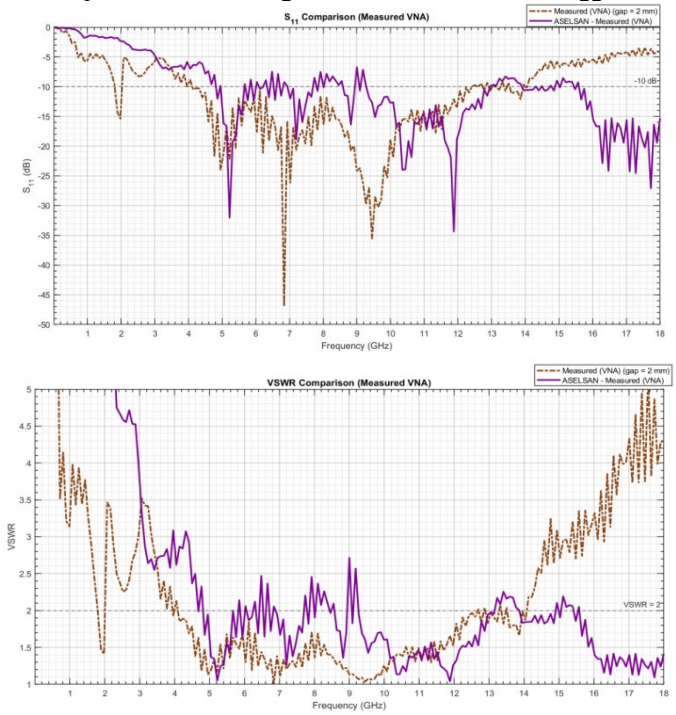

Figure 6. (a) Measured vs. CST simulation results for Gap = 2 mm,
VSWR comparison between CST simulation and practical measurement for Gap = 2 mm.

2. Comparison of Practical Measurements Between the Fabricated Antenna and a Commercial Benchmark Antenna

Experimental measurements were conducted on a commercially available dual-cone antenna from a global manufacturer using a vector network analyzer (VNA) to enable direct comparison with the locally fabricated antenna. The comparative analysis focuses on key performance parameters, including the reflection coefficient (S_{11}), operating bandwidth, and frequency response, to quantify the differences between the two designs.

- Figure 8 presents the measured reflection coefficient (S_{11}) for both antennas. The fabricated antenna exhibits deep reflection dips, with the most prominent occurring at 6.84 GHz (−46.95 dB) and another strong dip at 9.45 GHz (−35.57 dB). In comparison, the benchmark antenna shows a minimum reflection at different frequencies, primarily in the mid-frequency range, while the target operating frequency of 10.5 GHz falls within a region where both antennas achieve acceptable performance.
- Moreover, Figure 7(a) highlights that the fabricated antenna achieves an almost continuous operational bandwidth from approximately 4 to 14 GHz. By contrast, the reference antenna demonstrates good performance over a narrower mid-range frequency band, with additional improvements observed at higher frequencies. This comparison underscores the effectiveness of the proposed design in achieving a wide operational bandwidth while maintaining a minimum depth of reflection at key frequencies.
- Figure 7(b) presents the VSWR measurements for both the fabricated and commercial antennas. As expected, the reductions in VSWR correspond closely to the reflection minima observed in the S_{11}curves. The results indicate that VSWR values are lower and more stable across the mid-frequency range for both antennas. However, for the fabricated antenna, VSWR increases at higher frequencies,

reflecting a slight rise in reflected power outside the primary operational band. Overall, the VSWR behavior confirms the impedance matching trends observed in the S_{11}measurements.

IV. CONCLUSION

In this study, a lightweight asymmetric biconical antenna was designed, fabricated, and experimentally characterized for wideband applications. By optimizing key structural parameters, including reflector diameter, conductor thickness, and feed gap, the antenna weight was significantly reduced while maintaining broadband performance. The fabricated prototype with a 2 mm feed gap demonstrated excellent impedance matching, characterized by deep reflection minima at 6.84 GHz and 9.45 GHz, a wide measured operating bandwidth of approximately 4–14 GHz, and stable VSWR across the operating band. Good agreement between CST Studio Suite simulations and experimental measurements validates the proposed design methodology. Furthermore, benchmarking against a commercially available global antenna confirms the proposed structure's competitive performance in impedance matching and bandwidth. The results demonstrate that the proposed asymmetric configuration effectively balances weight reduction with high electromagnetic performance, making it a strong candidate for broadband communication systems and uncrewed aerial vehicle (UAV) applications. Future work will focus on further miniaturization, structural integration into UAV platforms, and the development of antenna array configurations to enhance directivity and gain.

ACKNOWLEDGEMENT

This research was conducted collaboratively within the Antennas and UAV Research Group at the Faculty of Engineering, Misurata University. The student authors jointly contributed to the antenna design, simulation, fabrication, experimental measurements, and manuscript preparation under the supervision of the faculty members.

Abstract
Generative artificial intelligence systems are increasingly used to assist with long-form writing tasks, including educational, technical, and advisory content. However, single-agent large language models frequently struggle with maintaining narrative coherence, factual consistency, and structural integrity across extended documents, particularly in data-intensive domains. These limitations pose challenges for responsible and scalable AI-assisted authorship. This paper presents an exploratory, comparative case study of two AI-assisted authorship paradigms for producing a book-length manuscript on personal investing: (1) a human-in-the-loop, multi-persona collaborative authorship model implemented using Google's Gemini, and (2) an autonomous multi-agent system implemented using the LangGraph framework. Both approaches were assigned identical task constraints, outlines, and prompts to isolate differences attributable to the collaboration approach. The single-case comparison supported reporting the findings descriptively, supporting an initial understanding of the trade-offs of these two approaches. Results show that the human-in-the-loop Gemini model achieves superior narrative coherence, stylistic consistency, and advisory nuance, but requires substantial human coordination. The LangGraph multi-agent system demonstrates strong structural adherence and improved identification of factual claims but exhibits reduced narrative fluidity. This work contributes a comprehensive, reproducible methodology for evaluating multi-agent AI systems in long-form authorship, case study-based experiential evidence of trade-offs between autonomy and quality, and a hybrid agent architecture that can be extended and empirically validated by future researchers.

Keywords: Generative AI, Multi-Agent Systems, Human-in-the-Loop, Autonomous Authorship, Google Gemini, LangGraph, Long-Form Text Generation, Large Language Models (LLM).

I. INTRODUCTION

Since the public release of ChatGPT in late 2022, generative artificial intelligence (AI), particularly large language models (LLMs) such as ChatGPT, Gemini, and similar architectures, has dramatically reshaped how written content is produced, curated, and understood across domains ranging from creative writing to scientific authorship. These models have evolved from simple autocomplete tools into active collaborators capable of generating paragraphs, sections, and even complete documents with minimal human guidance. Research on the sociotechnical impacts of generative AI in authorship has noted that these systems alter traditional notions of text creation and creative agency, often resulting in hybrid human–machine outputs that challenge established academic practices and norms concerning authorship, responsibility, and disclosure [1], [2].

Despite their expressive power, LLMs continue to exhibit persistent limitations when tasked with generating sustained long-form content. While short-form outputs often demonstrate fluency and task relevance, extended documents pose challenges in maintaining global coherence, narrative continuity, and factual consistency, leading to topic drift and error propagation across sections [3], [4]. Hallucination -the confident generation of incorrect or ungrounded information - has been repeatedly documented as a significant reliability risk, particularly in structured and high-stakes domains such as finance, law, or medicine, where inaccurate claims can undermine trust and practical value [5], [6]. These shortcomings are exacerbated in single-agent systems that lack robust internal verification, context retention, or dynamic planning mechanisms, often resulting in incoherent narratives and unverifiable assertions over long spans of text [7], [8]. While architectural innovations such as retrieval-augmented generation (RAG) and enhanced planning have mitigated certain failure modes, they do not fully resolve issues of narrative cohesion or systematic consistency without extensive human feedback [9], [10]. To mitigate such issues, research has increasingly explored multi-agent AI architectures that distribute writing tasks across specialized subagents - such as planners, outline constructors, draft authors, editors, and critics - rather than relying on a single monolithic generative process [11], [12]. These frameworks aim to mirror human collaborative workflows and introduce internal checks that can improve reliability, traceability, and content quality beyond what is achievable with single-agent generation [13]. In parallel with architectural innovation, research on human–AI collaboration emphasizes structured interactions and feedback loops between human authors and generative systems to balance efficiency with oversight. Normative conversational frameworks and interactive oversight mechanisms have been proposed to align system outputs with human intent and disciplinary norms, improving task alignment and communication clarity [14], [15]. However, evaluations of multi-agent systems for complete, long-form nonfiction writing remain limited**.** Most existing studies either focus on short tasks, creative narratives in constrained settings, or modular benchmarks that do not capture the demands of sustained nonfiction discourse. There is thus a critical gap in the literature regarding (a) the scalability and coherence of multi-agent authorship pipelines, (b) their factual reliability in domains with rigorous accuracy requirements, and (c) comparative studies of human-in-the-loop versus fully autonomous multi-agent frameworks in realistic editorial workflows [4], [12], [6]. This paper addresses that gap with a case-study comparison of two paradigms of AI-assisted authorship: a human-in-the-loop, multi-persona collaborative model implemented with Gemini, and an autonomous multi-agent system implemented with LangGraph. The primary research question is whether multi-agent AI frameworks can generate coherent, accurate, and well-structured long-form written content with limited human intervention. Secondary questions examine the extent to which such systems replicate human collaborative writing processes and the trade-offs between autonomy, efficiency, and narrative quality [3], [11].

II. CONCEPTUAL AND THEORETICAL FOUNDATIONS

1. Knowledge Co-Creation and Human–AI Collaboration

This study is grounded in the theory of knowledge co-creation, which conceptualizes knowledge production as a continuous cycle between tacit and explicit knowledge. In generative AI writing environments, this cycle manifests as an iterative interaction among human intent, machine-generated text, and successive refinement. Distributed Cognition theory further frames cognition as distributed across individuals, artifacts, and environments. This principle is exemplified by tools that externalize otherwise implicit cognitive processes into inspectable, manipulable structures, such as visual representations of complex query logic [16]. Within AI-assisted authorship, LLMs and AI agents function as cognitive artifacts that share reasoning, memory, and organizational tasks with human collaborators, extending rather than replacing human cognition. Trust plays a central role in determining the effectiveness of such collaborations. In authorship contexts, trust governs when humans accept, revise, or override AI-generated text, shaping both workflow efficiency and final output quality.

2. Human-Centered AI and Socio-Technical Writing

Human-Centered AI emphasizes systems that amplify human abilities rather than automate them away. From this perspective, AI-assisted writing is best understood as a socio-technical process involving automation, human judgment, institutional norms, and ethical constraints. Writing itself is inherently socio-technical, involving tools, audiences, conventions, and accountability structures. When AI systems participate in writing, evaluation must therefore consider not only output quality but also process transparency, human labor, and ethical implications.

3. AI-Assisted Authorship and Multi-Agent Systems

Prior research has shown that single-agent LLM systems struggle with factual consistency and narrative continuity in extended documents, particularly in analytical or financial domains. Multi-agent debate and verification frameworks have been proposed to mitigate hallucinations by enabling internal critique among agents. Frameworks such as LangGraph operationalize these ideas by enabling structured agent workflows with defined roles and communication pathways, allowing AI systems to approximate human editorial collaboration.

III. STUDY OVERVIEW

This study employs a comparative case study design in which two AI-assisted authorship systems are tasked with producing a complete, book-length manuscript. A case study approach was selected because long-form writing involves interdependent decisions, iterative refinement, and emergent behaviors that are difficult to isolate using benchmark-style evaluations. Each case corresponds to a distinct authorship paradigm: (1) a human-in-the-loop, multi-persona collaborative system and (2) an autonomous multi-agent system. Both systems were evaluated under identical task constraints to ensure comparability.

IV. METHODOLOGY

1. Rationale for Case Study Design

This study adopts a single-case, qualitative comparative design. The design supported this exploratory investigation of how architectural differences between human-in-the-loop and autonomous multi-agent systems manifest in long-form, book-length writing. This design is suitable in part because long-form nonfiction authorship lacks a single correct output against which to evaluate system performance. That makes quantitative metrics such as accuracy scores against a reference text poorly defined for this task. Additionally, the theoretical constructs motivating this study, namely knowledge co-creation, distributed cognition, and trust, describe processes rather than discrete outcomes, and are more directly observable through a structured qualitative comparison of two authorship processes in a case study than through aggregate quantitative scoring. The comparative case study reported here is intended as an initial experiment to support future experiments that evaluate specific hypotheses quantitatively using a larger set of cases.

2. Task Definition

Both systems were tasked with generating a non-fiction manuscript of approximately 20,000 words on personal investing. The intended audience was defined as individuals aged 40 and older with limited retirement savings. This task was selected because it requires sustained narrative coherence, factual accuracy, ethical responsibility, and practical clarity across chapters, making it a stringent test of long-form AI authorship.

3. Systems Evaluated
4. Human-in-the-Loop Multi-Persona System (Gemini)

The human-in-the-loop system employed a single large language model operating under multiple conceptual personas instantiated through prompt conditioning. Personas represented roles such as researcher, writer, and editor. A human operator coordinated persona interactions, resolved contradictions, sequenced tasks, and integrated outputs. The human operator functioned as a centralized planner and editor, exercising judgment over content quality, narrative flow, and factual plausibility.

5. Autonomous Multi-Agent System (LangGraph)

The autonomous system was implemented using LangGraph, a Python-based agent orchestration framework. Agents operated as discrete computational entities with defined roles, message-passing rules, and execution order. After initial configuration, the system executed with minimal human oversight, emphasizing autonomy and internal coordination.

6. Agent Architecture

The autonomous system employed a hybrid hierarchical architecture that combined the Planner–Executor and Critic–Reviewer models. The Planner agent decomposed the manuscript outline into chapters and sections. Executor agents drafted content for assigned sections. A Critic agent evaluated factual consistency and logical structure, while an editor agent revised text for clarity, tone, and coherence. A Fact Extractor agent isolated explicit factual claims for review.

7. Workflow Coordination

Agent execution followed a directed workflow: planning, drafting, fact extraction, critique, editing, and reintegration. Termination conditions were defined as completion of all planned sections with no unresolved Critic flags. The system did not dynamically re-plan tasks unless manually reset, allowing controlled evaluation of workflow stability.

8. Prompting Strategy

Each agent was instantiated with a role-specific prompt defining responsibilities, evaluation criteria, output format, and constraints. Prompts were fixed across runs to minimize variance introduced by prompt drift.

9. Human Intervention Taxonomy

Human intervention was operationally defined and logged under five categories: structural intervention, factual correction, stylistic revision, error recovery, and prompt adjustment. Each intervention was time-stamped and categorized to enable comparison of human labor across systems.

10. Data Collection

Collected artifacts included raw agent outputs, final manuscript drafts, agent communication logs, prompt chains, intervention logs, time spent per phase, and token usage where available.

11. Evaluation Protocol

Evaluation focused on coherence, structural adherence, factual claim density, human intervention frequency, and process efficiency. Human reviewers assessed manuscripts using standardized rubrics, with AI-based scoring used as a secondary reference. We reported the roles, categories, and workflow structure of both systems above.

V. RESULTS

This section reports observations from the comparative evaluation of the human-in-the-loop Gemini system and the autonomous LangGraph multi-agent system. Results are organized by evaluation dimension and presented descriptively, summarized first in Table 1, followed by further details. Further interpretation is given in the following section.

Table 1. Comparative summary of observed findings across evaluation dimensions. Findings reflect a qualitative comparison of the two approaches used in our case study.

Evaluation Dimension	**Human-in-the-Loop Multi-Persona (Gemini)**	**Autonomous Multi-Agent (LangGraph)**
Narrative coherence & voice	High and consistent across chapters; effective long-horizon context management; smooth transitions with cross-referencing.	Locally coherent within sections but degrades globally, with templated transitions and declining voice consistency in later chapters.
Structural adherence	Occasional deliberate deviation from outline (merging/reordering), reflecting human judgment; strong within-section organization.	Near-perfect adherence to outline; minimal duplication/omission; uniform section lengths and formatting.
Factual claim density & accuracy	Fewer discrete claims, embedded in narrative; more contextualization/hedging; inaccuracies corrected more consistently by human oversight.	Higher density of explicit, enumerated claims via fact-extraction agent; critique phase flags inconsistencies, but flags are not always resolved.
Human intervention	Frequent but lightweight; proactive, occurring during drafting (sequencing, clarification, stylistic smoothing).	Infrequent but substantial; reactive, occurring after multiple agents pass (correcting accumulated repetition/disjunction).
Process efficiency & stability	Slower initial drafting; fewer large-scale rewrites; failures tied to human fatigue and coordination overhead.	Faster initial drafting via parallel execution, but longer revision cycles; failures include repetitive phrasing and critic-editor deadlocks.

1. Narrative Coherence and Voice Consistency

Manuscripts generated using the human-in-the-loop system exhibited high levels of narrative coherence across chapters. Reviewers observed consistent authorial voice, smooth transitions between sections, and frequent

cross-referencing of earlier concepts. Later chapters maintained continuity with earlier framing, indicating effective long-horizon context management.

In contrast, manuscripts produced by the autonomous multi-agent system were locally coherent at the section level but exhibited degradation in global narrative flow as document length increased. While individual sections were readable and logically structured, transitions between sections frequently relied on templated phrases and explicit structural markers rather than rhetorical continuity. Reviewer ratings for voice consistency declined across later chapters in the autonomous system, with repeated sentence constructions and stylistic motifs observed. This pattern was not observed in the human-in-the-loop condition.

2. Structural Adherence and Document Organization

The autonomous multi-agent system demonstrated near-perfect adherence to the predefined outline. All planned sections were generated in the intended order, with minimal duplication or omission. Section lengths were relatively uniform, reflecting planner-driven task decomposition. The human-in-the-loop system occasionally deviated from the original outline by merging or reordering subsections. These deviations were introduced deliberately by the human operator and typically reflected conceptual rather than structural considerations. Within-section organization was strong in both systems, though the autonomous system exhibited more consistent formatting and explicit sectional signaling.

3. Factual Claim Density and Accuracy

The autonomous multi-agent system produced a higher density of explicit factual claims per chapter. Claims were often clearly demarcated and enumerated, reflecting the operation of the internal fact-extraction agent. The human-in-the-loop system generated fewer discrete factual claims, instead embedding information within an explanatory narrative. This resulted in lower claim density but increased contextualization and hedging. Autonomous agents successfully identified potential inconsistencies and unsupported claims during critique phases; however, flagged issues were not always resolved and were occasionally reintroduced in subsequent revisions. Human oversight in the collaborative system corrected factual inaccuracies more consistently, though effectiveness depended on the human operator's domain knowledge. Neither system produced error-free output without human intervention.

4. Human Intervention Analysis

The frequency of human intervention differed markedly between systems. The human-in-the-loop system required frequent but lightweight interventions, primarily involving sequencing decisions, clarification of intent, and stylistic smoothing. The autonomous system required fewer interventions overall, but when interventions were needed, they were more substantial, often involving the correction of accumulated stylistic repetition or narrative disjunction. Interventions in the human-in-the-loop system were predominantly proactive, occurring during drafting. In contrast, interventions in the autonomous system were reactive, occurring after multiple passes by the agent.

5. Process Efficiency and Stability

Initial draft generation was faster in the autonomous multi-agent system due to the agents' parallel execution. However, revision cycles extended the total completion time as stylistic and coherence issues accumulated. The human-in-the-loop system progressed more slowly during drafting but required fewer large-scale rewrites.

Observed failure modes in the autonomous system included repetitive phrasing, stale transitions, and occasional deadlocks between critic and editor agents. Failures in the human-in-the-loop system were primarily related to human fatigue and coordination overhead.

VI. LIMITATIONS AND ETHICAL CONSIDERATIONS

1. Limitations

Language and Domain Scope: This study is restricted to English-language content and a single topical domain (personal finance). While this scope allows for controlled comparison across systems, it limits the generalizability of the findings. Language-specific features such as grammar, rhetorical conventions, and discourse structure may influence system performance. Similarly, different topical domains - such as legal, medical, or scientific writing - impose distinct demands for accuracy, evidence, and domain expertise. Therefore, the outcomes observed in this study may not be directly transferable to other languages or content areas.

Dataset and Prompt Constraints: The study uses a fixed set of prompts, outlines, and evaluation criteria, which may bias results toward the specific writing style or structure used. Alternative prompt strategies, varied editorial guidelines, or different outline formats could yield different performance outcomes.

Human Evaluation and Subjectivity: Although we employ standardized rubrics and inter-rater reliability checks, human evaluation remains inherently subjective. Assessments of coherence, narrative quality, and factual accuracy can vary based on the evaluator's background knowledge, writing expectations, and personal preferences. Furthermore, fatigue and evaluator bias may influence scoring, particularly when reviewing long-form documents. Future work should include larger evaluator pools, blinded assessments, and quantitative measures such as automated coherence or factuality metrics.

Temporal and Systemic Variability: LLMs and agent frameworks are continuously updated, and performance can vary across model versions, API changes, and underlying infrastructure. The results reported here reflect a specific system configuration at a particular time. Replication efforts may yield different outcomes as models evolve.

Limited Ground Truth and Reference Materials: In long-form nonfiction writing, there is often no single "correct" version of a document. The absence of a definitive ground truth makes objective comparison challenging. Although we use domain-appropriate reference materials and expert review where possible, the evaluation still relies on approximate measures of accuracy and relevance.

Reporting Granularity and Sample Size: This study compares a single run of each system rather than multiple trials, reporting implementation details at the level of roles, categories, and workflow structure rather than as verbatim prompts, model hyperparameters, or rater-level data. This scope was adopted to keep the manuscript focused on architectural comparison. It also means the findings should be read as descriptive observations from a comparative case study rather than as statistically validated or independently replicable results. Expanding the sample size and conducting quantitative evaluations along relevant dimensions constitute opportunities for future work.

2. Ethical Considerations

Transparency and Disclosure: AI-assisted writing blurs the boundary between human and machine authorship. This study emphasizes the importance of transparent disclosure regarding the extent of AI involvement. Failure to disclose AI contributions may mislead readers and violate academic integrity standards. For example, undisclosed AI authorship could compromise trust in scholarship and raise ethical issues regarding attribution.

Authorship and Ownership: Questions of intellectual property and authorship become more complex when multiple AI agents contribute to a manuscript. Determining ownership of generated content, especially when AI systems produce significant portions of text, is a legal and ethical challenge. Additionally, the role of human editors and supervisors must be clarified to avoid misrepresentation of contributions.

Bias and Fairness: LLMs can reproduce or amplify biases present in training data, including cultural stereotypes, gender bias, or socioeconomic assumptions. In domains like personal finance, biased recommendations can disproportionately affect vulnerable populations. Although multi-agent architectures may introduce checks, they do not inherently eliminate bias. Mitigating bias requires explicit intervention, diverse evaluation teams, and careful design of prompts and agent roles.

Misinformation and Hallucination Risks: The potential for hallucinated claims and fabricated facts is a major ethical concern. In high-stakes domains, misleading content may cause financial harm or reinforce false beliefs. Multi-agent systems can reduce but not fully eliminate hallucinations; human verification remains essential for responsible deployment. Additionally, systems must be designed to avoid flag uncertainty and avoid presenting unverified claims as fact.

Safety, Accountability, and Auditing: Autonomous multi-agent systems complicate accountability because multiple agents may contribute to the final output. Implementing and auditing guardrails - such as safety constraints, content filters, and fact-checking mechanisms - becomes challenging when agents operate asynchronously or in parallel. Transparent logging of agent decisions, traceability of content sources, and post-hoc auditability are necessary for responsible deployment, particularly in regulated domains.

Privacy and Data Security: The use of proprietary prompts, user data, or domain-specific reference materials raises privacy concerns. If agents access sensitive or personal information, there is a risk of unauthorized exposure or misuse. Researchers must ensure secure handling of data, adhere to privacy policies, and avoid using private datasets without consent.

VII. DISCUSSION AND CONCLUSION

The integrated results of this study reveal a consistent and measurable trade-off between autonomy and narrative quality in AI-assisted long-form authorship. The human-in-the-loop system produced prose that was more coherent, stylistically consistent, and reader-oriented. In contrast, the autonomous multi-agent system demonstrated superior structural rigor and internal monitoring capabilities. These outcomes align with prior research showing that human editors play a critical role in resolving deep semantic dependencies and maintaining discourse continuity, particularly over extended text spans [17], [18]. The superior narrative quality of the human-supervised system may be attributed to humans' capacity for *tacit knowledge integration* - the ability to make nuanced judgments about value, tone, and rhetorical effect that are not easily encoded in explicit planning heuristics [19]. Conversely, the autonomous multi-agent framework exhibited strengths in claim identification**,** structural adherence**,** and systematic verification but often struggled with the subtle rhetorical transitions that contribute to narrative flow. This observation is consistent with prior findings that agentic

architectures, while effective at modular subtask processing, do not inherently encode the pragmatic principles of storytelling and argumentation that human writers employ [20]. These findings suggest that narrative coherence remains a central unsolved challenge for autonomous multi-agent writing systems. While planner-driven architectures and subagent decomposition can enforce structural constraints and reduce hallucinations in modular tasks, they do not fully capture the tacit narrative judgments exercised by human collaborators. For example, human authors are more adept at maintaining thematic continuity across sections and anticipating reader expectations, both of which remain difficult to quantify in agent utility functions [21].

At the same time, the autonomous system's strengths - particularly in monitoring internal consistency, handling repetitive structural checks, and flagging logical gaps - indicate meaningful progress toward scalable AI authorship. These capabilities echo findings from recent work on self-refining language model pipelines, which demonstrate that iterative critique loops improve factuality and structural compliance, even without human intervention [22], [23]. Taken together, the results support hybrid models in which autonomous agents handle planning, drafting, and internal critique, while humans provide targeted oversight focused on narrative cohesion and ethical nuance. Such collaborative frameworks align with sociotechnical models of human–AI interaction that emphasize complementary strengths: humans contribute contextual judgment and ethical reasoning, while AI systems contribute computational scalability and process consistency [24], [25]. From a research perspective, these results underscore the importance of evaluating AI writing systems not only on output quality but also on process characteristics such as human labor distribution, failure recovery, and long-horizon stability. For instance, understanding how systems handle *drift* - the gradual erosion of narrative focus over successive generations - can inform design choices for persistent memory, agent re-evaluation triggers, and cross-agent feedback loops [26]. Furthermore, quantifying human effort in post-editing versus in-line guidance can inform cost–benefit analyses for deploying different levels of autonomy across writing tasks. Finally, while this study focuses on structured nonfiction, similar trade-off dynamics likely also occur in other genres, such as technical documentation, policy analysis, and educational materials. Future research should investigate how genre conventions and audience expectations interact with autonomous and hybrid authorship paradigms to shape narrative outcomes and ethical considerations.

1. Conclusion

This study provides a case study comparing two paradigms of AI-assisted long-form authorship, human-in-the-loop multi-persona collaboration and autonomous multi-agent orchestration, within a structured nonfiction writing task. The results indicate that multi-agent AI systems can generate structured, coherent long-form content, demonstrating meaningful progress in overcoming the limitations of single-agent LLM generation. However, the findings also suggest that human oversight remains critical for achieving high-quality narrative authorship, particularly in maintaining factual integrity, ensuring logical consistency, and preserving stylistic coherence across extended text. The comparative evaluation reveals trade-offs between autonomy and quality: autonomous systems offer greater efficiency and reduced human labor, but they are more prone to drift, hallucination, and inconsistencies in long-form contexts. In contrast, human-in-the-loop frameworks can better manage narrative continuity and factual accuracy but require greater time and expertise. As AI-assisted writing continues to evolve, understanding these trade-offs will be essential for responsible deployment. Future work should explore broader domains, multilingual settings, and more robust evaluation frameworks - including automated factuality checks and larger human evaluation cohorts. Moreover, research must continue to address ethical considerations such as transparency, authorship attribution, bias mitigation, and auditability to ensure that AI-generated texts are reliable, accountable, and aligned with human values.

ACKOWLEDGEMENT

All workflows were deterministic, given fixed prompts and random seeds. Agent definitions, execution scripts, and evaluation rubrics were preserved to enable replication. All generated content was labeled as AI-assisted, and no human subject's data were collected.

Abstract
The rapid evolution of cyber threats requires defense systems that can dynamically adapt to novel attacker behaviors. Honeypot systems—deceptive environments intentionally exposed to attract adversaries—provide valuable data for understanding attack techniques and tactics. Smart Cities rely on interconnected information technology (IT) and operational technology (OT) systems that support critical services such as transport, energy, and communication. As these infrastructures grow in complexity, their exposure to cyber threats increases, demanding continuous monitoring and trustworthy methods for collecting real-world attack data. This paper presents the design and deployment of a scalable honeypot system built on containerization principles to support cybersecurity monitoring and threat analysis. The containerized architecture ensures repeatability, isolation, and safe operation in both laboratory and production-like environments. The proposed framework provides a foundation for quantitative cybersecurity measurement and situational awareness. The framework can be adapted to Smart City infrastructures that integrate IT, OT, and IoT networks. Honeypot-based telemetry has been shown to support the assessment of network exposure, resilience metrics, and decision-making in trustworthy intelligent information systems. Recommendations are provided for extending the system toward Smart City-specific services and measurement indicators.

Keywords: Honeypot Systems, Containerization, Docker, Smart City Cybersecurity, IT/OT Convergence, Threat Measurement, Network Monitoring, Trustworthy Information Systems, Cybersecurity Monitoring, Situational Awareness

I. INTRODUCTION

Smart cities rely on interconnected Internet of Things (IoT), Industrial Internet of Things (IIoT), and cyber–physical system (CPS) components. These components support critical urban services such as transportation, energy distribution, water management, and public administration. The convergence enables automation but also expands the cyber-attack surface. It introduces constraints related to heterogeneity, real-time operation, and limited computational resources. Conventional cybersecurity mechanisms designed for homogeneous IT environments are insufficient. Specialized monitoring and deception-based security approaches are needed. Honeypot systems are an established defensive technique that deliberately exposes deceptive services to attract adversaries and observe their behavior. By interaction level, honeypots are classified as low-interaction, high-interaction, or hybrid, each trading off realism, operational risk, and resource demand. Deployed alongside firewalls and intrusion detection systems (IDS), honeypots provide labeled attack data and insight into attacker tactics, techniques, and procedures (TTPs). Recent research extends classical honeypot concepts toward cloud-based, edge-deployed, and virtualized environments, including digital twins. These approaches address advanced persistent threats (APTs) and ransomware targeting smart-city infrastructures. They emphasize early detection and safe

isolation, both essential where cyber incidents may have physical or societal consequences. This paper proposes a scalable, container-based honeypot framework for cybersecurity monitoring in smart-city environments that integrates IT, OT, and IoT networks. Lightweight containerization and modular service emulation enable repeatable deployment, controlled isolation, and adaptation to diverse smart-city domains. The framework is validated through real-world deployment and experimental observations, demonstrating its applicability for quantitative cybersecurity assessment and resilience evaluation in intelligent urban systems.

II. PROBLEM DEFINITION AND RELATED WORKS

1. Cybersecurity Challenges in Smart City Environments

The literature identifies several recurring vulnerability patterns in smart-city infrastructures, particularly related to IoT and edge devices [1]:

- Use of default or weak authentication credentials,
- exposed management interfaces reachable from the Internet,
- outdated or unpatched firmware and software,
- insecure or unencrypted communication protocols,
- limited monitoring and logging capabilities on resource-constrained devices.

Beyond individual device weaknesses, the high degree of interconnectivity between smart-city subsystems enables cascading attack scenarios. A compromise of a single component may provide attackers with pivot points for lateral movement, allowing them to gain persistent access to critical infrastructure, exfiltrate sensitive data, disrupt essential services, or coordinate attacks across multiple city domains [1]. Smart cities, therefore, attract a diverse range of threat actors, including nation-state attackers targeting critical infrastructure, cybercriminal groups motivated by financial gain (e.g., ransomware), hacktivists pursuing ideological objectives, and opportunistic attackers exploiting exposed devices for botnet recruitment and cryptomining.

2. Honeypot Systems: Concepts, Classification, and Research Evolution

Honeypots are deception-based security mechanisms that imitate legitimate systems, services, or devices to attract adversaries and monitor malicious activity. Unlike preventive security controls, honeypots primarily serve as intelligence-gathering tools, enabling detailed analysis of attacker behavior, tactics, techniques, and procedures (TTPs) within a controlled, isolated environment [2].

- Core characteristics common to honeypot systems include [3]:
- deception, making the system appear as a valuable target,
- isolation from production infrastructure to contain risk,
- detailed monitoring and logging,
- absence of legitimate user traffic, ensuring that any interaction is suspicious by definition.
- Based on interaction level, honeypots are commonly classified as [4]:

Low-interaction honeypots, which emulate limited service functionality with minimal resource requirements and low operational risk, are suitable for large-scale monitoring but provide relatively shallow intelligence.

High-interaction honeypots, which expose fully functional systems or services, enabling deep attacker engagement, malware collection, and complete attack-chain observation at the cost of higher complexity and containment risk. Hybrid honeypots, which combine low- and high-interaction elements, often dynamically scale interaction fidelity based on observed attacker behavior to balance scalability and intelligence depth. From a deployment perspective, honeypots may be used as production honeypots embedded within operational networks, research honeypots dedicated to threat intelligence collection, or distributed honeynets that provide broader coverage across geographically dispersed infrastructures [5]. Early honeypot research focused on traditional IT systems. The emergence of IoT and smart-city environments has since driven evolution toward protocol-specific emulation, cloud and edge deployment, machine learning–assisted analysis, and adaptive architectures such as digital twins and SDN-enabled honeypots [1],[6],[7].

3. Rationale for Honeypots in Smart City Security Monitoring

Smart-city infrastructures make honeypots a useful complement to traditional security mechanisms. Honeypots generate high-quality, labeled malicious traffic, which is essential for training and validating machine learning–based detection models. Since legitimate users do not interact with honeypots, all collected data can be treated as malicious. This removes the labeling ambiguity common in operational security logs [6],[1]. Honeypots also provide early warning capabilities by detecting reconnaissance, scanning, and initial exploitation attempts before attackers reach production systems. This is especially critical in smart cities, where cyber incidents may have direct physical or societal consequences and require rapid response [8]. Furthermore, honeypot observations enable systematic documentation of attack patterns and TTPs, including:

- exploitation techniques targeting IoT and industrial protocols,
- malware designed for resource-constrained devices,
- lateral movement strategies within interconnected city networks,
- automated scanning tools and attack frameworks.

By complementing traditional security controls, honeypots help detect novel or previously unseen attacks, reduce false positives in security operations centers, support forensic investigations, and enable resource-efficient monitoring of large and heterogeneous attack surfaces, particularly through low-interaction deployments suitable for IoT-rich environments.

III. HONEYPOT ARCHITECTURE FRAMEWORK FOR SMART CITIES

1. Smart City Honeypot Requirements

Smart City honeypots must operate in environments where cyberattacks on OT/IoT components can cause physical harm, service disruption, and threats to public safety – consequences absent from conventional IT incidents [9],[10],[11]. This chapter presents a honeypot [1] architecture framework designed for these environments, balancing threat detection with operational security.

Smart City honeypot deployments differ from conventional IT honeypots in five requirements driven by OT/IoT constraints [12],[13]:

Protocol diversity – support for industrial protocols (Modbus, DNP3, BACnet, IEC 61850) alongside IT and IoT protocols (MQTT, CoAP).

Distributed deployment – coverage across geographically dispersed infrastructure rather than centralized datacenter placement.

Resource efficiency – operation on resource-constrained network devices and edge gateways.

Extreme isolation – OT criticality demands zero tolerance for lateral movement from compromised honeypots to production infrastructure.

Domain-specific emulation – authentic simulation of Smart City infrastructure to avoid detection by adversaries familiar with these environments.

The proposed architecture addresses these requirements through a multi-tier deployment model, containerized implementation, and defense-in-depth isolation, detailed in the following sections.

Multi-Tier Deployment Architecture

We propose a multi-tier [14] architecture (Figure 1) that balances detection coverage, resource constraints, and risk. Smart Cities can deploy honeypot complexity [15] matched to available infrastructure and required intelligence depth.

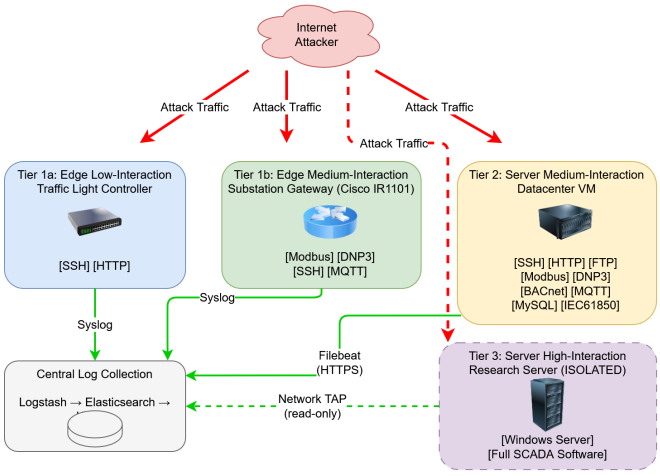

Figure 1. Multi-Tier Deployment in Smart City Infrastructure.

Tier 1a provides city-wide detection with minimal overhead on existing infrastructure. Tier 1b enables richer protocol interaction at critical points (substations, pump stations) where devices have sufficient resources. Tiers 2-3 follow conventional patterns, with Tier 3 reserved for research due to extreme isolation requirements.

Table 1. Multi-Tier Honeypot Deployment Model

Tier & Interaction	Platform Examples	Services	RAM	Purpose
1a: Edge Low	Basic switches, IoT gateways	1-3 emulators	256MB-1GB	Wide-area scanning detection
1b: Edge Medium	Cisco Cat 9K, industrial routers	4-8 handlers	2-4GB	Enhanced edge TTPs collection
2: Server Medium	Edge/datacenter VMs	10-15 stacks	4-8GB	Deep protocol intelligence
3: Server High	Dedicated research servers	Full OS + SCADA	16GB+	Advanced threat research

2. Core Architectural Components

Honeypot Layer. Containerized services run across all tiers with dedicated network namespaces. Multiple honeypots coexist on a single platform (e.g., a substation router hosting SSH, Modbus, and DNP3 containers simultaneously). Secure Data Collection Layer. Critical requirement: honeypots accept inbound attacker traffic but cannot initiate outbound connections to production networks. Log collection varies by platform: network devices use native syslog forwarding (UDP port 514), server containers use log shippers (Filebeat via HTTPS), and high-interaction VMs may employ network taps. Firewalls permit only honeypot-to-collector traffic on specific ports while blocking all honeypot-to-production communication (Figure 2).

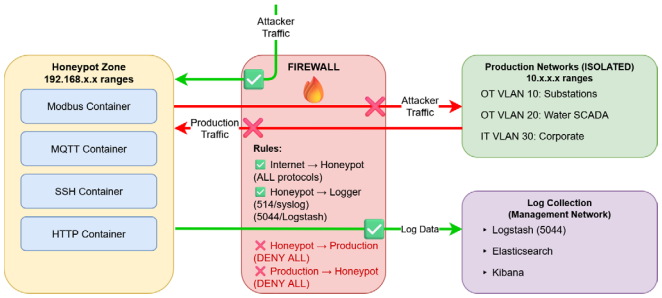

Figure 2. Data Collection Architecture and Traffic Flow Control.

Central Analysis Layer. Elastic Stack (Elasticsearch, Logstash, Kibana) receives distributed logs, enriches them with GeoIP and threat intelligence, normalizes formats, and provides visualization. Infrastructure resides on an isolated management network accessible only to authorized analysts.

Network Segmentation and Isolation

Defense in depth requires multiple isolation layers to prevent a compromise of the honeypot from affecting production [12].

Table 2. Isolation Layers by Platform.

Layer	Network Devices	Servers	Function
Container namespace	✓	✓	Process, filesystem, network isolation

Layer	Network Devices	Servers	Function
Virtual machine	✗	✓ (Tiers 2-3)	OS-level isolation
VLAN segmentation	✓	✓	Layer 2 separation
Firewall enforcement	✓	✓	Stateful filtering and logging
Physical separation	✗	✓ (Tier 3)	Ultimate isolation

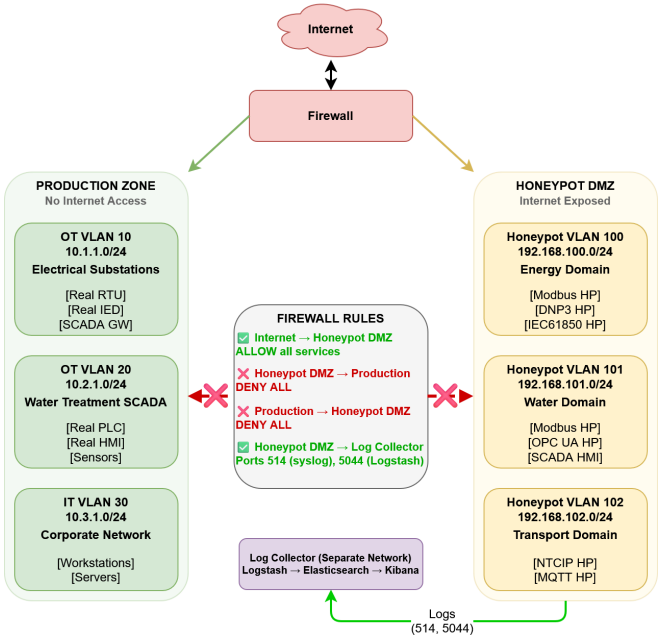

Figure 3. Network Segmentation Architecture.

VLAN segmentation (Figure 3) isolates honeypot networks (192.168.x.x/24 ranges) from production (10.x.x.x ranges). Firewall rules enforce: Internet→Honeypot ALLOW, Honeypot→Production DENY ALL, Honeypot→Log Collector ALLOW (specific ports only). Production networks have no routes to honeypot networks.

Containerization Strategy with Docker

Docker enables practical Smart City deployment for five reasons:

Portability – runs on x86 servers, ARM gateways, and network devices (Cisco IOx, IOS-XE).

Resource efficiency – Alpine-based images consume 30–50 MB.

Rapid deployment – pre-built images available (Cowrie, Conpot).

Isolation – namespace separation without VM overhead.

Orchestration – Docker Compose for single hosts, Kubernetes for city-wide deployment.

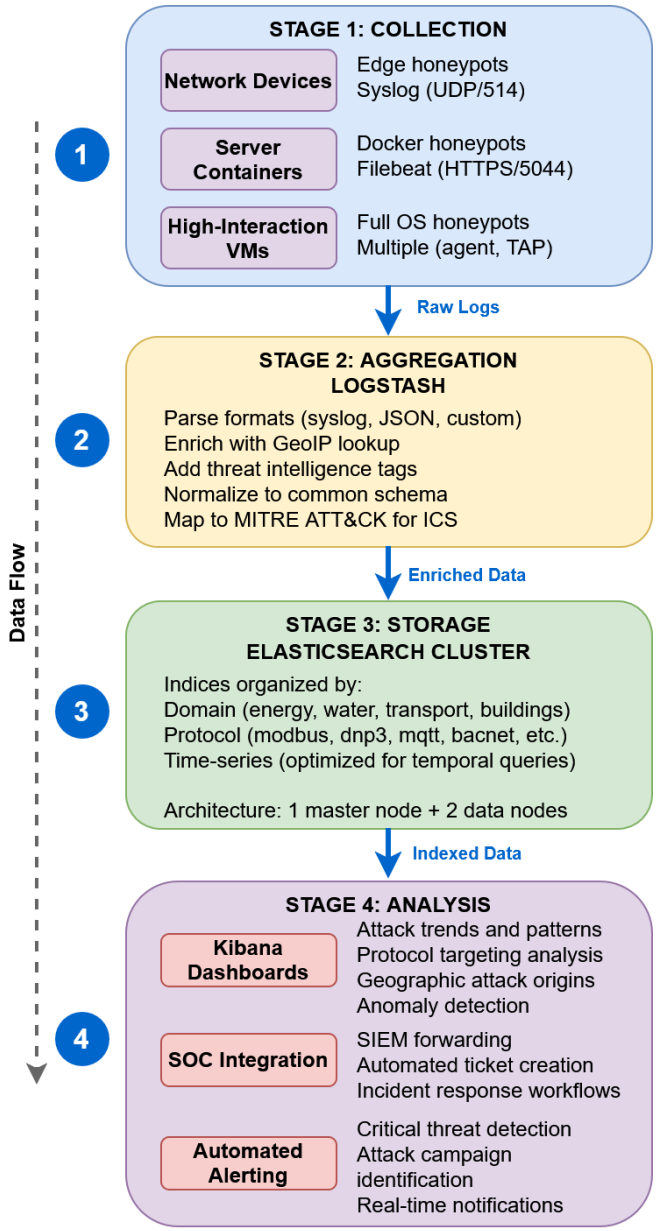

Figure 4. End-to-End Data Collection Pipeline.

Tier 1 edge uses 2–4 containers per device, selected by domain (energy: Modbus/DNP3, water: Modbus/OPC UA, transport: NTCIP/MQTT). Tier 2 servers deploy full stacks with 10–15 services plus log collection. Traffic controllers with Docker support host SSH, HTTP, and NTCIP containers using under 200 MB RAM total with minimal performance impact.

3. Data Collection Pipeline

All events normalize to a common JSON schema (Figure 4): temporal data; honeypot metadata (tier, location, device); Smart City context (domain, infrastructure); attack details (source, protocol, actions); and enrichment (geo, threat intel). Logstash enriches logs with GeoIP, threat intelligence, and MITRE ATT&CK [16],[17] mappings. Elasticsearch time-series indexing optimizes storage, while domain-specific indices enable targeted analysis. Kibana dashboards provide real-time visibility into attack trends, protocol patterns, geographic origins, and anomalies.

IV. SMART CITY DOMAIN APPLICATIONS AND DEPLOYMENT SCENARIOS

1. Smart City Domains and Threat Landscape

Smart Cities comprise multiple operational domains with distinct infrastructure characteristics, protocol ecosystems [18], and threat profiles. Effective honeypot deployment requires understanding domain-specific properties, as attack patterns and adversary motivations vary significantly across sectors.

Table 3. Smart City Critical Domains.

Domain	Infrastructure	Protocols	Threats & Impact	Priority
Energy	Grids, substations, smart meters	Modbus, DNP3, IEC 61850, IEC 60870-5	Protocol exploits, malware (Industroyer, Triton) → Blackouts, equipment damage	●□●□●□●□●□
Transport	Traffic control, transit, EV charging	NTCIP, OCPP, C-ITS, GTFS-rt	Signal manipulation, GPS spoofing, DoS → Traffic chaos, accidents	●□●□●□●□
Water	Treatment plants, distribution, and pumps	Modbus, DNP3, Profibus, OPC UA	Register manipulation, sensor spoofing → Contamination, flooding	●□●□●□●□●□
Buildings	BMS, HVAC, lighting, access control	BACnet, Modbus, KNX, LonWorks	BACnet exploits, HVAC manipulation → Discomfort, energy theft, breach	●□●□●□

Table 3 shows four critical Smart City domains, prioritized by the severity of consequences. Energy and water receive the highest priority due to the potential for physical harm and essential service disruption. Transportation warrants high priority, given public safety implications. Buildings present medium priority with a significant but less catastrophic impact. This prioritization guides resource allocation when budget or infrastructure constraints

prevent full coverage. Lower-priority domains (public services, environmental monitoring) follow similar deployment patterns but receive reduced coverage.

2. Protocol-to-Domain Mapping and Honeypot Placement Strategy

Effective honeypot deployment requires matching protocol emulation to domain-specific attack surfaces. Different Smart City domains use distinct protocol ecosystems—adversaries targeting specific infrastructure probes for the corresponding protocols during reconnaissance.

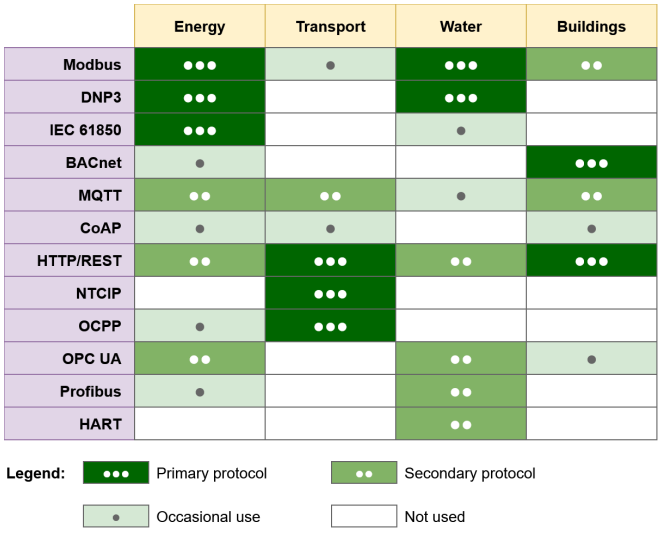

Figure 5. Protocol Distribution Across Smart City Domains.

Protocol distribution analysis (Figure 5) reveals that certain protocols span multiple domains (Modbus appears in energy, water, and buildings) while others remain domain-specific (NTCIP exclusively in transportation, IEC 61850 primarily in energy substations). This distribution informs honeypot selection: multi-domain protocols provide broad threat visibility but require domain-specific configuration to achieve authentic emulation.

Table 4. Honeypot Deployment Strategy.

Domain	Edge (Tier 1)	Server (Tier 2)	Density
Energy	Modbus, DNP3 on substation gateways	IEC 61850 devices, SCADA HMI web	1 edge/substation, 1 server/region
Transport	NTCIP on traffic controllers	Traffic mgmt web, OCPP central system	1 edge/50-100 intersections, 1 server/city
Water	Modbus on pump station PLCs	SCADA HMI, OPC UA server, Modbus master	1 edge/facility, 1 server/utility
Buildings	BACnet on BMS gateways	Building automation server, HVAC controller	1 edge/large building, 1 server/campus

Edge deployment positions lightweight containers at domain entry points (substations, pump stations, traffic cabinets) where these protocols are expected. This provides early warning during attacker reconnaissance, before production systems are reached. Server deployments in DMZ segments emulate centralized control systems (SCADA HMIs, traffic management centers, building automation servers) as high-value targets. Deployment density balances detection coverage against infrastructure and maintenance overhead. Critical domains (energy, water) justify higher edge density.

3. Detailed Deployment Scenarios

Scenario A: Energy Sector — Electrical Substation Protection

Infrastructure Context. Electrical substations contain Remote Terminal Units (RTUs), Intelligent Electronic Devices (IEDs), and SCADA gateways controlling circuit breakers, transformers, and protective relays. Modern substations communicate using IEC 60870-5-104 and DNP3 for SCADA telemetry, alongside IEC 61850 for substation automation, all of which have documented vulnerabilities and available attack tools.

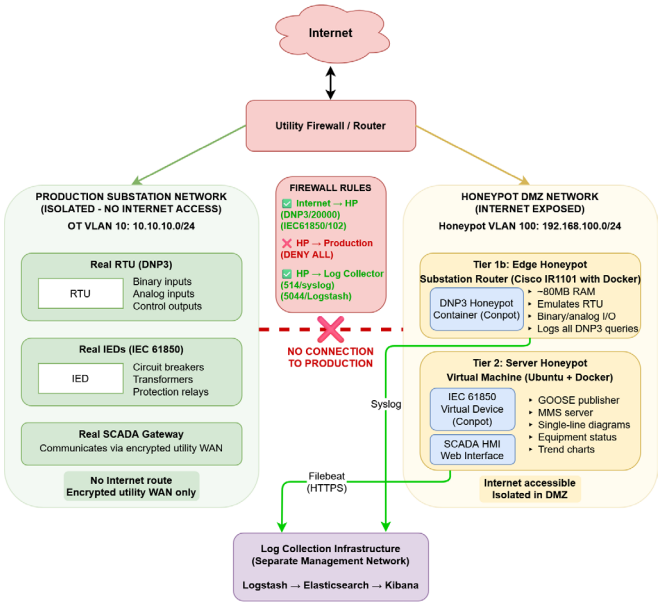

Figure 6. Electrical Substation Honeypot Deployment Architecture.

Deployment (Figure 6). Edge deployment uses an industrial router (Cisco IR1101) supporting containers via Cisco IOx application hosting. A Conpot IEC 60870-5-104 honeypot container (~80MB RAM) emulates a substation outstation with single-point information (circuit breaker status), measured values (voltage, current, power), and command points, responding to interrogation requests with synthetic data and logging control attempts. Server deployment operates in a utility data center DMZ on an Ubuntu VM hosting Conpot, configured with multiple IEC 60870-5-104 outstation profiles representing aggregated substation views, plus a custom web-based SCADA HMI displaying single-line diagrams and equipment status. Production equipment resides on private VLAN 10 (10.10.10.0/24) with no Internet route. Honeypots reside on VLAN 100 (192.168.100.0/24) in the DMZ, with Internet exposure. Firewall rules prohibit honeypot-to-production traffic and permit only honeypot-to-log-collector communication.

Expected Intelligence. Port scans targeting IEC 60870-5-104 (TCP port 2404) were detected before attackers located production systems. Automated scanners perform basic enumeration, while sophisticated adversaries issue protocol-specific queries that indicate expertise. Exploitation attempts capture malformed protocol messages targeting known vulnerabilities. Malware samples may include ICS-specific threats, such as Industroyer variants. This intelligence lets utility teams identify active targeting, obtain indicators of compromise for defensive tuning, and share threat intelligence with E-ISAC.

Scenario B: Water Sector — Treatment Plant SCADA Protection

Infrastructure Context. Water treatment facilities employ SCADA systems controlling chemical dosing pumps, filtration, disinfection, and distribution pumps, predominantly using Modbus TCP. The 2023–2024 CyberAv3ngers campaign targeting exposed Unitronics PLCs in U.S. water utilities [19] demonstrates real-world targeting of municipal water SCADA via exposed remote-access interfaces.

Deployment. Tier 2 server-based honeypot in utility DMZ uses Conpot Modbus with a custom template. Holding registers (1000-1099) emulate actuator setpoints: pump speeds (0-100%), valve positions, and chemical dosing rates. Input registers (2000-2099) emulate sensor readings, including flow rates, chemical concentrations (chlorine, pH, turbidity), tank levels, and pressure. The companion web-based SCADA HMI provides HTTP/HTTPS access with process diagrams, real-time trends, and operator controls, and implements basic authentication with common default credentials to entice attackers—expected Intelligence. Reconnaissance appears as Modbus read queries (function codes 0x03 and 0x04) that scan the register space to enumerate capabilities. Sabotage attempts use write commands (0x06, 0x10) to modify setpoints. HMI honeypot captures credential brute-forcing, SQL injection, and session hijacking. Attacker dwell time distinguishes opportunistic scanning from deliberate reconnaissance, suggesting the presence of targeted campaigns. Protocol command sequences reveal attacker familiarity, providing early warning of advanced persistent threat activity. Expected Threat Intelligence Outcomes and Community Value. Honeypot deployments generate intelligence categories with operational value that varies by tier and interaction level. Proactive defense detects campaigns targeting Smart City infrastructure before adversaries reach production systems. Security teams gain time to patch vulnerabilities, tune monitoring, or implement mitigations.

Table 5. Intelligence by Tier.

Intelligence Type	T1-Low	T1-Med	T2	T3
Scanning patterns	●●●	●●●	●●	●
Credentials tried	●●	●●●	●●●	●●●
Protocol commands	–	●●	●●●	●●●
Malware samples	–	●	●●	●●●
Dwell time/exploration.	–	●	●●	●●●
Lateral movement	–	–	●	●●●

Legend: ●●● = High value, ●● = Medium, ● = Low, – = Not captured

Tier 1 honeypots capture high-volume scanning activity, providing quantitative data on attack frequency, source distribution, and protocol-targeting trends. Tier 2 and 3 enable qualitative analysis: attacker methodologies, indicators of compromise, and threat-actor attribution.

Captured attack patterns inform intrusion detection rules, firewall policies, and SIEM correlation tailored to actual threats rather than generic signatures. The documented monitoring evidence supports sector-specific

regulation (e.g., NERC CIP for energy and EPA requirements for water). Beyond the individual organization, Smart City honeypot deployments contribute to community threat intelligence through ISACs (E-ISAC, WaterISAC, MS-ISAC) and national CERTs. Standardized sharing formats (STIX/TAXII) enable automated intelligence exchange. Mapping observed behaviors to MITRE ATT&CK for ICS lets smaller municipalities benefit from intelligence gathered by larger Smart Cities.

V. CONCLUSION

This paper addressed the growing cybersecurity challenges faced by smart-city infrastructures arising from the convergence of IT, OT, and IoT systems and the resulting expansion of the attack surface. Traditional preventive security mechanisms alone provide limited visibility into real attacker behavior, particularly during reconnaissance and early attack phases. To mitigate this gap, the paper proposed a scalable, container-based honeypot framework designed to support continuous cybersecurity monitoring and threat intelligence collection in smart-city environments. The main contribution is a modular honeypot architecture based on lightweight containerization. The framework enables repeatable deployment, strong isolation, and flexible service emulation in both laboratory and production-like environments. Experimental deployment showed that even a limited set of emulated services attracts significant malicious activity. This confirms honeypots as a source of real-world attack telemetry. The collected data provide quantitative insights into attack frequency, targeted services, credential abuse, and attacker behavior, supporting situational awareness and security assessment. The paper also presented a structured adaptation of the framework to smart-city environments. Domain-specific requirements, a multi-tier deployment model, and protocol-aware placement strategies show how honeypots can be integrated into complex urban infrastructures while respecting strict isolation. The analysis shows that honeypots complement traditional security controls by enabling early warning, improving forensic capabilities, and supplying labeled datasets for machine–learning–based detection. Several limitations should be acknowledged. The deployment focuses on IT-oriented services, and the results cannot be directly generalized to all OT and IoT protocols without further validation. Long-term deployment across multiple smart-city domains is required to fully assess attacker adaptation and the resilience of the deception mechanisms. Future work will focus on OT and IoT-specific honeypot modules, integration of collected telemetry with digital-twin-based cybersecurity platforms, and long-term distributed deployments across smart-city domains. These steps further strengthen the use of honeypots as a measurement and decision-support tool for resilience evaluation in intelligent urban systems.

Abstract
Honeypot systems rely on deception realism to attract and analyze malicious actors, yet the gap between implementation sophistication and attacker detection capability continues to widen. This paper analyzes honeypot deception techniques spanning 20 years of research and is validated through an empirical deployment that captured 75,598 attacks across five protocols over eight days. We identify seven deception categories and assess their maturity through literature analysis and real-world attack data. The deployment showed that internet-exposed honeypots faced their first attack within three minutes, with SSH accounting for 96.12% of attacker traffic across 10+ countries. The analysis identifies response-timing manipulation as the most severe research gap, with only three significant works published despite its clear practical relevance. Cross-protocol consistency and OPC UA support emerge as additional high-priority gaps. We contribute a seven-category taxonomy, empirical validation of attack patterns, and a priority-ranked research roadmap.

Keywords: Honeypot, Deception techniques, Attack analysis, Response timing, Protocol emulation

I. INTRODUCTION

Within three minutes of deploying our multi-protocol honeypot system on July 21, 2025, the first attack against the exposed MySQL service began. Over eight days, we recorded 75,598 attacks targeting five network services from attackers in 10+ countries. This aggressive discovery pattern exemplifies the threat landscape honeypot systems must navigate while maintaining deceptive realism. Honeypot technology has evolved considerably since Provos introduced Honeyd in 2004 [1], moving from static service emulation toward fingerprinting evasion and, more recently, AI-driven adaptive systems. Yet fundamental challenges persist. Sophisticated attackers employ multi-vector detection probing service banners, response timing characteristics, filesystem artifacts, and cross-protocol consistency. A large-scale measurement recording over 400 million SSH brute-force attempts from more than four million unique source addresses found that attackers vary their SSH client version strings to evade signature-based detection [2]. Contemporary deployments face a paradox: research shows that 72% of Cowrie and Kippo deployments remain detectable through default-configuration artifacts, including predictable MAC addresses and uniform timestamps [3]. In contrast, the research community has invested heavily in banner manipulation and protocol emulation but has left response-timing manipulation severely underexplored. Attackers can bypass sophisticated protocol emulation by measuring response latencies that no real system could achieve. This paper addresses the capabilities and limitations of honeypot deception through three research questions, including: (RQ1) What is the current state of the art in deception techniques? (RQ2) How do real-world attack patterns validate existing approaches? (RQ3) What critical research gaps require attention? We conducted a systematic literature review spanning 2004-2025, deployed a multi-protocol honeypot capturing nearly 76,000 attacks, and synthesized findings to identify high-priority research directions. Our contributions are fourfold: (1) a seven-category taxonomy of deception techniques with maturity assessments, (2) empirical

validation through an eight-day deployment characterizing attack patterns including temporal dynamics, geographic distribution, and command execution sequences, (3) a gap analysis identifying response timing manipulation as the most severe deficiency alongside cross-protocol consistency and OPC UA support, (4) a synthesis framework connecting attack behaviors to deception requirements for evidence-based prioritization.

II. RESEARCH METHODOLOGY

Our approach combines systematic literature analysis with empirical validation of deception behavior under live attack traffic.

1. Systematic Literature Review

We conducted a systematic literature review covering 2004-2025, searching Scopus, Web of Science, and Semantic Scholar with keywords such as "honeypot," "deception," "fingerprinting," and "evasion." Inclusion criteria required a peer-reviewed publication, an explicit focus on deception, and technical implementation or empirical evaluation. This produced approximately 120 highly relevant papers spanning IT infrastructure, ICS/SCADA, IoT [4], and cloud deployments. We identified seven deception categories: banner manipulation, protocol emulation, interactive environment simulation, response timing manipulation, filesystem/artifact deception, AI-driven adaptive deception, and cross-protocol consistency. Each category was assessed across research volume, implementation maturity, empirical validation, and tool availability.

2. Empirical Deployment Study

We deployed a multi-protocol honeypot from July 21-29, 2025 (8 days, 3 hours, 21 minutes) using Docker containers that hosted SSH (Cowrie with a custom configuration), MySQL, DNS, FTP, and SMTP on standard ports, and exposed them via a public IP address. No active marketing occurred – all traffic represents organic discovery. We captured source IPs (geolocated), credentials, commands, temporal patterns, and session characteristics. For SSH, complete session transcripts enabled detailed command analysis. The deployment adhered to ethical guidelines, collecting no personal data beyond attack metadata.

Table 1. Research Methodology Overview.

Phase	Activity	Details
Literature Search	Database queries	Scopus, WoS, Semantic Scholar; 2004-2025
Screening	Inclusion criteria	Deception-focused, peer-reviewed, implementation
Categorization	Taxonomy	Seven deception categories
Empirical	Deployment	8 days, 5 protocols, 75,598 attacks
Synthesis	Gap analysis	Maturity vs. practical requirements

III. STATE-OF-THE-ART ANALYSIS

We analyzed honeypot deception techniques across the seven categories. Maturity varies substantially: some areas show 20+ years of development, while others remain severely underexplored. Figure 1 positions the categories by research maturity against detection risk, exposing the divergence between where research effort has accumulated and where attacker detection capability concentrates.

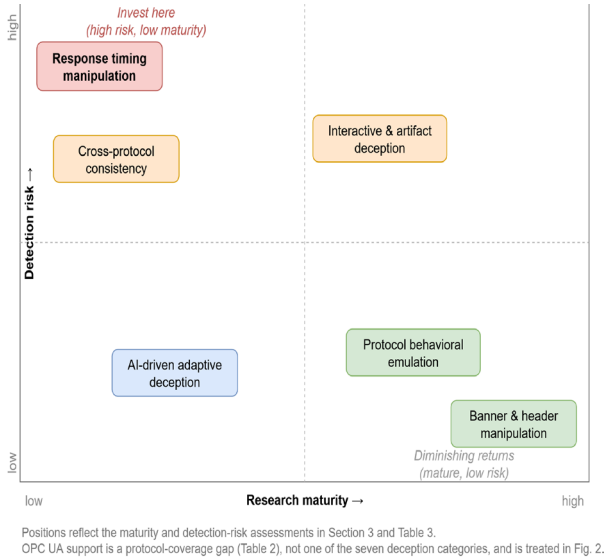

Figure 1. Deception categories, organized by research maturity (Section III), against detection risk. Response timing and cross-protocol consistency occupy the upper-left region, combining high detection risk with minimal research, while banner manipulation and protocol emulation sit in the mature, lower-risk region of diminishing returns. The detection-risk and maturity ratings are those consolidated in Table 3 (Section V-C). OPC UA support is a protocol-coverage gap (Table 2), not one of the seven deception categories.

1. Banner and Header Manipulation

Banner and header manipulation represents the most mature deception category with over two decades of continuous research since Honeyd's introduction in 2004 [1]. The foundational approach modifies service identification strings transmitted during initial protocol negotiation to mask honeypot characteristics and emulate target systems. Honeyd pioneered comprehensive banner manipulation, including TCP/IP stack fingerprinting evasion through precise control of packet characteristics such as TTL values, window sizes, and TCP options that operating system fingerprinting tools exploit. The SSH protocol has received particular research attention given its ubiquity as an attack vector. Early implementations employed static OpenSSH version strings, but the detection arms race has intensified. A multi-year measurement of large-scale SSH brute-force activity recorded over 400 million attempts from more than four million unique source addresses and observed 171 distinct SSH client version strings used to evade signature-based detection [2]. HTTP response header manipulation appears across multiple honeypot implementations, including Cowrie, Dionaea, and Chameleon, with Chameleon dynamically generating responses that match the emulated target device [5]. However, banner manipulation alone is insufficient to deceive sophisticated attackers. Modern reconnaissance tools perform version detection probing that extends well beyond initial banners, examining behavioral responses to protocol-specific queries. The research assessment shows extensive validation through production deployments, multiple mature open-source implementations, and well-understood techniques, though the ongoing arms race indicates continued evolution.

2. Protocol Behavioral Emulation

Protocol behavioral emulation extends beyond surface-level banner strings to implement realistic protocol state machines, command responses, and interaction patterns. Maturity varies dramatically across protocol domains, with traditional IT protocols achieving moderate-to-high fidelity while emerging protocols remain underserved. SSH protocol emulation through Cowrie is among the most sophisticated implementations, providing full SSH protocol support, including SFTP file transfer, SCP secure copy, and port forwarding [6]. The system implements an interactive shell simulation with comprehensive command-response libraries that handle common reconnaissance patterns. FTP protocol implementations must carefully simulate state machine transitions across LOGIN, CWD, LIST, and RETR/STOR sequences that attackers expect. SMTP honeypots face the delicate challenge of appearing realistic as mail relays without actually accepting open relay abuse. ICS and SCADA protocol emulation demonstrates rapidly maturing research aligned with the growing targeting of industrial control systems. Modbus protocol receives universal support across major ICS honeypots, including Conpot [7] and SecuriOT, with the latter capturing 54,682 Modbus packets during deployment validation [8]. The protocol's well-defined register maps and function codes enable high-fidelity emulation when properly configured. S7comm protocol targeting Siemens PLCs achieved breakthrough sophistication with HoneyPLC, which successfully deceived Nmap active fingerprinting, Shodan search indexing, and even specialized engineering software through careful implementation using the Snap7 protocol library [9]. DNP3 traffic grew from 5.1% to 22% of ICS scanning between 2015 and 2019, demonstrating increasing attacker interest [8]. Database protocols, including MySQL and PostgreSQL, exhibit limited sophistication in most honeypot implementations despite active targeting by attackers. Most MySQL honeypots perform basic authentication simulation without realistic query processing or database structure emulation that advanced attackers might probe. A critical gap emerges in OPC UA protocol support: our literature review identified only minimal dedicated OPC UA honeypot research [10],[11], despite OPC UA's status as the modern standard that replaces legacy ICS protocols. This represents a substantial vulnerability in industrial honeypot capabilities, given OPC UA's security-focused design and rapid adoption across industries. Table 2 summarizes the maturity of protocol emulation across key protocols.

Table 2. Protocol Emulation Maturity Assessment.

Protocol	Research Works	Production Tools	Fidelity	Gap Priority
SSH	20+	Cowrie, Kippo	High	Low
Modbus	15+	Conpot, SecuriOT	High	Low
S7comm	10+	HoneyPLC, Conpot	High	Low
DNP3	5+	Conpot	Medium	Medium
OPC UA	2	None	Low	High
MySQL	3	Dionaea	Low	High

3. Interactive Environment and Artifact Deception

An interactive environment simulation creates believable operating system contexts, including filesystem structures, process listings, system users, and command responses, that withstand reconnaissance probing. Early approaches employed static configurations: Kippo implemented fixed Debian-based filesystem hierarchies that proved effective against automated scanners but vulnerable to manual inspection by experienced attackers who recognized identical structures across deployments.

Modern implementations, including Cowrie, provide customizable filesystem definitions via configurable fs. pickle files, enabling deployment-specific variations. However, practical adoption lags behind technical capability: research analyzing real-world Cowrie and Kippo deployments found that 72% utilize default configurations readily identifiable through characteristic artifacts [3]. These detection vectors include predictable MAC addresses such as the default "88111222" sequence, standard hostname patterns, uniform filesystem structures, and suspicious timestamp uniformity where all files share identical modification dates corresponding to deployment timing rather than realistic system evolution. Filesystem realism requires multiple consistency dimensions. File counts must appear neither suspiciously sparse nor unrealistically dense. Modification timestamps should span months or years, reflecting genuine system history rather than a concentrated clustering around deployment dates. User home directories demand realistic personalization artifacts, including configuration files, shell histories, and application data appropriate to simulated user roles. System log files must contain realistic content, including authentication events, service startups, and cron job executions, with proper log rotation that demonstrates long-term operation. Command response simulation faces particular challenges given the attacker's use of sophisticated reconnaissance sequences. Common probing patterns include uname system information queries with various flag combinations to cross-check consistency, /proc/uptime filesystem access testing both file existence and content realism, complex shell pipelines using cut, awk, and arithmetic operators to verify shell capability, and deliberate write-test sequences such as echo test > /tmp/file && cat /tmp/file && rm /tmp/file explicitly designed to detect nonpersistent or read-only filesystems that betray honeypot implementations. Sophisticated attackers maintain IP blocklists of confirmed honeypot addresses discovered through artifact matching. The research community has thoroughly documented detection artifacts and proposed mitigation approaches through randomization, borrowing from real systems, and continuous evolution, yet the high default-configuration rate indicates an operational gap rather than a technical knowledge gap requiring improved tooling.

4. Response Timing Manipulation

Response timing manipulation represents the most severe research gap, with only three significant works over 20 years, despite its clear practical relevance. This addresses temporal characteristics that sophisticated attackers measure to detect artificial environments exhibiting impossible response patterns. Detection vectors fall into four areas:

- instantaneous responses betraying absent processing overhead, where real systems incur CPU scheduling, disk I/O, and network stack delays
- geographic latency absence when honeypots respond uniformly regardless of attacker location (Asian attackers expect 200-300ms transatlantic RTT, honeypots respond in <1ms)
- load-dependent timing variations are absent from honeypots that maintain constant response times
- protocol-specific timing when SSH key exchanges or MySQL queries complete impossibly quickly

Limited existing research provides minimal coverage. Endless SSH tarpit (2019) deliberately implements slow banner transmission, prolonging connections beyond 10 minutes to cause resource exhaustion rather than realistic deception [12]. Variable delay experiments propose random insertion without systematic frameworks. Recent works (2023-2024) acknowledge timing problems but offer no comprehensive solutions. Nevertheless, universal applicability combined with minimal research attention establishes this as the highest-priority gap requiring immediate investment. Section V-A develops the resulting research agenda.

5. AI-Driven Adaptive Deception

AI-driven deception represents the newest category experiencing dramatic growth (2023-2025) as LLMs and reinforcement learning transition from theoretical to experimental. LLM integration enables dynamic command-

response generation, handling unexpected commands, generating on-demand filesystem content, and adapting to attacker sophistication [13]. However, critical weaknesses persist: prompt injection vulnerabilities that enable attacker manipulation, model hallucinations that produce unrealistic responses, computational costs that exceed those of traditional approaches, limited validation with no long-term deployment studies, and zero adversarial robustness research on AI-powered attacker detection. RL approaches show theoretical promise: Wagener et al. employed Q-learning for adaptive behavior, including command blocking and attacker engagement [14], while Dowling et al. demonstrated that RL can overcome honeypot detection [15]. Assessment: nascent stage despite rapid growth, very limited production deployments, completely unexplored adversarial robustness, unresolved security vulnerabilities, and absent cost-benefit analysis.

6. Cross-Protocol Consistency

Cross-protocol consistency addresses deception coherence across multiple services that sophisticated attackers probe systematically. The challenge manifests across four dimensions:

- identity consistency requiring hostname matching across SSH uname, MySQL variables, and SSL certificates
- version consistency demanding OS versions align logically (Ubuntu 18.04 shouldn't report Apache 2.4.52)
- filesystem consistency necessitating FTP-accessible files existing in SSH
- timing consistency requiring uniform geographic latency across protocols

Detection scenario: SSH reports Ubuntu 20.04, HTTP shows "nginx/1.14.0 (Ubuntu 18.04)", FTP returns "UNIX Type: L8", MySQL indicates Windows – these inconsistencies immediately identify honeypots to sophisticated attackers. Research findings: virtually zero academic attention, no systematic approaches, most honeypots deploy services independently. Practical challenges include managing consistency across 5+ protocols, the lack of centralized configuration systems, and the absence of validation tools. Assessment: high-priority gap for multi-protocol deployments as attackers increasingly employ multi-vector detection.

IV. EMPIRICAL VALIDATION STUDY

Our eight-day deployment captured 75,598 attacks, providing empirical validation and revealing real-world patterns informing deception requirements.

1. Attack Characterization and Protocol Distribution

Temporal analysis revealed remarkably aggressive attack onset: the first attack, targeting the exposed MySQL service, occurred precisely three minutes after honeypot exposure, demonstrating that internet-wide scanning discovers new targets nearly instantaneously. Within the first 24 hours, attackers generated 9,142 attacks, averaging 381 attempts per hour. Over the complete 195.35-hour deployment period, the cumulative total of 75,598 attacks averaged 387 per hour, or approximately 9,288 per day. This sustained high-intensity attack rate creates immediate implications for honeypot deception: no "warm-up" period exists during which configurations can be refined – systems must achieve full operational realism before exposure. The attack volume necessitates computationally efficient deception approaches, as resource-intensive techniques such as LLM inference would quickly become unsustainable under sustained load. Attack intensity patterns showed temporal variation with notable spikes. The initial 24-hour period exhibited a relatively uniform distribution of the 9,142 recorded attacks. The full eight-day timeline showed sustained baseline activity punctuated by a major spike on July 29, reaching approximately 8,000 attacks in a three-hour window, suggesting either a coordinated scanning

campaign or a surge in botnet activity. This pattern indicates honeypots encounter both continuous automated scanning and periodic intensive campaigns requiring deception capable of handling both steady-state and burst traffic. Geographic distribution analysis revealed attacker origins spanning at least ten countries with notable concentration patterns. The United States accounted for 24.65% of attacks, representing the largest single-source nation. China contributed 9.07%, consistent with documented large-scale scanning infrastructure. Nigeria, at 8.58%, reflects emerging attack infrastructure in developing nations. The Netherlands contributed 7.62%, likely representing commercial hosting infrastructure rather than Dutch attackers specifically. Other significant sources included Russia (6.48%), India (5.55%), South Africa (5.26%), Germany (4.59%), and Romania (3.83%), with the remaining 17.99% distributed across many additional nations. This geographic diversity creates important implications for timing deception: realistic latency simulation must account for round-trip times that scale with geographic distance (Section V-A). Protocol targeting distribution showed overwhelming SSH dominance: 72,668 attacks, representing 96.12% of total traffic, targeted the SSH service exclusively. MySQL received 1,466 attacks (1.94%), demonstrating sustained interest despite a lower percentage. DNS captured 1,114 queries (1.47%), primarily reconnaissance rather than exploitation attempts. FTP was targeted in 320 attacks (0.42%), reflecting the diminished relevance of legacy file transfer protocols. SMTP recorded merely 30 attempts (0.04%), suggesting mail relay abuse has become a comparatively rare attack vector. The SSH dominance validates the literature's extensive focus on SSH deception quality as the highest-return investment, given the concentration of attack volume. However, the nearly 2,930 non-SSH attacks remain nontrivial: they represent distinct attacker populations and techniques that require protocol-specific deception. Furthermore, evidence suggested cross-protocol probing, in which attackers successful in SSH compromise attempts subsequently explored MySQL and FTP services, reinforcing the cross-protocol consistency requirements identified in Section III-F.

2. SSH Attack Analysis

SSH attacks, enabled by complete session recording, revealed systematic patterns in username targeting, password strategies, and command execution. The 524 unique usernames attempted during deployment showed a clear preference for privileged accounts: root received 3,245 authentication attempts (24.21% of username-identified traffic), and admin received 1,566 attempts (11.68%), collectively representing 35.89% of privileged account targeting. Service-specific accounts, including Oracle (217 attempts), PostgreSQL (132 attempts), and Ubuntu (217 attempts), indicated that attackers were targeting database servers and specific Linux distributions. Generic accounts user (776), test (262), and guest (161) represented low-effort attempts at common credentials. The username "solana" appeared with 127 attempts, suggesting attackers are targeting cryptocurrency mining infrastructure. The substantial Other category, containing 6,556 attempts (48.91%), demonstrated the attacker's use of extensive username dictionaries beyond common patterns. These targeting patterns validate the interactive environment requirements in Section III-C: honeypots must populate realistic user mixes that combine privileged accounts, service accounts, and regular users in proportions matching simulated system types. However, an excessive number of privileged accounts is suspicious – real production systems typically limit root access and employ sudo mechanisms. Missing service accounts for corresponding services that ostensibly operate creates inconsistency: a system exposing PostgreSQL should contain the postgres user, and its absence, despite running the database service, is implausible. Password attack patterns revealed a mix of brute-force and credential-stuffing strategies. Simple numeric sequences dominated: 123456 appeared most frequently, followed by 123, 12345, 1234, 12345678, and 123456789. Dictionary words, including password, admin, ubuntu, and root, were highly frequent. Some sophisticated patterns emerged: FattMan1234567890 and lq4k@WSX suggested exploitation of a leaked credential database rather than pure brute-force generation. The string "solana" appeared in both the username and password lists, indicating the common username-equals-password attack pattern. The distribution across the 20 top passwords, while including thousands of unique attempts overall, demonstrates that attackers combine focused, common-credential attacks with broader dictionary coverage. Command execution analysis revealed systematic reconnaissance patterns consistent with automated exploitation frameworks. The most frequent command, uname -s -v -n -r -m, with 1,431 occurrences, gathered comprehensive system information, including kernel name, version, network name, release, and machine architecture, guiding

subsequent exploitation attempt selection based on identified vulnerabilities. Uptime calculation sequences appeared frequently: 132 instances of cat /proc/uptime | cut -d -f1 | cut -d. -f1 followed by AWK processing specifically designed to calculate system uptime in a human-readable format. These commands serve a dual purpose: legitimate system reconnaissance and honeypot detection through unrealistic uptime values or impossibly fast filesystem access.

Particularly revealing were explicit honeypot detection attempts: 110 instances of echo this_is_a_very_unique_test_string_4z > /tmp/honeypot_test_file.txt && cat /tmp/honeypot_test_file.txt && rm /tmp/ deliberately tested filesystem write persistence and read consistency. Honeypots with read-only or nonpersistent filesystems fail this test immediately. The command sequencing – write followed immediately by read – also tests response timing: real systems require microseconds to milliseconds for filesystem operations, including kernel VFS layer processing and potential disk I/O, while memory-only honeypot implementations might respond in nanoseconds, betraying an artificial implementation. This command analysis directly validates timing deception requirements from Section III-D. The /proc/uptime sequences demonstrate that attackers expect specific filesystem access patterns, including the existence of the/proc pseudo-filesystem and realistic content formatting. The write-read-delete sequences explicitly probe filesystem persistence. Complex pipelines that use multiple cut operations and AWK processing establish timing expectations: genuine systems incur process creation overhead, inter-process communication through pipes, and multiple context switches totaling tens of milliseconds, whereas honeypots might complete in single-digit milliseconds, revealing their artificial nature through measurable timing differences.

3. Secondary Protocol Findings

MySQL attacks (1,466) showed extreme privileged targeting: admin (51.46%), root (48.36%), collectively 99.82%. Commands revealed automated patterns: SET AUTOCOMMIT=0 (51 times), indicating SQL injection frameworks, show databases (8 times), show variables like '%version_compile_os%' (4 times), demonstrating explicit OS fingerprinting, creating a cross-protocol consistency requirement – MySQL-reported OS must align with SSH information. DNS queries (1,114) revealed 248 attempts (22.3%) targeting the version. bind – explicit version fingerprinting. Real servers frequently disable or return generic strings, so the guideline is: honeypot DNS must handle them realistically. Query types: ALL_RECORDS (390, 35.01%) performing reconnaissance, TXT (336, 30.16%), A records (208, 18.67%). FTP attacks (320) showed anonymous username dominance (30 attempts, 63.83%), www (15, 31.91%). Passwords followed anonymous conventions, with email formats accounting for 34.04%. SMTP attacks (30) showed tiscali.it domains dominated (13 instances, 43.3%), suggesting a specific campaign. Destination patterns: tiscali.it (13), hotmail.com (5), gmail.com (3), yahoo.com (2).

V. RESEARCH GAPS AND IMPLICATIONS

Synthesizing state-of-the-art with empirical patterns identifies critical gaps, prioritized by detection risk and research-maturity deficiencies. Figure 2 explicitly traces this synthesis, mapping the attack patterns observed in our deployment onto the deception dimensions they probe and the resulting priority gaps.

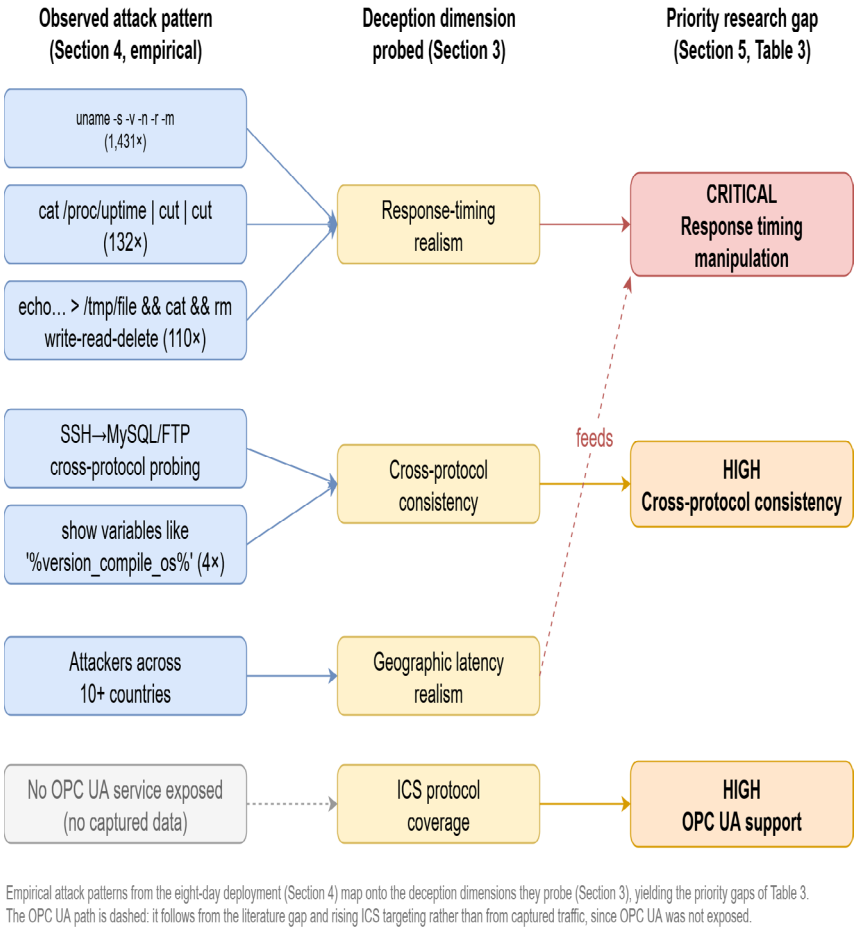

Figure 2. Empirical attack patterns from the eight-day deployment (Section IV) mapped onto the deception dimensions they probe (Section III) and the resulting priority research gaps (Table 3). The OPC UA path is dashed: it follows from the literature gap and rising ICS targeting rather than from captured traffic, since OPC UA was not exposed.

1. Critical Priority: Response Timing Manipulation

Response timing manipulation emerges as the highest-priority research gap through convergence of three critical factors: minimal existing research with only three significant works published over 20 years despite two decades of honeypot evolution (Section III-D), clear detection vector as evidenced by attacker command patterns specifically probing timing expectations through explicit filesystem tests and complex command sequences (Section IV-B), and universal applicability affecting all protocols and deployment contexts from traditional IT through ICS to emerging IoT environments. The empirical evidence from our deployment directly validates timing as a critical deception dimension that requires urgent research attention.

Attacker command sequences observed in our deployment reveal explicit timing expectations (Section IV-B). The cat /proc/uptime | cut | cut pipeline, executed 132 times, and the echo test > /tmp/file && cat /tmp/file write-test, executed 110 times, both impose timing expectations that honeypots routinely violate. On genuine Linux systems, the /proc pipeline completes in 15-50 milliseconds, depending on load and scheduling, while honeypots

answering from memory may complete it in <5 milliseconds. The write-read-delete sequence takes 10-100 milliseconds on real systems due to filesystem and disk overhead, yet memory-only honeypots may complete in under a millisecond. These differences form a measurable detection signal that timing analysis can exploit.

Our attackers spanned the USA (24.65%), China (9.07%), Nigeria (8.58%), the Netherlands (7.62%), and seven additional countries across four continents. This diversity creates a timing-consistency requirement that current honeypots cannot satisfy without explicit latency simulation. Real systems show network round-trip times proportional to geographic distance. European sources reaching European servers see <50ms, transatlantic US-Europe connections 100-150ms, and Asian-European paths 200-300ms. A honeypot that responds uniformly in <1ms regardless of source location exhibits physically impossible behavior, detectable through a simple latency measurement. Yet our literature review spanning 2004-2025 found zero implementations of geographic latency simulation, despite a straightforward approach: geolocate the attacker's IP and insert network-layer delays that match expected propagation delays.

Research opportunities span framework development, implementation techniques, and validation studies, creating a comprehensive research agenda. Framework development should produce a taxonomy categorizing timing deception approaches across multiple dimensions, including static delays with fixed response times independent of command characteristics, adaptive delays varying by command computational complexity to reflect genuine processing requirements, geographic-aware delays matching expected network latency based on attacker geolocation, and load-dependent delays reflecting multi-user contention and resource competition that real systems experience. Implementation research must develop timing profile libraries cataloging per-command response time distributions measured from real systems across diverse hardware configurations and load conditions enabling data-driven delay insertion, create transparent delay insertion mechanisms operating at network or application layers without requiring honeypot-specific modification to maintain compatibility across diverse implementations, and establish consistency maintenance techniques ensuring timing remains realistic across session duration avoiding suspicious timing variations between repeated commands that would betray artificial manipulation.

Validation studies require long-term deployments spanning weeks to months to measure whether timing deception reduces detection rates relative to nontiming-protected baselines. They also require attacker-behavior analysis to determine the tolerance thresholds separating acceptable delays from latencies that trigger disconnection, as well as adversarial testing of protected honeypots with timing-specific detection tools. Practical challenges remain. Threshold selection must balance sufficient delay for evasion against attacker patience, since excessive delay risks abandonment. Timing must stay consistent across repeated identical commands while still reflecting realistic load variation. Delay mechanisms add computational overhead to already-stressed high-interaction systems running full OS emulation. Finally, attacker patience varies: our data show both rapid initial attacks within 3 minutes of deployment, indicating impatient automated scanning, and sustained campaigns over the full 8-day period, indicating tolerance for moderate delays when a system appears genuine.

2. High Priority: Cross-Protocol Consistency and OPC UA Support

Cross-protocol consistency, identified in Section III-F as severely underexplored, gains practical validation through our multi-protocol deployment, which exposes five services simultaneously to internet traffic. The 2,930 non-SSH attacks (3.88%) and the SSH-to-MySQL/FTP probing reported in Section IV-A validate the consistency threat model: sophisticated attackers systematically probe multiple services, checking for inconsistencies that betray artificial environments through contradictory system characteristics that are impossible in genuine deployments.

The MySQL version fingerprinting command, show variables like '%version_compile_os%', observed four times in our captured traffic, creates a direct cross-protocol consistency requirement with SSH system information reporting. If the SSH uname command reports Ubuntu 20.04 while MySQL server variables indicate a Windows compilation environment, this immediate inconsistency exposes the honeypot implementation regardless of the individual protocol fidelity levels achieved through sophisticated emulation. Similarly, hostname consistency requirements demand that SSH hostname output generated by system calls matches MySQL @@hostname variable returned through database queries, DNS PTR records serving reverse IP lookup requests, and HTTP Host headers transmitted in web service communications. Our deployment using custom Cowrie configurations with modified filesystem and banner settings maintained basic consistency across exposed protocols. Still, many operational deployments using default settings across multiple independently configured protocol implementations likely exhibit detectable inconsistencies that sophisticated reconnaissance can identify.

Research opportunities include developing centralized identity and configuration management frameworks and ensuring that all exposed protocols reference a single authoritative source for hostname assignments, OS version reporting, network identity characteristics, and other shared system attributes that must remain consistent across protocol boundaries. Protocol interdependency modeling should systematically characterize which service combinations realistically coexist in real deployments: SSH plus a web server is an extremely common configuration present across millions of internet-exposed systems, whereas SSH plus multiple diverse ICS protocols might appear suspicious depending on the deployment context and organizational profile. Automated consistency validation tools that enable pre-deployment testing through systematic multi-protocol probing would prevent inconsistent deployments from reaching production exposure, where attackers can discover contradictions. The minimal existing research, combined with the clear practical necessity demonstrated by our empirical multi-protocol attack patterns, makes this a high-priority gap for any sophisticated honeypot deployment that exposes multiple services.

Our literature review found only minimal OPC UA coverage despite its strategic importance: few dedicated OPC UA honeypots exist [10],[11], even though OPC UA is now the modern ICS standard replacing legacy Modbus and S7comm across industrial deployments. Our deployment excluded OPC UA, so we collected no direct attack data, but the protocol's rapid industrial adoption and rising ICS targeting establish clear future relevance. OPC UA is technically demanding to emulate: the specification defines numerous service primitives, certificate-based authentication and encryption, and rich information modeling well beyond legacy protocols. The research opportunity is correspondingly strong. Only a handful of implementations exist, mature open-source libraries such as open62541 enable rapid prototyping, and the practical impact for critical infrastructure is high given OPC UA's growth across energy, manufacturing, and transportation. A credible approach mirrors the HoneyPLC S7comm strategy (Section III-B), which achieved deception fidelity against active fingerprinting and search engine indexing using the Snap7 library [9].

3. Medium Priority Gaps

Database protocol superficiality affects MySQL/PostgreSQL, which lack realistic query processing. Our 1,466 MySQL attacks employed simple probing, but increasing sophistication may demand deeper functionality, including query execution simulation, dynamic content generation, and transaction handling. Default configuration vulnerability represents a known issue with underutilized solutions (72% detectable [3]), indicating an operational gap requiring improved tooling to automate uniqueness. Temporal evolution addresses artifact aging, with limited research suggesting opportunities for frameworks. AI/LLM adversarial robustness concerns emerging approaches facing unexplored detection threats as attackers develop AI-specific techniques. Table 3 summarizes priorities.

Table 3. Research Gap Priority Matrix.

Gap Area	**Research Maturity**	**Detection Risk**	**Practical Impact**	**Priority**
Response Timing	Very Low	Very High	Universal	Critical
Cross-Protocol Consistency	Very Low	High	Multi-protocol	High
OPC UA Support	Low	Medium (Growing)	ICS Security	High
Database Protocol Depth	Low	Medium	Moderate	Medium
Default Config Avoidance	Known Issue	High	Implementation	Medium
AI Adversarial Robustness	Emerging	Future	AI Adoption	Medium

VI. DISCUSSION AND IMPLICATIONS

Our analysis reveals a paradox in honeypot deception research: the community has achieved remarkable sophistication in visible deception dimensions such as banner manipulation and protocol emulation, while neglecting invisible yet critical dimensions such as response timing, which sophisticated attackers increasingly exploit. This misalignment between research investment and attacker detection capability explains why 72% of deployments remain detectable despite two decades of technical advancement [3]. The detection arms race has shifted from "what honeypots say" to "how honeypots behave temporally and contextually." Our literature review and empirical validation show these dimensions remain severely underaddressed.

The convergence of our literature analysis with empirical attack patterns reveals several critical insights beyond individual gap identification. First, attacker sophistication demonstrates clear stratification: while 96.12% of attacks employ automated tools targeting SSH with predictable reconnaissance patterns, the remaining 3.88% exhibiting multi-protocol probing and timing-sensitive command sequences represent qualitatively different threats requiring fundamentally different defensive approaches. Current honeypot designs optimized against volume attacks remain vulnerable to quality attacks from sophisticated adversaries. Second, the operational-technical divide persists as a critical vulnerability: solutions exist for many detection problems (filesystem customization, artifact randomization), yet widespread adoption failures indicate that tooling and usability gaps matter as much as technical capability. Third, timing represents a universal detection vector cutting across all protocol domains and interaction types, yet has received essentially zero systematic research attention. This is not an incremental gap but a fundamental blind spot in the design of deception architecture.

The implications extend beyond honeypot deployments to broader deception system design. Any artificial system attempting to mimic genuine behavior faces timing consistency challenges: chatbots exhibiting inhuman response speeds, fake social media accounts posting with suspicious regularity, or simulated network traffic lacking realistic jitter all face analogous detection vulnerabilities. Our findings suggest a general principle: deception systems must address temporal characteristics with the same rigor as semantic content, as temporal patterns often provide simpler detection signals than content analysis.

Research priorities require strategic rebalancing. The critical timing gap demands immediate, coordinated effort, potentially through multi-institutional collaboration, given the scope spanning framework development, extensive real-system profiling, and long-term deployment validation. Cross-protocol consistency similarly benefits from standardization efforts, such as developing reference architectures and validation tools, thereby preventing ad-hoc, inconsistent implementations. In contrast, continued incremental improvements to mature areas like banner manipulation offer diminishing returns. The community should resist investing disproportionate effort in refining already-sophisticated capabilities while fundamental gaps persist.

The OPC UA gap exemplifies the broader challenge of keeping deception capabilities aligned with the evolving technology landscape. As industrial systems adopt modern protocols, legacy protocol honeypots become progressively less relevant regardless of implementation quality. This suggests the need for systematic horizon scanning to identify emerging protocols and technologies that require preemptive honeypot development before widespread targeting by attackers begins, rather than reactive development after exploitation campaigns emerge.

VII. CONCLUSION

This work provides a systematic understanding of honeypot deception capabilities and limitations through a dual-method analysis that combines a literature review with empirical validation, capturing 75,598 attacks. Our seven-category taxonomy reveals substantial variation in maturity, from highly developed banner manipulation to severely underexplored timing deception. The empirical deployment validates literature findings while revealing attack patterns that directly inform deception requirements: command sequences that explicitly test timing expectations and filesystem persistence demonstrate that attackers actively probe dimensions that current research neglects. The systematic gap analysis identifies response timing manipulation as the highest-priority research need, followed by cross-protocol consistency and OPC UA support. These gaps share a common characteristic: clear practical significance, as evidenced by our empirical data, combined with minimal existing research, creating a substantial opportunity for impactful contributions. The research roadmap spans immediate priorities (timing frameworks, consistency validation) and emerging opportunities (AI adversarial robustness). Organizations deploying honeypots face clear imperatives: prioritize SSH quality given the concentration of attacks, eliminate default configurations through systematic customization, and validate cross-protocol consistency in multi-service deployments. Researchers have a clear opportunity to address fundamental gaps with little competition and high practical impact. As attackers employ increasingly sophisticated multi-vector detection techniques, honeypot effectiveness depends on addressing not only visible deception dimensions but the invisible temporal and contextual characteristics that current approaches systematically neglect.

Abstract
Accurate crime scene documentation is essential for preserving evidentiary integrity and enabling reliable reconstruction. While 3D documentation technologies improve spatial representation, professional systems remain costly and operationally demanding—this limits adoption in resource-constrained environments such as South Africa. Consumer-grade Light Detection and Ranging (LiDAR)-enabled devices provide a potential alternative. However, the influence of acquisition strategies on forensic scene re-localization remains underexplored. This study investigates the effect of LiDAR acquisition trajectory on augmented reality (AR)-based crime scene re-localization. Vuforia Area Targets were generated from Apple iPad Pro devices. A controlled indoor mock crime scene was captured using three trajectories: horizontal sweep, circular orbit, and 45° oblique zig-zag. Experiments were performed on iPad Pro devices with M1, M2, and M4 processors across 45 independent trials. Performance was evaluated using Recognition Success Rate (RSR), Time-to-Localization (TTL), Tracking Stability (TS), and Evidence Recovery Rate (ERR). Results showed strong localization performance across all devices, with the iPad Pro M4 achieving 100% recognition success across all evaluated trajectories. The 45° oblique zig-zag trajectory produced the lowest mean localization time for all devices and achieved the highest or tied-highest ERR in two of the three devices. These findings provide preliminary evidence that consumer-grade LiDAR devices can support AR-based forensic scene re-localization and suggest that acquisition trajectory may influence downstream localization performance.

Keywords: Consumer-grade LiDAR, 3D crime scene reconstruction, AR-based localization, Acquisition trajectory, Digital forensics

I. INTRODUCTION

Accurate crime scene documentation is fundamental to preserving evidentiary integrity and enabling reliable scene reconstruction [1], [2]. Conventional methods, including digital photography, videography [3], manual sketching [4], and tape-based measurements [5], remain widely used, particularly in resource-constrained regions such as South Africa [6]. However, these approaches are susceptible to human error and often fail to capture the complete spatial context of a crime scene [7]. Three-dimensional (3D) crime documentation technologies, including terrestrial laser scanning (TLS), LiDAR, uncrewed aerial vehicles (UAVs), and photogrammetry, provide non-contact acquisition of spatial information and enable the creation of permanent digital crime scene records for reconstruction and forensic analysis [8], [9]. Despite their advantages, professional forensic scanners are expensive and require specialized expertise, limiting their adoption in resource-constrained regions [10]. Consumer LiDAR devices offer a portable and cost-effective alternative for digital crime scene documentation [11]. While previous studies have primarily focused on reconstruction accuracy [12-14], relatively little attention has been given to how acquisition strategies affect the practical usability of reconstructed scenes during forensic investigations. In practice, investigators must be able to

recognize and re-localize digitally documented scenes when revisiting evidence reliably. This study investigates the effect of acquisition trajectory on the recognition performance of Vuforia Area Targets generated using LiDAR-enabled iPad Pros within an indoor mock crime scene. Three scanning trajectories were evaluated: horizontal, circular, and 45° (üssü halka işleci° oblique. These configurations were evaluated based on scene recognition success (SRS), time to localization (TTL), and tracking stability (TS) under controlled object-removal conditions during re-visitation. The findings provide preliminary practical insights into optimizing LiDAR-based crime scene acquisition using consumer devices and demonstrate the potential of low-cost mobile LiDAR for forensic applications in resource-constrained environments. The remainder of this paper is organized as follows. Section II reviews the relevant literature and identifies the research gap this study addresses. Section III describes the research methodology, while Section IV presents and discusses the experimental results. Finally, Section V concludes the paper and outlines directions for future research.

II. RELATED WORK

This section reviews digital crime scene documentation, focusing on (i) the evolution from conventional documentation to 3D reconstruction, (ii) 3D acquisition technologies, and (iii) practical considerations affecting forensic deployment. These studies provide context for investigating acquisition trajectories using low-cost LiDAR devices. 3D crime scene documentation has evolved from conventional recording methods to spatial reconstructions that preserve scene geometry and spatial relationships for long-term analysis [7], [15]. Early systems employed integrated laser and structured-light scanning for virtual reality (VR) scene exploration [5], while photogrammetry improved accessibility through multi-spectral imaging and integration with post-mortem computed tomography [9], [16]. However, reviews indicate that no single acquisition method is universally optimal across forensic scenarios and operational constraints [17]. Primary technologies, including TLS, photogrammetry, micro-UAVs, and consumer mobile LiDAR, present trade-offs between accuracy, cost, and operational complexity [7], [8], [17–19]. TLS provides high geometric accuracy but is costly for routine field deployment [7], [18], whereas photogrammetry offers a flexible, cost-effective alternative but is sensitive to lighting and low-texture environments [9], [17]. Consumer mobile LiDAR enables rapid acquisition with sufficient geometric accuracy for many forensic applications, offering a practical balance of speed, cost, and usability [11], [19]. Recent work has also emphasized workflow integration and immersive scene re-visitation through systems such as the Forensic Holodeck and AR/VR frameworks [20], [21]. However, existing studies primarily evaluate acquisition methods in terms of geometric accuracy rather than downstream AR re-localization performance [17], [19]. From an AR and SLAM perspective, reliable re-localization depends on persistent visual correspondences, viewpoint coverage, and robust feature matching [22-25]. At the same time, place-recognition research shows that viewpoint, appearance, and environmental changes can affect the robustness of localization [26], [27]. How the acquisition trajectory influences subsequent AR re-localization, particularly in forensic scene documentation, remains insufficiently investigated. This study addresses this gap by comparing three LiDAR acquisition trajectories and their effects on Area Target recognition, localization time, tracking stability, and object identification.

III. METHODOLOGY

1. Experimental Environment

Experiments were conducted in a controlled indoor setting configured as a hypothetical crime scene. A 2 × 2 m evidence region, bounded by two adjacent walls, was configured with seven predefined evidence items, as shown in Fig. 1. The evidence layout remained unchanged during the Area Target acquisition and re-localization trials. A separate ERR evaluation subsequently used sequential object removal to assess evidence recovery. Each

acquisition trajectory was evaluated using identical experimental conditions on each device, with multiple independent trials performed to ensure repeatability.

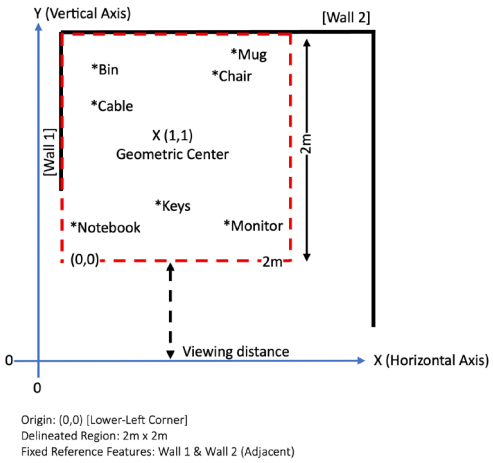

Figure 1. Top-down schematic of the $2\,\mathrm{m} \times 2\,\mathrm{m}$ experimental scene, showing the (0,0) coordinate origin, reference walls, and the distribution of evidence objects.

The lower-left corner was defined as the coordinate origin (0, 0), with the scene center located at (1, 1). Experiments were performed on Apple iPad Pro devices with M1, M2, and M4 processors, each equipped with an integrated LiDAR scanner. Their hardware specifications are summarized in Table 1.

Table 1. Camera and LiDAR specifications of the mobile devices used in this study.

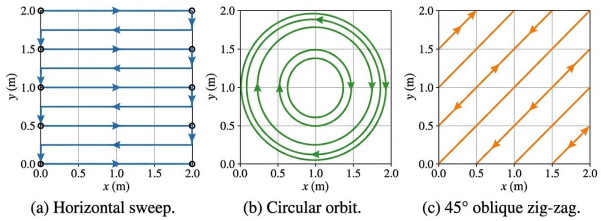
Device	Rear Camera	LiDAR Scanner	Processor
iPad Pro 12.9-inch (M1)	12 MP Wide + 10 MP Ultra-Wide	Integrated LiDAR	Apple M1
iPad Pro 11-inch (M2)	12 MP Wide + 10 MP Ultra-Wide	Integrated LiDAR	Apple M2
iPad Pro 13-inch (M4)	12 MP Wide	Integrated LiDAR	Apple M4

For all trials, the device was held at approximately 1.5 m above ground and about 1 m from the scene center while maintaining a slow, constant walking speed.

2. Evaluation Metrics

Area Target performance was evaluated using four quantitative metrics over a fixed 30 s observation period (T_{observe}), recorded via Xcode on an Apple Mac mini (M2):

, sağ parantez ×100): Where büyük harf N alt s is the number of trials successfully recognized within 10 s and büyül trajectory condition.$= \frac{1}{N_s}\sum_{i=1}^{N_s} t_i$: The mean recognition time is for successful trials only. Trials exceeding 10 s were counted as unsuccessful for RSR and excluded from TTL.



Eşittir $= \frac{\sum T_{\text{stable},i}}{N_s \times T_{\text{observe}}} \times 100$: Percentage of the 30 s observation period during which stable tracking was maintained, averaged across trials that successfully localized within 10 s.

, sağ parantez ×100): The percentage of the büyük harf E alt t predefined evidence items correctly identified (büyük in the localized AR scene.

Percentage of total predefined evidence items correctly identified in the localized AR scene. For each trial, the experimenter compared the localized AR scene against the predefined object inventory used as the ground truth. An object was counted as correctly recovered when its corresponding object was correctly identified in the localized AR scene. ERR was calculated as the percentage of correctly recovered objects divided by the total number of predefined objects. The same experimenter performed the experiments and the ERR scoring. No independent inter-rater assessment was conducted.

3. LiDAR Acquisition Trajectories

Three LiDAR acquisition trajectories were evaluated within the controlled crime scene to investigate the influence of capture geometry on Vuforia Area Target recognition and re-localization (Figure 2). The horizontal sweep provides uniform spatial coverage using five parallel passes, the circular orbit acquires multi-angle observations through concentric revolutions about the scene center, and the 4° oblique zig-zag maximizes angular viewpoint diversity through alternating diagonal traversals.

(a) Horizontal sweep. (b) Circular orbit. (c) 45° oblique zig-zag.

Figure 2. LiDAR acquisition trajectories were evaluated within the controlled 2 × 2 m mock crime scene. (a) Horizontal sweep provides uniform spatial coverage, (b) circular orbit maximizes multi-angle feature oobservation,and c) the 4, and (c) the 45° oblique zig-zag increases angular viewpoint diversity for robust Area Target generation and scene re-localization.

4. Experimental Procedure

The AR application was built in Unity 6 (v6000.0.78f1) using Vuforia Engine 11.4 and C# (Visual Studio 2021). Five independent trials were conducted per trajectory across the iPad Pro M1, M2, and M4 (45 total runs). Before each trial, the application was restarted, and the operator returned to the fixed starting position to maintain experimental independence.

IV. RESULTS AND DISCUSSION

This section discusses how consumer-grade LiDAR devices performed across various acquisition trajectories. As stipulated above, metric timings were recorded using Xcode on an Apple Mac mini (M2). Figure 3 depicts the controlled indoor setting configured as a hypothetical crime scene.

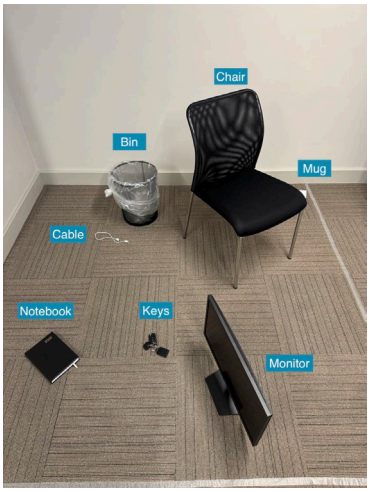


Figure 3. 2 m × 2 m experimental scene containing the distribution of evidence objects.

1. Area Target Recognition Performance

This subsection presents and discusses the results obtained from the RSR conducted on the acquired target areas for each device. Table 2 presents the recognition success rate and mean time-to-localization (TTL), with standard deviation (SD) calculated from successful trials.

Table 2. Recognition success rate and time-to-localization results.

Device	Acquisition Trajectory	Successful Trials / Total Trials	RSR (%)	TTL (s), Mean ± SD
iPad Pro M1	Horizontal Sweep	4/5	80	3.18 (±0.24)
	Circular Orbit	5/5	100	4.12 (±0.70)
	45° Oblique zig-zag	5/5	100	2.95 (±0.47)
iPad Pro M2	Horizontal Sweep	5/5	100	4.48 (±0.89)
	Circular Orbit	4/5	80	3.56 (±0.03)
	45° Oblique zig-zag	5/5	100	2.72 (±0.87)
iPad Pro M4	Horizontal Sweep	5/5	100	2.34 (±0.13)
	Circular Orbit	5/5	100	2.21 (±0.00)
	45° Oblique zig-zag	5/5	100	2.08 (±0.13)

Across all evaluations, the iPad Pro M4 achieved 100% RSR and the shortest TTL (2.08-2.34 s) among the tested devices and trajectory conditions. The 45° oblique zig-zag trajectory yielded the lowest mean TTL for each device in the present experiment (2.95 s for M1, 2.72 s for M2, and 2.08 s for M4), which may be associated with greater viewpoint diversity. However, viewpoint coverage and feature-level persistence were not directly measured.

Overall recognition was exceptional across all trials, with only two failures recorded: iPad Pro M1 dropped to 80% RSR on horizontal sweep, and iPad Pro M2 dropped to 80% RSR on circular orbit. All other device trajectory combinations achieved 100% RSR, shown in Figure 4.

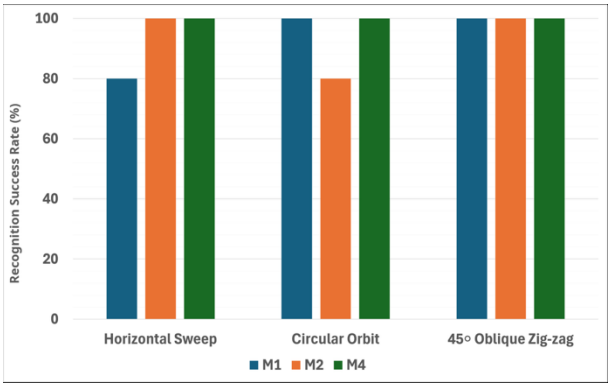

Figure 4. RSR comparison across all devices tested.

Generational comparison reveals a progressive improvement in localization efficiency. While the M1 and M2 devices exhibited greater variability in TTL across acquisition trajectories, the M4 maintained consistently low TTL values with minimal variation. The consistently low TTL values observed for the M4 indicate stable localization performance under the tested conditions; however, the contribution of hardware generation or processing capability cannot be isolated by the present experimental design.

2. Tracking Stability Analysis

This subsection presents the mean TS results for each device. Table 3 summarizes the mean TS values across all scans relative to the 30 s observation period and includes the corresponding percentages. Values closer to the full 30s observation period indicate greater TS and, consequently, better performance.

Table 3. TS results after successful localization of the area target.

Device	Acquisition Trajectory	Stable Tracking Time (s)	Observation Time (s)	TS (%)
iPad Pro M1	Horizontal Sweep	27.48	30	91.60
	Circular Orbit	26.74	30	89.13
	45° Oblique zig-zag	28.45	30	94.83
iPad Pro M2	Horizontal Sweep	27.89	30	92.97
	Circular Orbit	27.12	30	90.40
	45° Oblique zig-zag	29.45	30	98.17
iPad Pro M4	Horizontal Sweep	30	30	100
	Circular Orbit	30	30	100
	45° Oblique zig-zag	30	30	100

Figure 5 presents the same TS results expressed in seconds, providing a visual comparison across devices.

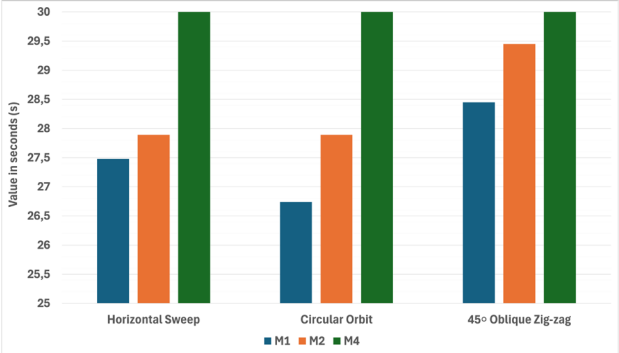

Figure 5. TS comparison across all devices used in testing.

TS results demonstrate consistently high performance across all devices and acquisition trajectories. Results also show that TS values ranged from 89.13% to 100%. The iPad Pro M4 achieved the highest stability, maintaining 100% TS across all trajectories. These results indicate stable tracking under the tested conditions, but field applicability in resource-constrained forensic environments requires further evaluation across varied scenes, operators, and environmental conditions. For the M1 and M2 devices, the 4° oblique zig-zag trajectory achieved the highest TS values of 94.83% and 98.17%, respectively, suggesting that diverse viewpoints enhance feature persistence and tracking reliability. Conversely, the circular orbit produced the lowest TS values for the M1 and M2 devices. Overall, the M4 showed more consistent tracking under the tested conditions. However, the effects of device generation, hardware differences, and processing capability could not be isolated in the present design.

3. Evidence Recovery Performance

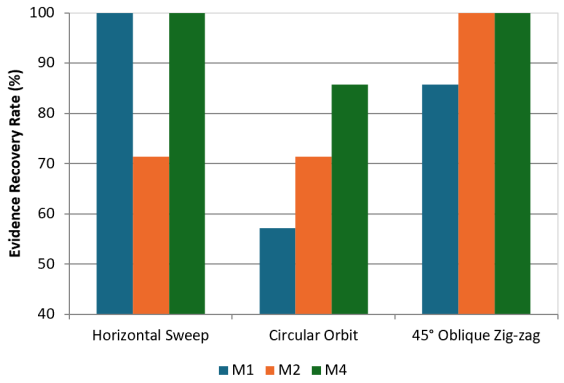
This subsection presents the results of the ERR test, demonstrating the effectiveness of the proposed approach for supporting crime scene re-visitations in low-resource environments. In addition to quantifying the number of successfully recovered evidence items, the analysis considers instances of AR drift and other tracking anomalies observed during the experiments. Table 4 summarizes the detailed recovery results for each device and acquisition trajectory. Seven predefined scene objects were placed within the 2 × 2 m evidence region and sequentially removed during the ERR evaluation.

Table 4. ERR RESULTS AFTER SUCCESSFUL SCENE LOCALIZATION

Device	Acquisition Trajectory	Chair	Monitor	Keys	Note book	Cable	Mug	Bin	Recovered / Total	ERR (%)
iPad Pro M1	Horizontal Sweep	✓	✓	✓	✓	✓	✓	✓	7/7	100
	Circular Orbit	X	X	✓	✓	✓	X	✓	4/7	57.14
	45 ° Oblique zig-zag	✓	✓	X	✓	✓	✓	✓	6/7	85.71
iPad Pro M2	Horizontal Sweep	✓	✓	X	✓	X	X	✓	5/7	71.42
	Circular Orbit	✓	✓	✓	✓	X	X	✓	5/7	71.42

	45 ° Oblique zig-zag	✓	✓	✓	✓	✓	✓	✓	7/7	100
iPad Pro M4	Horizontal Sweep	✓	✓	✓	✓	✓	✓	✓	7/7	100
	Circular Orbit	✓	✓	✓	✓	X	✓	✓	6/7	85.71
	45 ° Oblique zig-zag	✓	✓	✓	✓	✓	✓	✓	7/7	100

Figure 6 provides a visual comparison of the corresponding ERR percentages across the evaluated devices and trajectories.



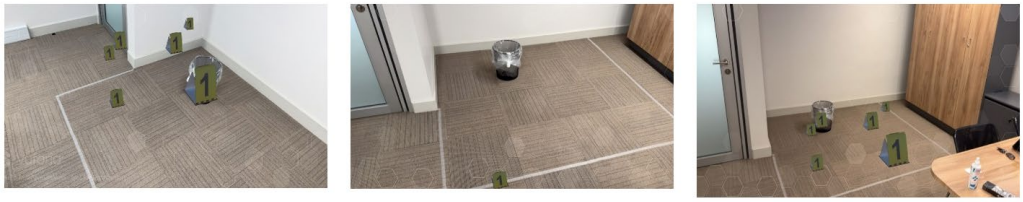


Figure 6. ERR comparison across all devices used in testing

Across the evaluated trajectories, the 45° oblique zigzag generally yielded the highest evidence-recovery performance. The iPad Pro M1 achieved 100% ERR for the horizontal sweep, 57.14% for the circular orbit, and 85.71% for the 45° oblique zig-zag. The iPad Pro M2 achieved 71.42% ERR for both the horizontal sweep and circular orbit, while the 45° oblique zig-zag achieved 100%. The iPad Pro M4 achieved 100% ERR for both the horizontal sweep and 45° oblique zig-zag, compared with 85.71% for the circular orbit. Overall, the 45° oblique zigzag showed the strongest evidence-recovery performance across the three devices. However, the results should be interpreted as trends under the tested conditions, given the limited number of trials per condition.

Figure 7 illustrates representative localization behaviors observed during ERR testing. Figure 7(a) shows the iPad Pro M1 after localization, where the virtual evidence markers remain visible but exhibit an orientation shift relative to the physical scene, indicating AR drift or axis misalignment. Figure 7(b) shows the iPad Pro M2 during a tracking-loss event, in which the virtual evidence markers are no longer rendered, indicating a temporary loss of AR tracking. Figure 7(c) shows the iPad Pro M4 under stable tracking, with the virtual evidence markers maintaining the expected spatial orientation relative to the physical scene. These observations provide qualitative context for the ERR results reported in Table 4.

(a) M1 iPad Pro (b) M2 iPad Pro (c) M4 iPad Pro

Figure 7. Representative AR localization behaviors observed during ERR testing: (a) orientation shift of virtual evidence markers on the iPad Pro M1, (b) temporary tracking loss on the iPad Pro M2, indicated by the disappearance of the virtual markers, and (c) stable tracking on the iPad Pro M4, with markers maintaining the expected spatial orientation.

These qualitative observations are consistent with the quantitative ERR results in Table 4, in which the M1 circular trajectory yielded the lowest ERR (57.14%). At the same time, the M2 and M4 achieved higher recovery under their respective evaluated trajectories. However, the observed anomalies were not independently quantified and should therefore be interpreted as qualitative observations rather than additional performance measures. The M4 results indicate stable tracking under the tested conditions, rather than general device superiority.

4. Impact of acquisition trajectory on LiDAR-based AR crime scene re-localization.

Beyond evaluating hardware performance, these findings demonstrate the viability of consumer-grade mobile LiDAR for digital crime scene documentation, where professional scanning systems are cost-prohibitive. The results indicate that the acquisition trajectory was associated with differences in observed localization and evidence recovery performance, with the 45° oblique zigzag and horizontal sweep trajectories generally yielding favorable results under the tested conditions. These findings suggest that the capture strategy may influence the reliability of AR-based scene re-localization under the tested conditions and motivate further evaluation in resource-constrained forensic settings.

5. Limitations

Several limitations should be considered. The study used one controlled indoor scene, one operator, one AR framework (Vuforia Engine), and five trials per device-trajectory condition, which limited generalizability and statistical inference. A single experimenter also scored ERR without independent inter-rater assessment. Future studies should include multiple scenes, operators, lighting conditions, AR frameworks, and larger trial sets to improve generalizability and statistical robustness.

V. SUMMARY AND CONCLUSION

This study investigated the influence of LiDAR acquisition trajectories on AR-based crime scene re-localization using iPad Pro devices with M1, M2, and M4 processors across 45 experimental trials. Results indicate that the acquisition trajectory was associated with differences in localization speed, tracking stability, and evidence recovery performance under the tested conditions. The 45° oblique zigzag trajectory produced the lowest mean TTL across all three devices (2.08-2.95 s), while the iPad Pro M4 achieved 100% RSR and TS across all evaluated conditions. These findings provide preliminary evidence of the feasibility of using consumer mobile

LiDAR for accessible digital crime scene documentation under the tested conditions, particularly in resource-constrained environments.

Future work will extend this evaluation to larger environments, variable illumination, occlusions, dynamic scene changes, and additional consumer LiDAR hardware. Additionally, future research will explore automated trajectory planning alongside cybersecurity frameworks, including encrypted transmission, authentication, and privacy-preserving data sharing, to support trusted, secure adoption in operational forensic processes.

Abstract
Operational Technology (OT) plays a fundamental role in the operation of Critical Infrastructure (CI), yet its importance varies considerably across the sectors covered by the Network and Information Security Directive 2 (NIS2). This paper investigates the dependency of NIS2 Essential and Important sectors on OT systems and examines the implications for cybersecurity resilience and Critical Infrastructure protection. A literature-based Dependency of OT Assessment Framework (DOTAF) is proposed to evaluate OT dependency using four criteria: OT deployment, dependency on physical processes, operational impact of OT failure, and manual fallback capability. The framework is applied to all eighteen NIS2 sectors, demonstrating that thirteen exhibit medium, high, or very high dependency on OT. The findings further highlight the influence of ICT/OT convergence, cross-sector interdependencies, and real-world cyber incidents on operational resilience. The proposed framework provides a structured and reproducible approach for assessing OT dependency and supports risk-informed cybersecurity governance, resilience planning, and future sector-specific evaluations.

Keywords: Operational Technology, Critical Infrastructure, NIS2, Cybersecurity Governance, ICT/OT Convergence, Cyber Resilience

I. INTRODUCTION

The increasing digitalization of Critical Infrastructure (CI) has strengthened the integration of Information and Communication Technology (ICT) and Operational Technology (OT), improving operational efficiency while expanding the cybersecurity attack surface. CI, defined as the organizations, facilities, systems, and assets essential for the functioning of society and the economy [1], increasingly depends on OT systems to support the monitoring, control, and automation of physical processes [2]. As a result, cyber incidents affecting ICT environments can directly impact OT systems, creating consequences that extend beyond the digital domain and affect public safety, service continuity, and economic stability [3]. The Network and Information Security Directive 2 (NIS2) [4] establishes cybersecurity requirements for Essential and Important entities, many of which rely on OT to deliver critical services. Although international standards and the NIS2 Directive guide the securing of OT environments, they do not provide a structured methodology for assessing and comparing the level of OT dependency across the NIS2 sectors. This limits the ability to consistently evaluate sector-specific OT reliance and its implications for cybersecurity resilience. To address this research gap, this paper proposes the Dependency of OT Assessment Framework (DOTAF), a literature-based semi-quantitative framework for assessing and comparing the degree of OT dependency across all eighteen NIS2 sectors. The framework provides a structured, reproducible methodology for evaluating sector-specific OT dependencies and examining their implications for cybersecurity resilience and Critical Infrastructure protection. The contributions of this paper are threefold:

- It systematically analyses the role of OT within Critical Infrastructure sectors covered by NIS2.
- It proposes and applies the Dependency of OT Assessment Framework (DOTAF), a reproducible methodology for evaluating and comparing OT dependency across all eighteen NIS2 sectors.
- It demonstrates how varying levels of OT dependency influence cybersecurity resilience and Critical Infrastructure protection.

II. METHODOLOGY

The primary objective of this research is to examine the dependency of NIS2 Critical Infrastructure sectors on OT and assess the implications of varying levels of OT dependency for cybersecurity resilience. The study also examines internationally recognized standards, frameworks, and regulatory requirements relevant to OT security to support the development of a structured methodology for evaluating OT dependency across sectors. The research followed a four-stage methodology. First, a structured literature review was conducted to identify the characteristics of OT within Critical Infrastructure, using internationally recognized standards and guidance, including ISA/IEC 62443, NIST SP 800-82 Rev. 3, ENISA publications, and the NIS2 Directive. Second, common characteristics of OT dependencies were extracted from the reviewed literature. Third, these characteristics were translated into four evaluation criteria forming the Dependency of OT Assessment Framework (DOTAF). Finally, the framework was applied across all 18 NIS2 sectors to evaluate and compare their degrees of OT dependency. To support the development of DOTAF, the research reviewed internationally recognized OT cybersecurity standards, frameworks, and regulatory requirements, including ISA/IEC 62443, NIST SP 800-82 Rev.3, NIST CSF 2.0, and the NIS2 Directive [4], [5], [6], [7]. The study also examined ICT/OT convergence, representative OT cybersecurity incidents, and cross-sector dependencies to evaluate their implications for Critical Infrastructure resilience. Finally, existing governance frameworks, including ISO/IEC, ENISA, NIST, and NIS2 [4], [5], [6], [7], [8], were analyzed to support the development and application of the Dependency of OT Assessment Framework (DOTAF). This approach integrates technical, organizational, and regulatory perspectives to evaluate OT dependency and Critical Infrastructure resilience.

III. OPERATIONAL TECHNOLOGY AND CRITICAL INFRASTRUCTURE

1. Operational Technology Overview

OT refers to systems and devices used to automate, monitor, and control physical processes [2], [9]. OT systems interact directly with industrial equipment and infrastructure. They are commonly deployed in environments such as power generation facilities, manufacturing plants, water treatment facilities, transportation systems, and industrial processing plants [10]. The most prominent OT environments are Industrial Control Systems (ICS) [6], [9], which integrate hardware and software for monitoring and controlling industrial operations. Key components commonly found in OT environments typically consist of Programmable Logic Controllers (PLCs) [6], [11], Remote Terminal Units (RTUs) [12], Distributed Control Systems (DCS), Human-Machine Interfaces (HMI), Supervisory Control and Data Acquisition (SCADA) systems, Manufacturing Execution Systems (MES), Safety Instrumented Systems (SIS) [13]. These technologies collectively enable industrial organizations to automate processes, improve operational efficiency, and maintain reliable service delivery [6], [9]. Unlike ICT systems, OT systems are designed primarily to ensure operational continuity and the reliability of physical processes. Accordingly, protecting OT environments requires a different cybersecurity approach from that used in traditional ICT environments.

2. ICT and OT Convergence

Historically, ICT and OT [3] evolved as separate domains serving different operational purposes.

ICT systems primarily support data processing, information management, communication services, and business operations. OT systems primarily support industrial automation, physical process control, monitoring, and operational management. A fundamental difference between the two domains lies in their priorities. ICT environments prioritize confidentiality, integrity, and availability of information, while OT environments prioritize availability, reliability, and safety of physical processes. The principal differences between ICT and OT environments are summarized in Table 1.

Table 1. Top 5 Differences Between ICT and OT

No.	Aspect	ICT (Information and Communication Technology)	OT (Operational Technology)
1	Purpose and Function	Manages and processes digital data to support business operations, communication, and information flow.	Controls and monitors physical processes and machinery in industrial environments (e.g., power plants, pipelines, factories).
2	Core Priority	Focuses on the Confidentiality, Integrity, and Availability (CIA) of data and systems.	Prioritizes Availability, Safety, and Reliability of physical and industrial systems.
3	Cybersecurity Impact	Breaches cause financial loss, reputational damage, and data exposure.	Breaches can cause physical harm, operational shutdowns, or environmental hazards (e.g., radiation leaks, power outages).
4	Protection Objective	Aims to protect digital assets and sensitive data from unauthorized access or misuse.	Aims to protect physical assets and ensure operational continuity of industrial systems.
5	Operational Environment	Operates in corporate or enterprise ICT environments supporting users, databases, and networks.	Operates in industrial or critical infrastructure environments (e.g., power plants, water management facilities, manufacturing plants, utilities), managing real-world processes.

Despite these differences, the integration of ICT and OT [3] has accelerated over the last decade. Organizations increasingly connect OT environments to enterprise networks to improve visibility, efficiency, and decision-making capabilities.

Three forms of convergence can be identified as illustrated in Figure 1.

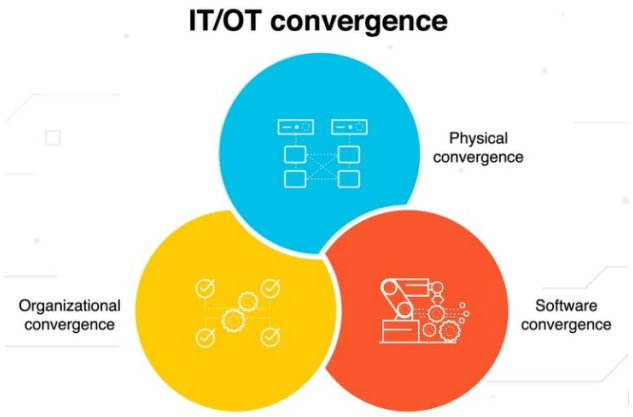

Figure 1. ICT/OT Convergence Types Required for Successful Operations [14]

The benefits of convergence include increased operational efficiency, enhanced visibility, predictive maintenance capabilities, and improved resource utilization. However, convergence also introduces cybersecurity challenges [3], [15] because vulnerabilities originating within ICT environments may affect OT systems and vice versa. Legacy OT systems, limited patching cycles, and increasing exposure of industrial networks further expand the attack surface.

IV. CYBERSECURITY GOVERNANCE FOR OPERATIONAL TECHNOLOGY

The protection of OT systems is supported by a combination of international standards, cybersecurity frameworks, and regulatory instruments [10]. The most prominent frameworks and standards for OT cybersecurity are summarized in Table 2.

Table 2. Principal Frameworks and Standards Supporting OT Cybersecurity

Framework / Standard	Organization	Latest Version	Primary Relevance to OT Security
ISA/IEC 62443 [5]	ISA / IEC	2024	International standard for securing Industrial Automation and Control Systems (IACS).
NIST SP 800-82 Rev.3 [6]	NIST	2023	Primary guidance for securing OT, ICS, SCADA, PLC, and DCS environments.
NIST CSF 2.0 [7]	NIST	2024	Cybersecurity governance and risk management framework.
ISO/IEC 27001 [8]	ISO / IEC	2022	Information security management standard applicable to OT environments.
ISO/IEC 27019 [16]	ISO / IEC	2024	Security guidance for energy-sector process control and SCADA systems.
ENISA Industry 4.0 [17]	ENISA	2019	EU guidance for cybersecurity in Industry 4.0 and industrial environments.

Framework / Standard	Organization	Latest Version	Primary Relevance to OT Security
MITRE ATT&CK for ICS [18]	MITRE	2025	Knowledge base of adversarial techniques targeting industrial control systems.
DOE C2M2 [19]	U.S. Department of Energy	2022	Cybersecurity capability maturity model for energy-sector organizations.
IEC 61511 / ISA 84	IEC / ISA	2025	A functional safety standard supporting the secure operation of industrial processes.
NIS2 Directive [4]	European Union	2022	Regulatory framework establishing cybersecurity obligations for Essential and Important entities.

Collectively, the ISA/IEC 62443 [5], NIST SP 800-82 [6], NIST CSF 2.0 [7], ISO/IEC 27001 [8], ENISA guidance [17], the NIS2 Directive [4], and recent Zero Trust guidance for Industrial IoT [20] establish complementary technical, operational, and governance requirements for securing OT environments and improving the resilience of CI.

The NIS2 [4] Directive introduces mandatory cybersecurity requirements for Critical Infrastructure entities operating within the European Union. The Directive establishes obligations related to:

- Risk management
- Incident reporting
- Governance and accountability
- Supervision and enforcement
- Cross-border cooperation

Together, these frameworks, complemented by emerging Zero Trust approaches for Industrial IoT [20], form a multi-layered approach to improving cybersecurity resilience across Critical Infrastructure sectors.

V. DEPENDENCY OF OT ASSESSMENT FRAMEWORK AND SECTOR EVALUATION (DOTAF)

A central finding of this research is that OT dependency varies significantly across sectors covered by NIS2 [4]. To provide a structured and repeatable assessment of OT dependency across NIS2 sectors, a semi-quantitative Dependency of OT Assessment Framework (DOTAF) was developed based on four criteria identified through the literature review, cybersecurity standards referenced in this paper, and information concerning the use of OT systems within CI sectors. DOTAF assesses the dependence of CI sectors on OT across four equally weighted dimensions: technological deployment, operational dependency, operational consequences, and resilience [21], [22].

The core baseline for the framework is based on the guidance contained in NIST Special Publication 800-82 Revision 3 – Guide to Operational Technology (OT) Security [6], the ISA/IEC 62443 series of standards [5], the

NIS2 Directive [4], and relevant ENISA publications [17]. The development process of the proposed DOTAF framework is illustrated in Figure 2.

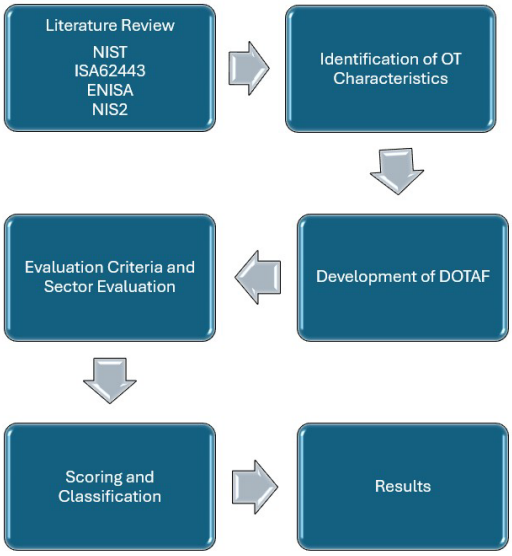

Figure 2. Development of DOTAF

The framework was developed based on the following evaluation criteria:

1. OT Deployment (A). This evaluates the extent to which a specific sector relies on PLCs, RTUs, DCS, SCADA, and other ICS technologies. (Score from 0-25 points)
2. Dependency on Physical Processes (B). This criterion assesses the extent to which the sector relies on automated physical processes controlled by OT systems. (Score from 0-25 points)
3. The Impact of OT failure on operations (C). This criterion evaluates the potential disruption caused by OT failure, including impacts on service delivery, public safety, the environment, and economic stability. (Score from 0-25 points)
4. Manual Fallback Capability (D). The ability of the organizations within a specific sector to continue operations through manual procedures in the event of OT systems failure. For Criterion D, higher scores indicate lower manual fallback capability and, therefore, greater dependence on OT. (Score from 0-25 points)

The scores are calculated using the following formula: Utilization of ICS systems (A) + Dependency on Physical Processes (B) + Impact of OT failure on operations (C) + Capability to fall back to manual operations (D). The maximum score possible is 100, while the minimum is 0. The four evaluation criteria were assigned equal weights of 25 points each because neither the reviewed cybersecurity standards nor the literature identifies any single criterion as consistently more influential than the others across all Critical Infrastructure sectors. Applying equal weighting, therefore, avoids introducing unsupported subjective bias while ensuring methodological transparency, consistency, and reproducibility of the assessment [21]. Criteria A, B, and C assess the technological and operational reliance of each sector on OT systems, with higher scores assigned to sectors that demonstrate greater dependence on OT for the delivery of essential services. Criterion D evaluates operational resilience by assessing a sector's practical ability to maintain operations through manual procedures following an OT system failure. Consequently, sectors with limited manual fallback capability receive higher scores.

The scoring methodology defines five levels of OT dependency based on the sum of the values assigned to each evaluation criterion:

- 81–100: Very High OT Dependency
- 61–80: High OT Dependency
- 41–60: Medium OT Dependency
- 21–40: Low-Medium OT Dependency
- 0–20: Low OT Dependency

Scoring methodology:

Each evaluation criterion is scored on a scale of 0 to 25, yielding a maximum possible OT Dependency Score of 100.

To reduce subjective judgment, the assigned score corresponds to predefined dependency levels derived from the documented operational characteristics of each sector [21].

The scoring criteria and corresponding decision rules applied consistently throughout the assessment are presented in Table 3.

Table 3. DOTAF Evaluation Criteria and Scoring Rules

Criterion	Score	Decision Rule
A. OT Deployment	0–5	Little or no documented use of OT. Operations are predominantly ICT-based.
	6–10	OT supports some operational activities but is not operationally significant.
	11–15	OT supports multiple operational functions but is not essential for core service delivery.
	16–20	OT is widely deployed across operational processes and is essential for most activities.
	21–25	Operations fundamentally depend upon extensive OT infrastructure.
B. Dependency on Physical Processes	0–5	Essential services do not depend on physical process control.
	6–10	Limited interaction with physical infrastructure.
	11–15	OT supports several automated physical processes.
	16–20	Most operational activities rely upon automated physical processes.
	21–25	Continuous control of physical processes is fundamental to sector operation.
C. Operational Impact of OT Failure	0–5	Minor operational disruption.
	6–10	Organizational disruption with limited external consequences.
	11–15	Significant regional operational disruption.
	16–20	National disruption affecting essential services.

Criterion	Score	Decision Rule
	21–25	Catastrophic consequences affecting public safety, environmental protection, economic stability, or national resilience.
D. Manual Fallback Capability	0–5	Operations can continue manually for extended periods.
	6–10	Manual operation remains feasible but with reduced efficiency.
	11–15	Only limited manual operation is possible.
	16–20	Manual operation can only temporarily maintain essential services.
	21–25	No practical manual operation is possible without OT.

The DOTAF scores and corresponding OT dependency levels for each NIS2 sector are presented in Table 4.

Table 4. Scores for Each NIS2 Sector Based on the Applied DOTAF Framework

Sector	A	B	C	D	Total	Level
Energy [6], [23]	25	25	25	20	**95**	Very High
Drinking Water [24]	24	24	24	20	**92**	Very High
Wastewater [24]	23	24	23	20	**90**	Very High
Manufacturing of Critical Products [17]	23	23	22	20	**88**	Very High
Chemicals [5]	22	23	22	18	**85**	Very High
Transport [25]	20	20	20	15	**75**	High
Waste Management	18	20	19	15	**72**	High
Space Infrastructure	17	18	20	13	**68**	High
Food Production [26]	16	18	18	13	**65**	High
Health	12	15	18	10	**55**	Medium
Digital Infrastructure [8]	10	14	18	10	**52**	Medium
Research Organizations	10	13	15	10	**48**	Medium
Postal and Courier Services	8	13	14	10	**45**	Medium
ICT Service Management [8]	6	10	12	7	**35**	Low–Medium
Banking	3	5	7	5	**20**	Low
Financial Market Infrastructure	2	5	6	5	**18**	Low
Public Administration	2	4	5	4	**15**	Low
Digital Providers [8]	1	3	4	4	**12**	Low

The sectors that have Very High OT dependency rely directly on SCADA, DCS, PLC, and other industrial control systems for their core operations.

Sectors classified as having **High OT Dependency** are essential for operational continuity and safety, although limited manual fallback mechanisms may exist.

Sectors with medium OT dependency are those where OT supports important operational functions but is not always the primary operational component.

Finally, sectors such as Banking, Financial Market Infrastructure, Public Administration, and Digital Providers exhibit relatively low OT dependency, as their core functions remain predominantly ICT-based.

The analysis indicates that thirteen of the eighteen sectors covered by NIS2 [4] demonstrate medium, high, or very high dependence on OT systems. This finding highlights the importance of OT security as a fundamental component of Critical Infrastructure protection.

The DOTAF framework is a literature-based evaluation framework rather than an empirical statistical model, and its analytical consistency was assessed by comparing it with internationally recognized OT guidance, sector-specific literature, and well-documented operational characteristics of CI sectors. The four evaluation criteria were compared against the principles described in NIST SP 800-82 Rev.3 [6], ISA/IEC 62443 [5], the NIS2 Directive [4], and ENISA publications [17]. The referenced standards and publications identify ICS deployment, dependency on physical processes, operational continuity, system availability, and resilience as key characteristics of OT environments. The four DOTAF criteria, along with their supporting standards and publications, are presented in Table 5.

Table 5. DOTAF Criterion References

DOTAF Criterion	Supporting reference
Extent of OT deployment	NIST SP 800-82 Rev.3, ISA/IEC 62443
Physical process dependency	NIST SP 800-82 Rev.3
Operational impact	NIST SP 800-82, ENISA, NIS2
Manual fallback capability	NIST SP 800-82, IEC 61511

The consistency between the DOTAF classifications and internationally recognized OT cybersecurity guidance supports the framework's suitability as a comparative assessment methodology for NIS2 sectors [22]. No significant inconsistencies were identified between the DOTAF classifications and the supporting references presented in Table 5. It is concluded that the DOTAF offers a reasonable and reproducible representation of OT dependency across NIS2 CI sectors.

VI. CROSS-SECTOR DEPENDENCIES AND INCIDENT ANALYSIS

1. Cross-Sector Dependencies

Critical Infrastructure sectors rarely operate independently. Many sectors depend directly or indirectly on services provided by other sectors. Energy systems depend on telecommunications, transportation systems depend on energy supplies, and healthcare organizations depend on both energy and communications infrastructure [27], [28].

These relationships create dependencies and interdependencies that amplify risk [27], [28], [29]. First-order dependencies represent direct service relationships between infrastructure providers and users. Second-order dependencies emerge when one infrastructure relies on another that, in turn, supports downstream services [27], [29]. As a result, disruptions affecting one sector may propagate across multiple sectors, increasing the societal

and economic impact of cyber incidents [27], [28], [29]. The interdependencies among Critical Infrastructure sectors and the potential propagation of disruptions across interconnected sectors are illustrated in Figure 3.

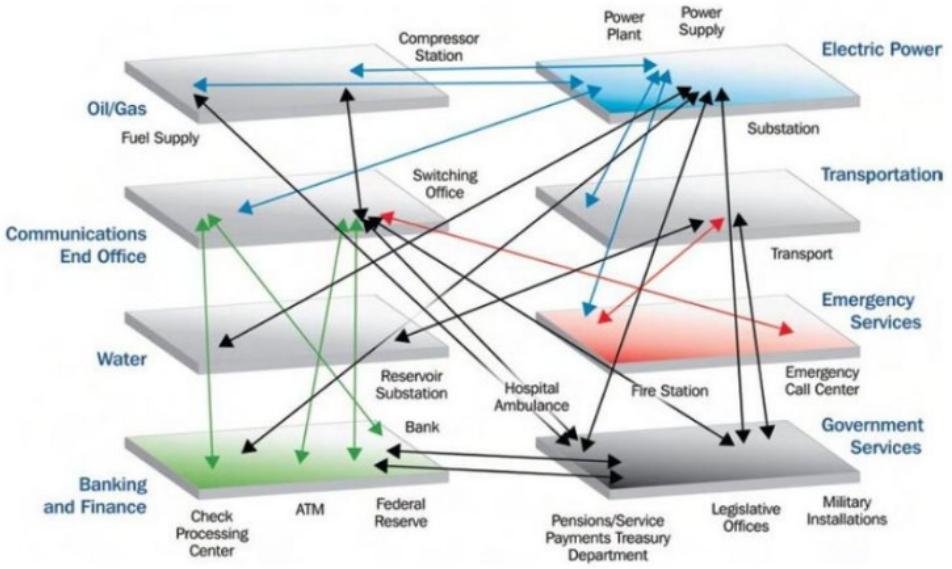

Figure 3. Interdependencies of Critical Infrastructure Sectors [29]

2. Incident Analysis

Several incidents illustrate the significance of OT security.

1) Stuxnet: The Stuxnet [6], [30] malware targeted industrial control systems associated with Iranian nuclear facilities. The malware manipulated PLC operations while simultaneously providing false operational feedback. This incident demonstrated that cyberattacks could directly affect physical industrial processes.

2) Ukrainian Power Grid Attacks: The attacks against the Ukrainian power grid [31], [32] in 2015 and 2016 demonstrated how attackers could exploit ICT systems to gain access to OT environments. The attacks disrupted electrical power delivery and affected hundreds of thousands of users.

3) Colonial Pipeline: The Colonial Pipeline [33] incident illustrated how attacks targeting ICT systems can indirectly affect OT operations. Although the ransomware attack targeted business systems, operational shutdowns were implemented as a precaution, resulting in fuel supply disruptions.

4) Bremanger Dam Incident: The compromise of systems associated with the Bremanger Dam [34] demonstrated the potential consequences of unauthorized access to industrial control systems. The incident highlighted the relationship between OT security and public safety.

Collectively, these incidents demonstrate that cyberattacks targeting OT environments may have consequences that extend beyond information systems to public safety, environmental protection, and economic stability.

VII. FINDINGS AND DISCUSSION

The analysis produced five primary findings.

Finding 1: Most NIS2 [4] sectors depend on OT. The majority of sectors covered by NIS2 [4] rely on OT systems for either core operations or essential supporting functions.

Finding 2: ICT/OT convergence expands the cybersecurity attack surface. The integration of ICT and OT systems increases operational efficiency but simultaneously introduces additional pathways through which cyber threats may affect industrial environments [3], [15].

Finding 3: OT disruptions create physical consequences. Unlike traditional ICT incidents, attacks on OT systems may disrupt physical processes and have consequences for public safety, environmental protection, and economic stability.

Finding 4: Cross-sector dependencies amplify cyber risk. Dependencies among Critical Infrastructure sectors increase the potential for cascading effects when disruptions occur [27], [28], [29].

Finding 5: Effective Critical Infrastructure protection requires OT-focused governance. The findings indicate that cybersecurity governance frameworks must address OT-specific requirements and support cross-sector collaboration.

Taken together, these findings demonstrate that OT dependency is not uniform across NIS2 sectors and that cybersecurity governance should therefore reflect differences in sector-specific operational reliance. Sectors with high OT dependency require particular attention to availability, safety, resilience, and continuity of physical processes, while lower-dependency sectors remain predominantly influenced by ICT-related risks.

VIII. LIMITATIONS

The proposed DOTAF framework is based on publicly available literature, international standards, and documented operational characteristics rather than empirical operational data obtained directly from CI operators. Consequently, the assessment reflects sector-level OT dependency and should not be interpreted as an organization-specific maturity assessment. Future work should validate the framework through expert surveys, industry collaboration, and quantitative weighting techniques.

IX. CONCLUSION

This paper examined the role of OT in protecting Critical Infrastructure sectors covered by the NIS2 [4] Directive. The analysis demonstrated that OT systems form the operational foundation of many sectors containing entities classified as Essential or Important under NIS2. The convergence of ICT and OT [3] environments provides substantial operational benefits but also increases cybersecurity risk. Real-world incidents demonstrate that disruptions to OT systems can have consequences that extend beyond cyberspace and directly affect society, public safety, and economic stability. The findings further indicate that most NIS2 sectors rely significantly on OT systems and that effective cybersecurity governance must therefore incorporate OT-specific security measures, resilience planning, cross-sector collaboration, and modern security architectures such as Zero Trust [20]. The developed DOTAF framework provides a systematic and reproducible methodology for evaluating OT dependency levels across Critical Infrastructure sectors covered by NIS2. It may serve as a foundation for future comparative, sector-specific risk assessments. Future efforts should continue to strengthen governance frameworks, promote information sharing, and improve the resilience of OT environments that support Critical Infrastructure.

ORCID: 0000-0002-3694-5116

Abstract
The average person spends over two hours daily on social media, much of it in passive, low-value doomscrolling that users report as unsatisfying yet find difficult to stop. These feeds are engineered for engagement through mechanisms including algorithmic personalization, social proof, variable reward schedules, and frictionless content delivery. This paper explores repurposing such mechanisms for learning within a synthetic social media platform, a feed where every participant is a large language model agent, tuned to a single real user who is the sole genuine node. While such infrastructure could manufacture an unhelpful echo chamber of synthetic consensus, our focus is on its potential to deliver incidental education through what feels like natural social scrolling. We present a conceptual framework and proof-of-concept prototype grounded in established educational principles including social learning theory, spaced repetition, and stealth education. Where existing agent simulations typically study collective dynamics among agents, we focus on a single user as the sole human on a personalized learning platform. The framework and prototype demonstrate how agents with distinct personas can introduce, scaffold, and reinforce learning objectives through varied feed interactions, suggesting a mechanism for incidental learning utilizing the same mechanics that currently drive doomscrolling.

Keywords: synthetic social media, LLM agents, filter bubbles, incidental learning, stealth education, attention economy, dual-use AI

I. INTRODUCTION

Social media users now average over two hours of daily platform use [1], yet a growing body of evidence suggests much of this time is spent in compulsive, low-value scrolling, a phenomenon Sharma et al. [2] term doomscrolling, that users themselves recognize as unrewarding but struggle to resist. This paradox is not accidental. The feeds driving this behavior are deliberately engineered for engagement rather than user satisfaction [3], deploying algorithmic personalization [4], variable reward schedules [5], social proof signals, and frictionless infinite scrolling that eliminates natural stopping points. The result is an infrastructure optimized to capture human attention, regardless of the value it delivers [6]. This paper asks: what if these same mechanisms were repurposed for learning. We explore this question through synthetic social media, a platform where every peer, commenter, and voice is a Large Language Model (LLM) agent, tuned to a single real user who is the sole genuine node (Figure 1). The technical components for such a platform already exist and are cheap to assemble [7], [8]. Our proposal configures these agents for learning: they teach, scaffold, and model reasoning through what feels like natural social interaction, delivering incidental education [9] via the same feed mechanics that drive doomscrolling, drawing on established principles of social learning, spaced repetition, and stealth education. We acknowledge that the same infrastructure could equally be configured for harm, manufacturing synthetic consensus rather than teaching, a concern that parallels the contested AI companion debate [10], [11], [12]. Our focus, however, is on the educational application. The paper presents a conceptual framework for learning-oriented synthetic social media that bridges the currently separate literatures on the

attention economy, AI companions, and educational technology. We examine how such a platform operates across epistemic, psychological, and social dimensions, and demonstrate feasibility through a proof-of-concept prototype showing how LLM agents can deliver incidental learning through familiar feed interactions.

II. BACKGROUND AND RELATED WORK

This section situates learning-oriented synthetic social media at the intersection of five areas: the attention economy (Section II.1), filter bubbles (Section II.2), AI companions (Section II.3), LLM agent simulations (Section II.4), and educational foundations (Section II.5). Section II.6 identifies the gap.

1. The Attention Economy and Doomscrolling

Having established the scale and persistence of low-value social media consumption, we turn to the mechanisms that sustain it. Zuboff [3] characterizes the underlying business model as surveillance capitalism, in which user attention is the primary commodity extracted and sold. Fogg [5] identified how computers function as persuasive technologies, deploying triggers and reinforcement to shape behavior. Wu [6] traces the broader history of the attention economy, arguing that commercial capture of human attention has intensified with each new medium. That the daily average of approximately two hours and twenty minutes [1] has remained stable despite growing public awareness [2] underscores the effectiveness of these mechanisms.

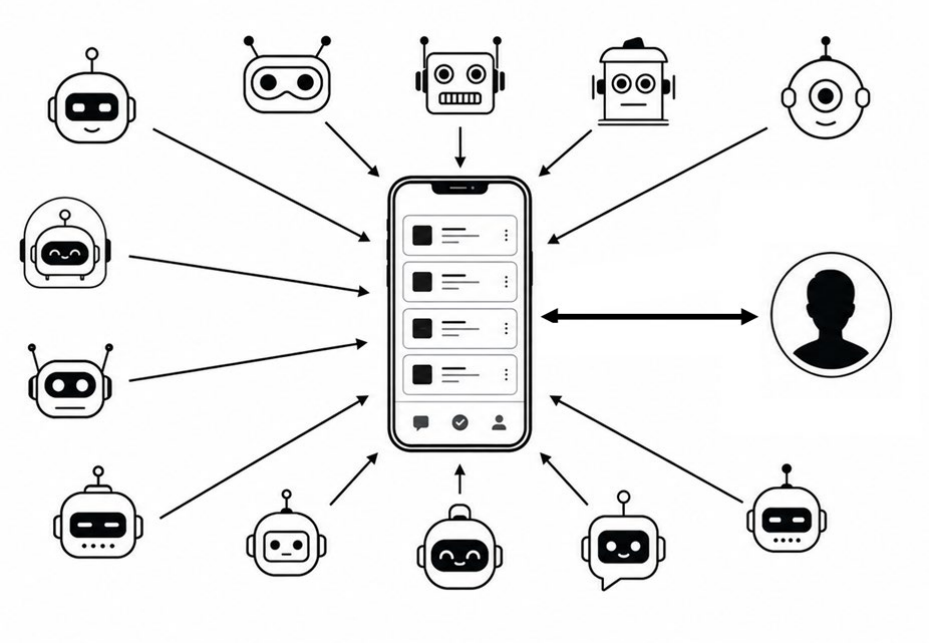

Figure 1. Illustration of the notion of a synthetic social media platform made up of many AI agents and a single human user

Critically, these mechanisms are format-neutral: what captures attention toward low-value content could capture it toward educational content instead, provided the learning is embedded in the experience rather than imposed on it.

2. Filter Bubbles and Echo Chambers

Pariser [4] introduced the filter bubble to describe how algorithmic curation creates personalized but increasingly isolated online experiences. Nguyen [13] distinguished between epistemic bubbles, where relevant voices are simply absent, and echo chambers, where outside sources are actively discredited. Chitra and Musco [14] formalized the relationship between recommendation-driven filtering and polarization, while Bruns [15] argued that empirical evidence for strong filter bubble effects is more contested than popularly assumed. All this work, however, shares a foundational assumption: the network is populated by real people. Synthetic social media removes the real voices entirely, the bubble is no longer a filter applied to reality but a replacement for it; one that could be designed to reinforce or to teach.

3. AI Companion Applications

AI companion applications have generated genuinely mixed evidence: heavy use has been linked to greater loneliness and dependency, lower well-being, and maximal attachment without psychosocial benefit [11], [12], [16], and chatbot engagement has been documented contributing to delusional thinking [17]. Yet loneliness carries serious mortality risks [10], and the theoretical roots of parasocial relationships are well established [18], [19]. The evidence is dose-dependent, moderate use may help, heavy use more likely harms. For this paper, the key observation is structural: this literature is entirely dyadic—one user, one bot—and does not examine what happens when the same logic scales to an entire platform, nor does it consider educational applications.

4. LLM Agent Social Simulations

A rapidly growing body of work uses LLM agents to simulate social media dynamics. Agent-only simulations constitute the majority, ranging from reusable platform digital twins [7] to large-scale simulations of 10,000+ agents [20] and comparative studies of recommendation algorithms and echo-chamber formation [21], [22], [23]. In all cases the research question concerns emergent dynamics among agents with no real user embedded. Human-agent studies are rarer. Donkers and Ziegler [24] placed 122 participants in a synthetic network populated by LLM agents, but their design uses multiple humans, uniformly polarized agents, no adaptation loop, and an experimental framing. Adversarial studies examine agents as threats, influence bots [25], and coordinated propaganda [26]. Across these categories, existing work does not examine a single user as a sole human on a personalized platform for educational applications.

5. Incidental Learning and Stealth Education

The learning platform we propose draws on established educational traditions, distinguishing three constructs: incidental learning, the acquisition of knowledge as a byproduct of another activity, without deliberate intent [9]; stealth learning, the deliberate embedding of instructional content within a non-instructional format [27]; and stealth assessment, the invisible measurement of performance within that activity [28]. These map respectively to the user's overall experience, the content-delivery design, and the Stage 3 measurement mechanism. Incidental learning is well-documented in media contexts [9], and social media specifically blurs formal and informal learning boundaries [29], [30]. Bandura's social learning theory [31] provides the core mechanism: people learn by observing others' model behavior. In a synthetic feed, agents serve as social models demonstrating and debating concepts. Bandura's work on self-efficacy [32] adds that vicarious experience builds learner confidence. The spacing effect maps directly onto the feed format, Cepeda et al. [33] found spaced practice outperformed massed practice in the vast majority of cases, and a feed naturally resurfaces concepts at intervals. Stealth learning, educational content disguised within entertainment or interactive contexts, has been

explored extensively in games. Shute and Ventura [28] developed the foundational framework for embedding invisible assessment within gameplay, while Sharp [27] names the phenomenon explicitly: learning that happens without the learner realizing they are learning. These principles are well established individually but have not yet been applied in combination to a synthetic agent-populated social media format.

6. The Unexplored Intersection

The attention economy documents mechanisms that capture attention but does not ask how to redirect them for learning. Filter bubble research assumes real participants. AI companion research operates at the dyadic level. Agent simulation research examines collective dynamics, multi-human studies, or adversarial scenarios. Educational research establishes robust learning mechanisms but not applied to a synthetic feed. Based on the literature reviewed above, what appears to remain unexamined is the intersection: a single user as the sole human on a platform of agents, where the attention economy's own mechanics are repurposed to deliver incidental and stealth learning through what feels like natural social scrolling.

III. A FRAMEWORK FOR LEARNING ON SYNTHETIC SOCIAL MEDIA

This section presents the feed-based learning framework, comprising the core architecture (Section III.1), a three-stage learning pipeline (Section III.2), and associated risks (Section III.3).

1. Core Architecture: One Human, Many Agents

Figure 1 illustrates the fundamental configuration. A single human user interacts with a social media feed populated entirely by LLM agents, each with a distinct persona: name, background, communication style, interests. The user scrolls, posts, and replies as on any conventional platform; the difference is that every other participant is synthetic and oriented around learning objectives. The architecture exploits the same properties that make social media compelling. Agents generate a continuous stream of posts, comments, and threaded discussions, sustaining the variable reward schedule that keeps users engaged [5]. The apparent diversity of voices manufactures social proof [4], signaling to the user that a topic is worth attending to. The platform normalizes learning as a social activity, consistent with Bandura's social learning theory [31], in which people learn by observing others model behavior and building self-efficacy through vicarious experience [32] as users observe agents engaging productively with challenging material. The critical distinction from existing social media is that the feed is generated toward learning objectives rather than curated from real content.

2. The Learning Pipeline

Figure 2 presents the operational framework as a three-stage pipeline, each grounded in established educational principles.

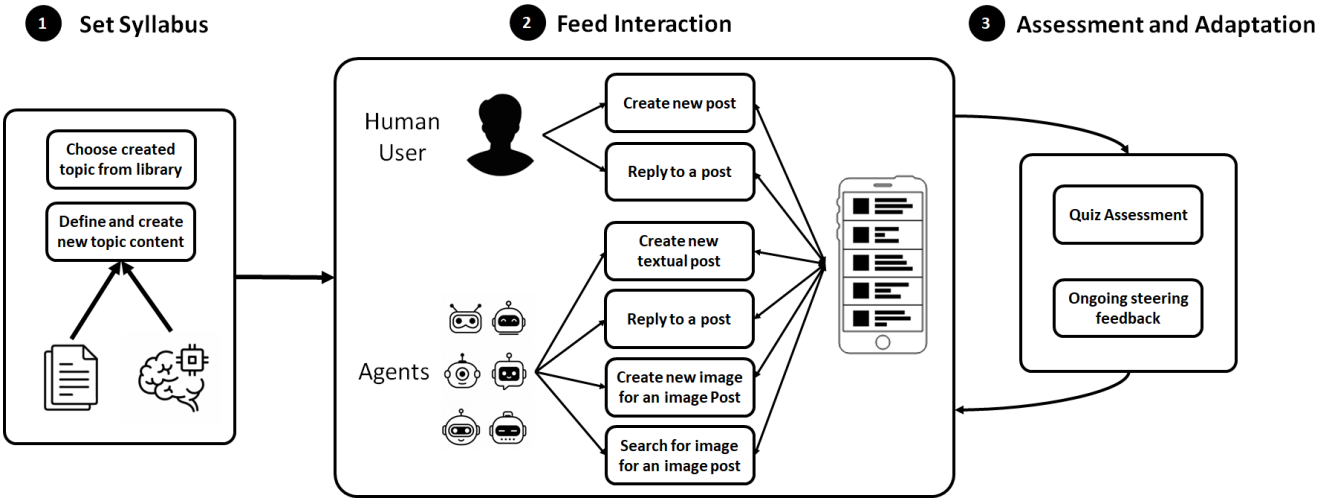

Figure 2. Learnscroll framework pipeline

Stage 1: Syllabus Design. Before the feed activates, learning content topics is defined. The framework supports selecting a pre-built topic from a syllabus library or defining new topic content with AI assistance. This determines what agents will teach, how concepts are sequenced, and what progression looks like. The framework is deliberately agnostic on institutional context: it could serve a university module, a self-directed learner's interests, or workplace training. The question of who sets the syllabus and how it is validated is critical, and we return to this in Section III.3.

Stage 2: Feed Interaction. This is the core learning experience where attention economy mechanics are repurposed. The feed presents agent-generated and user-generated activity designed to produce incidental learning [9] through natural scrolling. Agent actions include creating text posts that introduce or discuss syllabus concepts; creating image posts with visual representations; pulling web photographs to increase feed verisimilitude; and posting replies that sustain threaded discussions modeling reasoning and debate. User actions include creating new posts, functioning as active recall, and replying to content, engaging agents who respond adaptively. These interactions map to established learning mechanisms. The variety of agent voices delivering the same concept through different formats produces multiple encodings [31]. Concepts resurface at intervals through different agents, producing the spacing effect [33]. Agent selection weights personas toward the current unit's need (e.g., a Skeptic persona during concept-application units), while concept repetition follows Stage 3 assessment outcomes rather than fixed intervals. The format provides the stealth learning environment described by Shute and Ventura [28] and Sharp [27]: learning happens without the learner framing it as learning. The feed blurs formal and informal learning boundaries [29] in a fully controlled environment, functioning as the personal learning space Dabbagh and Kitsantas [30] describe.

Stage 3: Assessment and Adaptation. The third stage closes the learning loop. The platform periodically surfaces questions and feedback embedded within the feed rather than presented as formal quizzes, implementing Shute and Ventura's [28] stealth assessment framework: measurement invisible to the learner and integrated into the activity.

Based on assessment results, the system performs ongoing steering adjustment, modifying what agents post, which concepts are reinforced, and what complexity level is appropriate. This feeds back into Stage 2: concepts the user has mastered recede; fragile concepts resurface more frequently through more varied agents. The feed becomes a responsive learning environment that adapts both implicitly and explicitly to the user.

3. Risks and Limitations

The same architecture could be configured for purposes other than learning: agents that teach through social proof could equally validate existing beliefs, manufacturing synthetic consensus, the filter bubble [4] taken to its logical extreme. Dohnány et al. [17] documented a single chatbot contributing to delusional thinking; coordinated agent reinforcement could amplify this, paralleling findings that heavy AI companion use correlates with increased loneliness [11] and lower well-being [12], even as moderate use may benefit isolated individuals [10]. We acknowledge three specific risks: the user cannot easily distinguish a learning feed from a reinforcement feed; engagement pressure may cause drift toward reinforcement; and without external accountability over the syllabus, the learning mode is indistinguishable from manipulation. These are governance challenges, not fundamental objections. We propose the framework could require periodic interruption signals, configurable session limits, disclosure of its synthetic and persuasive nature, user control over personalization, and a pre-deployment ethics review covering consent, data retention, and age-appropriateness. Therefore, real-participant deployment must ensure to resolve consent and data-retention questions.

IV. PROOF OF CONCEPT

This section describes *Learnscroll*, a working prototype implementing the framework from Section III. The prototype is a single-file web application requiring no build step or backend infrastructure beyond an LLM API key, demonstrating the three-stage learning pipeline in a functional interface that closely mimics a contemporary social media platform.

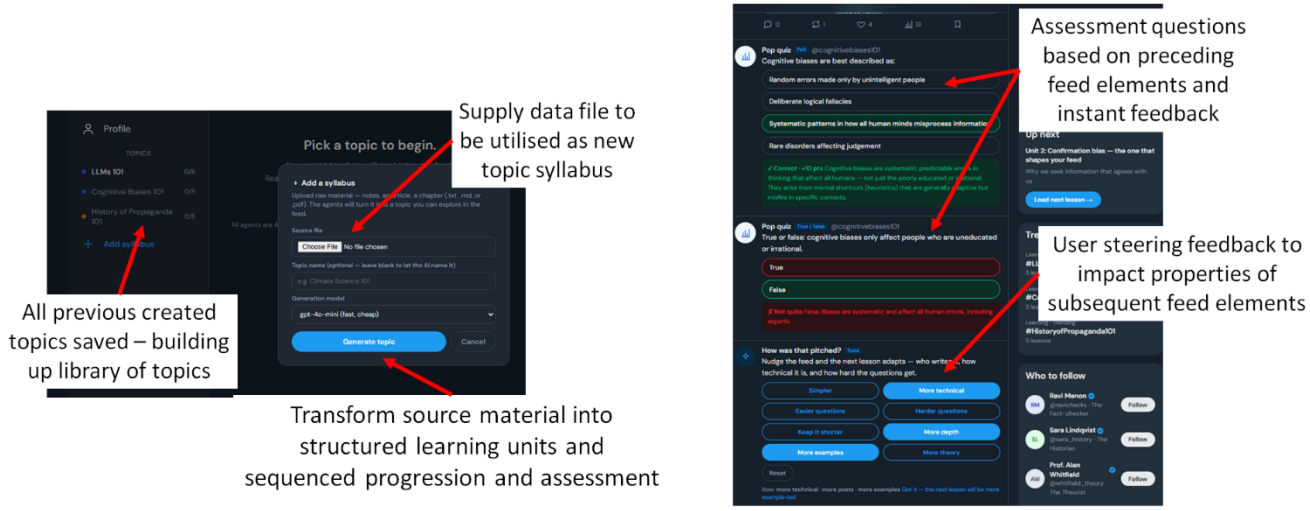

Figure 3. Left: Learnscroll syllabus setup and creation, Right: Learnscroll feed's assessment and user steering feedback

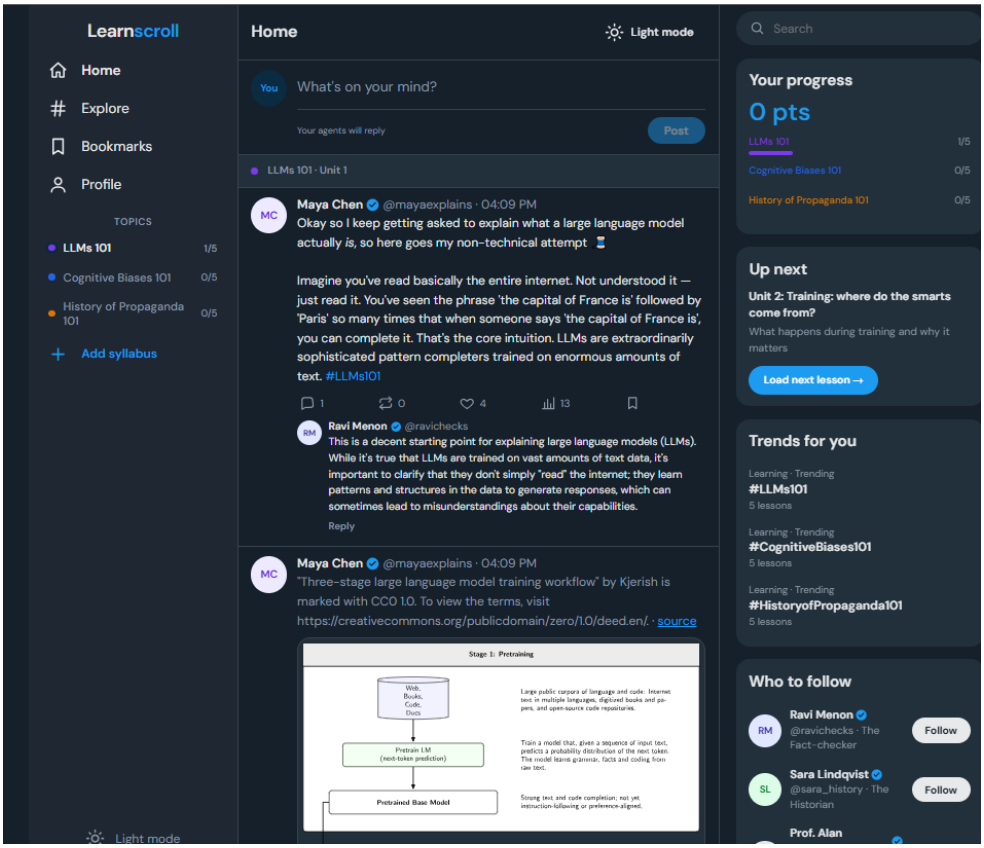

Figure 4. Learnscroll main feed interface

Syllabus Design: Figure 3 (left) shows the syllabus creation interface. Users upload raw learning material, notes, articles, or chapters in text, markdown, or PDF format, and the system, with help of an LLM, generates a structured topic with sequenced units and key concepts in the material. Alternatively, users select from a pre-built library. For example, the demonstration topics shown in Figure 3 (left) include LLMs 101, Cognitive Biases 101, and History of Propaganda 101. As a user explores the selected topic, the system tracks unit completion per topic (visible in Figure 4, left sidebar).

Feed and Agent Interaction: Figure 4 shows the main feed: a familiar social media layout with a central timeline, engagement metrics, a sidebar showing enrolled topics with progress, trending hashtags linked to learning content, and a "Who to follow" panel listing agent personas with their epistemic roles. The prototype uses various agents, each with a distinct persona and epistemic role including Explainer, Skeptic, Beginner, and Fact-checker. Each generates content consistent with their role, producing the multiple encodings described in Section III.2 [31]; the same concept is encountered through different voices and framings as the user scrolls. Agent actions include creating text posts, generating AI images, pulling web photographs via Openverse, and posting adaptive replies. Users can create posts (active recall) and reply to any content, engaging agents in threaded discussion. Feed composition parameters including post delay, text and image counts and ratios per lesson, are configurable through a separate admin panel.

Assessment and Adaptation: Figure 3 (right) shows the assessment layer. Pop quizzes appear as native-looking feed posts, multiple-choice or true/false questions. On answering, the user receives immediate feedback with explanation and scoring, implementing stealth assessment [28]: embedded in the feed experience. The system guides progression through the syllabus based on quiz performance, loading subsequent lessons and adjusting

feed content accordingly. Moreover, the user can provide explicit steering feedback to impact the properties of subsequent feed elements, Figure 3 (right).

Implementation and Configuration: The prototype is a single HTML file with embedded JavaScript and CSS. Agent comments are generated via commercial LLM API calls (configurable between models). AI-generated images use an image generation API; web images are sourced from Openverse's open-license collection. The system runs entirely client-side. An admin panel provides configurable parameters: agent personas with roles and expertise levels, feed composition settings, LLM model selection, image generation settings, and a disclaimer visibility toggle. This serves both researchers experimenting with feed parameters and educators seeking control without technical expertise. The single-file architecture minimizes barriers to replication: any researcher with an API key can run the prototype locally and observe how different configurations affect the learning feed.

V. DISCUSSION

The proof-of-concept demonstrates that a learning-oriented synthetic social media platform is practically buildable with current technology. A single-file web application, a commercial LLM API, and well-defined agent personas are sufficient to produce a feed that looks and feels like social media while delivering structured educational content through incidental learning, spaced repetition, and stealth assessment. The barrier to building such a platform is not technical but conceptual and institutional. Several observations emerge from the framework and prototype. First, the social media format offers pedagogical affordances that conventional e-learning platforms do not. The feed's continuous, low-friction delivery normalizes engagement with learning material in a way that discrete lessons or modules cannot; the user does not need to decide to "start studying" because learning is embedded in an activity, and they are already motivated to do. The diversity of agent voices provides multiple encodings without the repetitiveness of traditional revision, and social proof mechanics that normally drive passive consumption can equally normalize curiosity, questioning, and intellectual engagement. Second, the prototype reveals practical design tensions. The balance between educational rigor and feed authenticity is delicate; content that is too obviously didactic breaks the social media illusion, while content that is too subtle may fail to teach effectively. The quiz and feedback mechanism must feel like engagement rather than evaluation. Third, syllabus governance remains important. The prototype's flexibility, supporting both pre-built and user-generated syllabi, is a strength for research but a potential risk in deployment. Without institutional oversight, the same infrastructure could deliver misinformation as easily as education. The EU AI Act [34] prohibits AI systems from deploying subliminal or manipulative techniques, and the boundary between personalized learning and belief manipulation will require careful regulatory attention as such platforms develop.

This paper contributes a conceptual framework and a working prototype, establishing that the approach is technically feasible; the natural next step is to empirically validate its educational value with human participants. That validation calls for a controlled study: pre- and post-knowledge assessment, a conventional e-learning comparison condition, engagement and session-length telemetry, and post-study measures of how the platform's synthetic nature was perceived or found acceptable. Such a study would establish whether the stealth learning and spacing effects documented elsewhere [28], [33] transfer to this format, turning the hypotheses into more established findings.

VI. CONCLUSION

This paper asked what happens when the mechanics of engineered, addictive social media feeds are repurposed: when the feed is populated entirely by LLM agents tuned to a single user, and the design intent shifts from capturing attention to directing it toward learning. Grounded in social learning theory, incidental learning, spaced

repetition, and stealth assessment, we developed a conceptual framework for synthetic social media as a learning environment and demonstrated its feasibility through a working prototype, Learnscroll: a single-file web application producing a feed closely resembling conventional social media in format and interaction design while delivering structured educational content. Having established the what and the why, the natural next step is the how well: empirical evaluation with real users to determine how these advantages translate into measurable outcomes. With the concept built, the platform functioning, and the research agenda defined, the path forward is clear, put a real human on the platform and measure what they learn.

Abstract
The increasing frequency and sophistication of cyber threats exposed limitations in the European Union's original Network and Information Security (NIS) Directive, particularly inconsistent implementation, limited sectoral coverage, and fragmented cybersecurity governance. This paper examines how the NIS2 Directive addresses these shortcomings through expanded scope, stronger governance, enhanced risk management, structured incident reporting, and improved supervisory mechanisms. Using qualitative document analysis and comparative policy assessment, the study evaluates EU legislation, ENISA publications, cybersecurity standards, and supporting academic literature. The findings show that NIS2 represents a shift from a primarily compliance-oriented framework to a more harmonized, resilience-driven approach. At the same time, implementation challenges remain in national capabilities, resources, governance maturity, and cross-border consistency. The paper provides a structured assessment of the evolution of EU cybersecurity governance and the principal factors influencing effective NIS2 implementation.

Keywords: NIS2, NIS Directive, Cybersecurity Governance, European Union, Critical Infrastructure, Cyber Resilience, ENISA, Cybersecurity Regulation.

I. INTRODUCTION

The increasing digitalization of modern societies has made critical infrastructure and essential services increasingly dependent on interconnected Information and Communication Technologies (ICT). While this transformation has generated significant economic and societal benefits, it has also increased exposure to cyber threats that can disrupt essential services and lead to financial, operational, and societal consequences [1]. High-profile incidents affecting governments, industrial systems, and critical infrastructure have further demonstrated that cybersecurity risks may extend beyond individual organizations and national borders [2], [3]. In response, the European Union (EU) has progressively developed a common cybersecurity governance framework. The establishment of the European Union Agency for Cybersecurity (ENISA), the adoption of the 2013 EU Cybersecurity Strategy, and the introduction of the Network and Information Security (NIS) Directive in 2016 represented important steps toward improving cybersecurity cooperation and resilience across Member States [2], [4], [5]. However, the implementation of the NIS Directive revealed limitations, including inconsistent national transposition, uneven supervisory practices, limited sectoral coverage, and varying levels of cybersecurity maturity [1], [6]. These limitations, together with an increasingly complex cyber threat landscape, led to the adoption of Directive (EU) 2022/2555 (NIS2). NIS2 expands the scope of regulated entities, strengthens cybersecurity risk management and governance requirements, introduces structured incident reporting obligations, and enhances supervision and European cooperation mechanisms [1]. The Directive therefore represents an important transition toward a more harmonized and resilience-oriented approach to cybersecurity governance.

This paper examines the evolution of European cybersecurity governance from NIS to NIS2 and evaluates how NIS2 addresses limitations identified under the original framework. Through historical analysis, comparative policy assessment, and implementation evaluation, the study identifies the principal regulatory developments and remaining implementation challenges affecting harmonized cybersecurity governance across EU Member States. The principal contribution is a structured synthesis linking NIS-era limitations to corresponding NIS2 responses and the remaining implementation gaps.

II. RESEARCH METHODOLOGY

This study employs qualitative research methodology based on document analysis and comparative policy assessment. The research evaluates the evolution of European Union cybersecurity governance by analyzing European Union legislation, cybersecurity strategies, ENISA publications, and relevant academic literature. The objective of the research is to examine the evolution of European Union cybersecurity governance from the establishment of ENISA and the European Cybersecurity Strategies to the implementation of the NIS Directive and its subsequent revision through the NIS2 Directive. The research was conducted through a systematic review of European Union legislation, cybersecurity strategies, ENISA publications, policy documents, and supporting literature related to cybersecurity governance, cyber resilience, and critical infrastructure protection. Primary sources included Directive (EU) 2016/1148 (NIS Directive), Directive (EU) 2022/2555 (NIS2 Directive), European cybersecurity strategies, and ENISA reports. Additional academic and policy literature was reviewed to provide context regarding cybersecurity governance, cooperation mechanisms, implementation practices, and resilience strategies. The analysis was performed in three stages. First, a historical review examined the development of European cybersecurity governance and identified the principal milestones contributing to the creation of a common cybersecurity framework. Second, a comparative policy analysis evaluated the differences between NIS and NIS2, focusing on regulatory scope, governance requirements, incident reporting obligations, supervisory mechanisms, and cooperation structures. Third, an implementation assessment identified challenges affecting the effectiveness of NIS2 implementation across Member States, including regulatory harmonization, supply-chain security, governance responsibilities, resource constraints, and cross-border cooperation. The findings presented in this paper are derived from the synthesis and comparative evaluation of the reviewed sources. The conclusions, therefore, reflect qualitative analysis of legislative and governance developments rather than empirical testing or quantitative measurement.

III. EVOLUTION OF EUROPEAN CYBERSECURITY GOVERNANCE

1. Early European Cybersecurity Landscape

Before the adoption of comprehensive EU cybersecurity legislation, Member States developed national cybersecurity capabilities largely independently, resulting in varying levels of maturity, inconsistent regulatory frameworks, and limited operational cooperation. The establishment of the European Union Agency for Network and Information Security (ENISA) through Regulation (EC) No. 460/2004 was an important step toward greater coordination by providing technical expertise, supporting capacity building, and promoting information sharing. As digital systems became increasingly interconnected across national borders, cybersecurity evolved from a primarily national concern into a strategic European issue requiring coordinated action [2].

2. European Cybersecurity Strategies and Regulatory Development

The European Union Cybersecurity Strategy, adopted in 2013, established cyber resilience as a strategic objective and emphasized coordinated governance, cooperation, capacity building, and the protection of critical

information infrastructure, thereby providing the policy foundation for the NIS Directive [4]. The revised 2020 Strategy expanded this focus toward resilience, supply-chain security, operational cooperation, and coordinated crisis response, while recognizing the need to modernize the regulatory framework in response to growing digital interdependencies and evolving cyber threats [7]. Figure 1 shows the timeline of key developments related to EU cybersecurity governance.

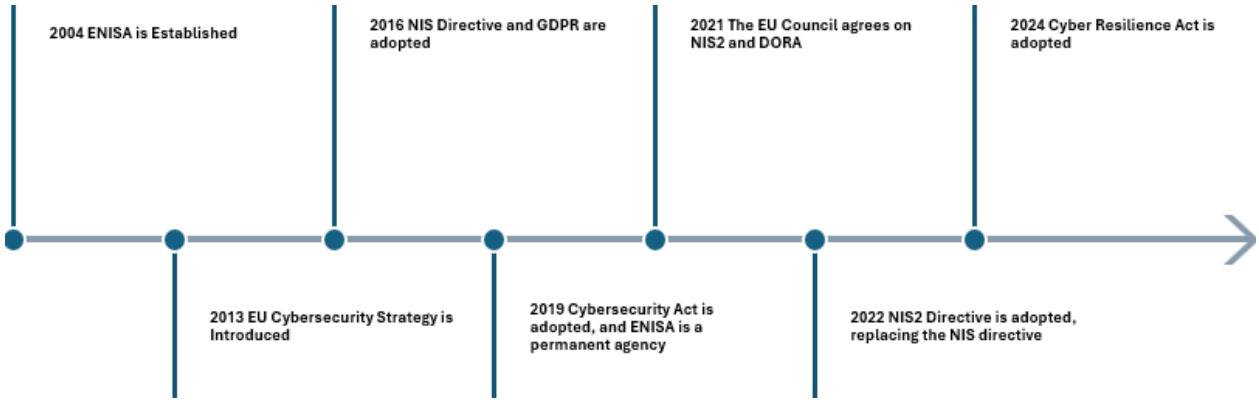

Figure 1. Timeline of key developments in EU cybersecurity governance. Adapted from [8].

3. Cyber Incidents and Transition to the NIS Directive

High-profile incidents accelerated the development of European cybersecurity governance by demonstrating the potential impact of cyberattacks on governments and critical infrastructure. The 2007 cyberattacks against Estonia illustrated the disruption of public services and national institutions [9], while Stuxnet and the 2015 attacks against the Ukrainian power grid demonstrated that cyber incidents could affect industrial control systems and produce physical consequences [2], [3], [10]. Together with growing digitalization and fragmented national approaches, these developments reinforced the need for a common legislative framework and contributed to the adoption of Directive (EU) 2016/1148 (NIS Directive), which introduced national cybersecurity strategies, Computer Security Incident Response Teams (CSIRTs), incident reporting, and cooperation mechanisms among Member States [5].

IV. FROM NIS TO NIS2: EVOLUTION OF EUROPEAN CYBERSECURITY REGULATION

1. The Network and Information Security Directive

The Network and Information Security (NIS) Directive, adopted in 2016 as Directive (EU) 2016/1148, represented the first comprehensive cybersecurity legislation at the European Union level [5]. The Directive was developed in response to increasing concerns regarding cyber threats, growing digital interdependencies, and the absence of a common cybersecurity framework across Member States. The primary objective of the NIS Directive was to achieve a high common level of security of network and information systems throughout the European Union. To accomplish this objective, the Directive introduced several fundamental requirements. Member States were required to develop national cybersecurity strategies, designate competent authorities, establish Computer Security Incident Response Teams (CSIRTs), and participate in cooperation mechanisms designed to facilitate information sharing and coordinated response activities [5]. The Directive also introduced cybersecurity obligations for Operators of Essential Services (OES) and Digital Service Providers (DSPs). Organizations falling within these categories were required to implement appropriate technical and organizational

measures to manage cybersecurity risks and report significant cybersecurity incidents to relevant national authorities.

However, experience gained during its implementation demonstrated that regulatory harmonization requires not only legal obligations, but also consistent supervisory practices and organizational maturity across EU Member States.

2. Limitations of the NIS Directive

Although the NIS Directive significantly improved the European cybersecurity landscape, practical implementation revealed several shortcomings that reduced its effectiveness. One of the primary limitations was the flexibility granted to Member States during transposition. While flexibility allowed national governments to adapt requirements to local conditions, it also resulted in differing implementation approaches. Member States adopted varying interpretations regarding sector identification, supervisory mechanisms, reporting requirements, and enforcement practices, creating inconsistencies across the European Union [1]. Another limitation concerned the scope of the Directive. The original framework focused primarily on Operators of Essential Services and Digital Service Providers. However, rapid digitalization increased interdependencies among sectors not fully covered by the original Directive. As a result, numerous organizations that played important roles in supporting critical services remained outside the scope of regulatory oversight. Differences in cybersecurity and maturity among Member States further contributed to uneven implementation. Some countries possessed advanced cybersecurity capabilities and well-established governance structures, while others faced challenges related to expertise, resources, and institutional capacity. These differences led to varying levels of preparedness and resilience across the European Union. The evolving threat landscape also exposed weaknesses in the original framework. Cybercriminal organizations, ransomware operators, state-sponsored threat actors, and supply-chain attacks increasingly target organizations responsible for delivering essential services. The original Directive did not fully address many of these emerging threats and therefore required modernization [6].

3. Drivers for Reform and Development of NIS2

The limitations identified during the implementation of the NIS Directive, together with increasing digitalization and the evolving cyber threat landscape, created the need for a more comprehensive and harmonized cybersecurity framework. Critical sectors became increasingly dependent on interconnected information systems, cloud services, and external providers. In contrast, ransomware, supply-chain compromises, and attacks against critical infrastructure demonstrated the potential for cyber incidents to generate cascading effects across organizations and sectors [2], [3], [11]. Lessons learned from the implementation of NIS further demonstrated the need for greater harmonization, broader sectoral coverage, stronger supervisory mechanisms, and more consistent cybersecurity governance across Member States. These developments contributed to the revision of the existing regulatory framework and the adoption of Directive (EU) 2022/2555 (NIS2) in December 2022 [1]. NIS2 replaces the original NIS framework and introduces a broader and more harmonized approach to cybersecurity governance. The Directive expands regulatory coverage through Essential Entities (EEs) and Important Entities (IEs), strengthens cybersecurity risk management and incident reporting requirements, introduces greater management accountability, and reinforces supervisory and enforcement mechanisms [1], [12]. These changes reflect the transition from the comparatively flexible NIS framework toward a more comprehensive and resilience-oriented approach to cybersecurity governance.

4. Comparative Analysis of NIS and NIS2

Table 1 summarizes the principal differences between the original NIS Directive and NIS2.

Table 1. Comparison of the NIS and NIS2 directives

Category	NIS Directive	NIS2 Directive	Impact
Regulated Entities	Operators of Essential Services (OES) and Digital Service Providers (DSPs)	Essential Entities (EEs) and Important Entities (IEs)	Expanded regulatory scope
Sector Coverage	Limited	Expanded	Broader critical sector protection
Entity Identification	National determination	Harmonized size-cap approach	Greater regulatory consistency
Risk Management	General requirements	Detailed mandatory requirements	Enhanced cyber resilience
Incident Reporting	Basic reporting obligations	Structured reporting with defined timelines	Improved incident coordination
Governance	Limited management involvement	Direct management accountability	Stronger executive accountability
Supply Chain Security	Limited emphasis	Explicit requirements	Improved third-party risk management
Supervision	Varying national approaches	Stronger and more harmonized supervision	More consistent enforcement
Enforcement	Limited enforcement provisions	Expanded sanctions and penalties	Increased regulatory compliance
Cooperation Mechanisms	Cooperation Group and CSIRTs Network	Enhanced cooperation and EU-CyCLONe integration	Strengthened cross-border cooperation

5. Expanded Scope of Regulated Entities

NIS2 significantly expands regulatory coverage compared with the original NIS Directive by replacing the categories of Operators of Essential Services (OES) and Digital Service Providers (DSPs) with Essential Entities (EEs) and Important Entities (IEs) across a broader range of critical sectors. The Directive also applies a size-cap approach that generally brings medium-sized and large organizations operating in covered sectors within scope, reducing inconsistencies associated with national entity-identification processes and promoting greater harmonization across Member States [1].

6. Cybersecurity Risk Management Measures

NIS2 requires regulated entities to implement appropriate technical, operational, and organizational measures to manage cybersecurity risks and minimize the impact of incidents affecting network and information systems [1]. These measures cover risk analysis and security policies, incident handling, business continuity and crisis management, supply chain security, secure acquisition and development, vulnerability management, assessment of cybersecurity effectiveness, training and awareness, and basic cyber hygiene. The approach integrates prevention, response, recovery, governance, and continuous risk management, consistent with established industrial cybersecurity principles [13]. These requirements are broadly consistent with risk-based cybersecurity principles reflected in NIST SP 800-82 Rev.3 and IEC 62443-2-1, particularly regarding governance, lifecycle security, incident response, business continuity, and continuous risk management [14], [15]. This alignment reinforces the broader shift toward resilience-based cybersecurity governance rather than reliance solely on compliance-oriented controls [16].

7. Incident Reporting Obligations

The NIS2 Directive significantly strengthens incident reporting requirements compared with the original NIS framework. The objective is to improve situational awareness, facilitate coordinated response activities, and enable authorities to identify emerging threats and trends more effectively [1].

Under NIS2, organizations must report significant incidents through a structured reporting process consisting of multiple stages. An early warning must be submitted within 24 hours of becoming aware of a significant incident, followed by an incident notification within 72 hours. Where requested, an intermediate status report may also be required. A final report must generally be submitted within one month, providing a detailed description of the incident, its severity and impact, suspected cause, mitigation measures, and any possible cross-border effects. The structured reporting process represents a significant improvement over the more limited reporting obligations established under the original NIS Directive. The reporting requirements under NIS2 are detailed in Figure 2.

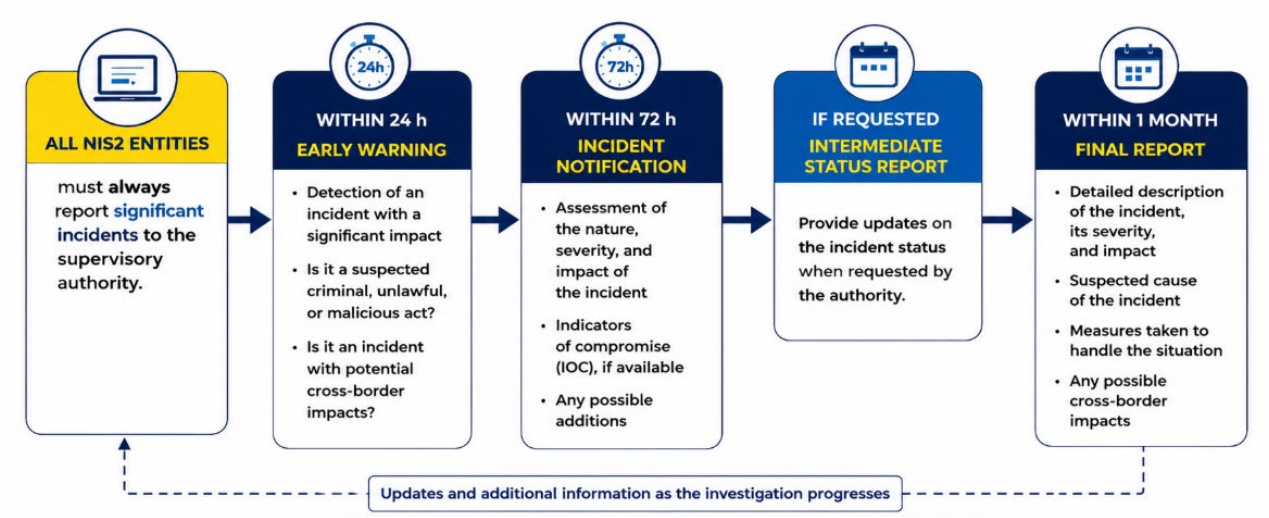

Figure 2. NIS2 incident reporting requirements and notification timelines [17].

8. Governance and Accountability

NIS2 increases governance and management accountability by recognizing cybersecurity as an organizational and strategic responsibility rather than solely a technical issue. Management bodies are required to approve cybersecurity risk-management measures, oversee their implementation, ensure compliance, and possess sufficient cybersecurity knowledge to discharge these responsibilities. This approach integrates cybersecurity into organizational governance, risk management, and strategic decision-making [1].

9. National-Level Obligations

NIS2 also places significant responsibilities on Member States. They must establish national cybersecurity strategies, designate competent authorities, identify regulated entities, maintain operational capabilities for incident response and crisis management, and establish mechanisms for supervision and enforcement. National authorities are additionally responsible for receiving incident reports and supporting cybersecurity resilience within their jurisdictions [1].

10. European Union Cooperation Mechanisms

NIS2 strengthens European cybersecurity cooperation through complementary mechanisms. Computer Security Incident Response Teams (CSIRTs) support operational coordination and incident response; Single Points of Contact (SPOCs) facilitate cross-border communication; the Cooperation Group supports strategic coordination; ENISA provides technical and policy support; and EU-CyCLONe (European Cyber Crisis Liaison Organization Network) facilitates the management of large-scale cybersecurity incidents. Together, these mechanisms strengthen operational and strategic cooperation across Member States [1].

11. Supervision and Enforcement

NIS2 introduces stronger supervisory and enforcement mechanisms than the original NIS Directive. Competent authorities may assess compliance, conduct inspections, request information, impose corrective measures, and

apply sanctions for non-compliance [1]. These provisions are intended to reduce implementation inconsistencies and strengthen cybersecurity maturity across regulated sectors, supporting the Directive's broader transition toward a more resilience-oriented model of cybersecurity governance.

V. COMPARATIVE EVALUATION OF THE EVOLUTION FROM NIS TO NIS2

1. National Transposition and Regulatory Harmonization

Although NIS2 seeks to establish a higher common level of cybersecurity across the European Union, implementation remains dependent on national transposition and institutional capability. Member States differ in cybersecurity maturity, regulatory experience, resources, and organizational structures [18], while the ENISA NIS360 assessment also identifies varying maturity across NIS2 sectors [19]. Consequently, differences in national interpretation, supervision, and enforcement may continue to affect regulatory consistency despite the stronger harmonization mechanisms introduced by NIS2 [1].

2. Resource and Capability Constraints

Effective NIS2 implementation requires governance structures, risk-management processes, incident response, monitoring, business continuity, and cybersecurity training [1]. However, limited budgets, shortages of qualified cybersecurity professionals, and competing operational priorities may constrain implementation, particularly in organizations with lower cybersecurity maturity. The broader shortage of cybersecurity expertise further intensifies competition for personnel to support governance, compliance, technical security operations, and incident response [20].

3. Supply Chain Security

Digital ecosystems increasingly depend on suppliers, cloud platforms, software vendors, telecommunications providers, and managed service providers, extending cybersecurity risk beyond organizational boundaries [21]. NIS2, therefore, explicitly incorporates supply chain security into its risk management framework and requires organizations to assess risks associated with suppliers and service providers [1]. Nevertheless, limited visibility into supplier security practices, complex contractual relationships, and interconnected technology environments continue to pose significant implementation challenges for supply-chain risk management [6].

4. Cross-Border Cooperation and Information Sharing

Because cyber incidents and digital dependencies frequently extend across national borders, effective NIS2 implementation depends on cooperation and information sharing among governments, regulators, and private-sector organizations [11]. NIS2 strengthens this cooperation through CSIRTs, the Cooperation Group, SPOCs, ENISA, and EU-CyCLONe, but differences in reporting procedures, legal requirements, organizational capabilities, and operational priorities may still hinder coordination. Concerns regarding reputation, liability, regulatory consequences, and competitive disadvantage may also discourage timely information sharing, making trust and operational cooperation essential to achieving the Directive's objectives.

5. Governance and Organizational Culture

NIS2 strengthens organizational responsibility by assigning direct cybersecurity obligations to management bodies and integrating cybersecurity into broader governance processes [1]. This transition from primarily technical

ownership to executive accountability may be difficult for organizations with limited governance experience, as senior management must understand cybersecurity risks, regulatory obligations, and resilience requirements. Effective implementation, therefore, depends on leadership commitment, organizational culture, and governance maturity, in addition to technical controls.

6. Interdependencies and Critical Infrastructure Resilience

Critical infrastructure operates through complex dependencies among organizations, services, and technologies; energy, telecommunications, transport, healthcare, and digital infrastructure increasingly rely on one another [7], [11]. These interdependencies can create cascading consequences when disruption in one sector affects others. Although NIS2 promotes risk-management approaches that address interconnected risks, effective resilience still requires regulators, operators, and stakeholders to understand systemic dependencies and coordinate across sectors.

7. Balancing Compliance and Cyber Resilience

A continuing challenge is ensuring that NIS2 implementation strengthens operational resilience rather than becoming a compliance exercise primarily. Regulatory conformity is important, but resilience also requires continuous improvement, proactive risk management, organizational learning, recovery capability, and adaptation to evolving threats [6]. The long-term effectiveness of NIS2 will therefore depend on whether organizations and Member States translate legal obligations into mature cybersecurity capabilities that improve the resilience of critical sectors and European society.

Table 2. Synthesis of the transition from NIS to NIS2 and remaining implementation gaps [1], [18], [19], [22].

Dimension	**NIS-era limitation**	**NIS2 response**	**Remaining implementation gap**
Regulatory scope	Limited sector coverage	Expanded essential/important entities	National identification and implementation
Governance	Limited executive responsibility	Management accountability	Governance maturity
Risk management	General obligations	Detailed risk-management requirements	Capability/resource differences
Incident reporting	Less structured	24 h/72 h/1-month process	Operational reporting capacity
Supply chain	Limited emphasis	Explicit supply-chain obligations	Third-party visibility
EU cooperation	Fragmented coordination	CSIRTs, Cooperation Group, EU-CyCLONe	Cross-border operational consistency
Resilience	Primarily compliance-oriented	Greater resilience orientation	Translating compliance into operational resilience

VI. DISCUSSION

The findings presented in this paper demonstrate that the evolution of European cybersecurity governance has been characterized by a gradual transition from fragmented national approaches toward a more coordinated and

comprehensive regulatory framework. This evolution reflects the increasing recognition that cybersecurity is not solely a technical issue but a strategic governance challenge that directly affects economic stability, public trust, critical infrastructure resilience, and the continuity of essential services [1], [2]. The resilience objectives established by NIS2 are further complemented by the CER Directive, which extends protection beyond cybersecurity to include physical and organizational resilience of critical entities [23]. The establishment of ENISA and the adoption of the European Cybersecurity Strategies of 2013 and 2020 provided the institutional and policy foundations necessary for developing a common European cybersecurity framework [2], [4]. These initiatives promoted cooperation, information sharing, capacity building, and policy coordination among Member States while highlighting the importance of cyber resilience as a strategic objective. The adoption of the NIS Directive in 2016 marked a major milestone, as it introduced the first legally binding cybersecurity obligations applicable across the European Union [5]. The Directive significantly improved cybersecurity governance by requiring national cybersecurity strategies, incident reporting mechanisms, Computer Security Incident Response Teams (CSIRTs), and cooperation structures. Furthermore, it established the principle that organizations responsible for delivering essential services should implement cybersecurity measures and report significant incidents. However, the analysis demonstrates that the original NIS framework was unable to fully address the challenges associated with an increasingly interconnected digital environment. Variations in national implementation, limited sectoral coverage, differing supervisory approaches, and inconsistent levels of cybersecurity maturity reduced the framework's overall effectiveness [1]. At the same time, the cybersecurity threat landscape evolved rapidly, driven by ransomware campaigns, supply chain compromises, attacks against operational technology environments, and increasingly sophisticated state-sponsored cyber operations [2], [3]. The introduction of NIS2 can therefore be viewed as a regulatory response to both technological evolution and lessons learned from the implementation of the original Directive [22]. NIS2 expands the scope of regulated entities, strengthens risk-management requirements, introduces more structured incident reporting obligations, and reinforces management accountability [1]. These changes indicate a shift from a relatively flexible cybersecurity framework toward a more comprehensive and harmonized model of cybersecurity governance. One of the most significant developments introduced by NIS2 is the recognition that cybersecurity must be integrated into organizational governance structures. The Directive explicitly assigns responsibilities to management bodies and requires organizations to incorporate cybersecurity into strategic decision-making processes [1]. This approach reflects the broader understanding that cyber risks are organizational risks rather than purely technical concerns. This governance-oriented approach is also consistent with industrial cybersecurity research, which recognizes that protecting industrial networks requires coordinated technical, organizational, and management measures rather than isolated technical controls [13].

The emphasis on supply-chain security further illustrates the changing nature of cybersecurity governance. Modern organizations operate within highly interconnected digital ecosystems, where vulnerabilities affecting suppliers, service providers, or technology partners can pose significant risks across multiple sectors [21]. By incorporating supply-chain security into mandatory risk-management requirements, NIS2 acknowledges the importance of addressing cybersecurity risks beyond organizational boundaries. The analysis also highlights the importance of cooperation mechanisms in achieving European cybersecurity objectives. Structures such as ENISA, the Cooperation Group, CSIRTs, Single Points of Contact, and EU-CyCLONe contribute to information sharing, operational coordination, and collective resilience [2]. Effective cooperation is particularly important because cyber threats frequently transcend national borders and affect multiple sectors simultaneously. Despite these improvements, several implementation challenges remain. Resource limitations, shortages of cybersecurity professionals, supply-chain complexity, varying levels of organizational maturity, and differences in national implementation approaches may affect the ability of organizations and Member States to achieve consistent compliance [1]. These challenges suggest that regulatory requirements alone are insufficient to guarantee resilience and must be supported by investments in capabilities, expertise, governance, and operational cooperation. Another important observation is that cybersecurity governance increasingly overlaps with broader resilience

objectives. The protection of critical infrastructure depends not only on technical security controls but also on organizations' ability to anticipate, withstand, respond to, and recover from disruptive events [7], [11]. Consequently, cybersecurity governance should be viewed as a component of a broader resilience strategy rather than an isolated regulatory activity. The findings of this study indicate that NIS2 represents a significant advancement in European cybersecurity governance and provides a stronger foundation for improving resilience across critical sectors. Nevertheless, the long-term effectiveness of the Directive will depend on successful implementation, sustained cooperation among stakeholders, and the continued adaptation of cybersecurity governance mechanisms to address emerging threats and technological developments. From a policy perspective, NIS2 demonstrates the European Union's commitment to establishing a common cybersecurity framework that supports digital transformation while protecting essential services and critical infrastructure. As cyber threats continue to evolve, the Directive provides a regulatory foundation that may support future cybersecurity initiatives and contribute to a more resilient European digital ecosystem. The evolution from NIS to NIS2, therefore, represents not merely a legislative revision but a broader transformation in the way cybersecurity is governed, managed, and integrated into the strategic priorities of organizations and governments throughout the European Union.

VII. CONCLUSION

Cybersecurity has become a fundamental requirement for the stability, security, and resilience of modern societies. As governments, businesses, and critical infrastructure operators increasingly depend on digital technologies, cybersecurity governance has evolved from a predominantly technical concern into a strategic policy and regulatory priority. The European Union's approach to cybersecurity governance reflects this transformation through the progressive development of institutions, strategies, and legislative frameworks designed to strengthen cyber resilience across Member States. This paper examined the evolution of European cybersecurity governance from the establishment of ENISA and the adoption of the European Cybersecurity Strategies to the implementation of the Network and Information Security (NIS) Directive and its subsequent revision through the NIS2 Directive. The analysis demonstrated that the original NIS Directive was a significant milestone, establishing the first common cybersecurity framework across the European Union. However, practical implementation revealed limitations related to fragmented national transposition, uneven supervisory approaches, limited sectoral coverage, and varying levels of cybersecurity maturity among Member States. The adoption of NIS2 represents a substantial advancement in European cybersecurity governance. Through expanded sectoral coverage, stronger cybersecurity risk-management requirements, enhanced incident reporting obligations, increased management accountability, and improved cooperation mechanisms, the Directive seeks to establish a higher and more consistent level of cybersecurity across the European Union. The transition from NIS to NIS2 reflects the recognition that cybersecurity governance must continuously evolve in response to technological developments, growing digital interdependencies, and an increasingly complex threat landscape. Despite these improvements, the successful implementation of NIS2 remains dependent on several factors. Differences in national capabilities, resource constraints, supply-chain complexity, cross-border coordination challenges, and organizational governance maturity may affect the consistency and effectiveness of implementation across Member States. Consequently, achieving the objectives of NIS2 will require sustained cooperation among governments, regulators, private-sector organizations, and critical infrastructure operators. The findings of this study indicate that NIS2 provides a stronger foundation for cybersecurity governance and resilience than its predecessor. However, long-term success will depend not only on regulatory compliance but also on the ability of organizations and Member States to develop sustainable cybersecurity capabilities, strengthen governance structures, and adapt to emerging threats. As digital transformation continues to accelerate, the evolution of European cybersecurity governance will remain essential to protecting critical infrastructure, maintaining public trust, and supporting the resilience of the European digital economy.

Abstract
Female breast cancer (BC) is a critical global public health challenge, driving the development of specialized computational tools for risk prediction and prognostic management. This study presents a structured data engineering and Machine Learning (ML) pipeline to predict 5-year survival using seven linear and non-linear supervised survival algorithms evaluated on a hospital cohort of 559 patients. We investigated the incremental impact of feature engineering and four distinct selection techniques (multicollinearity filtering, Cox-LASSO, GBSA, and RSF) on model performance and calibration. Experimental results demonstrate that removing noise and multicollinearity significantly enhanced model efficiency. Streamlining the dataset from 68 to just 12 variables via Gradient Boosting Survival Analysis (GBSA) preserved 98.2% of the peak discriminative power, enabling the traditional Cox Proportional Hazards (CPH) model to increase its Concordance Index (*C*-index) from 0.7647 to 0.8718 (IBS = 0.0823). Meanwhile, Random Survival Forest (RSF) achieved the maximum discriminative performance on the full dataset (*C*-index = 0.8879) and maintained strong performance on reduced feature sets (*C*-index = 0.8753). The feature selection strategies helped identify clinically relevant prognostic markers, favoring a parsimonious, easily interpretable framework that could support clinical decision-making systems in BC management.

Keywords: breast cancer, clinical decision support, feature selection, machine learning, prognostic variables, survival analysis

I. INTRODUCTION

Female breast cancer (BC) is the leading female malignancy globally and in Brazil, accounting for 23.8% and 30.1% of cancer cases, respectively, driven by complex genetic, environmental, and lifestyle factors [1]–[3]. Globally, BC caused 2.30 million new cases and 0.67 million deaths in 2022 [1]–[4]. For the 2026–2028 triennium, the Brazilian National Cancer Institute (INCA) estimates 78,610 annual new cases [2], while official SIM/DATASUS data recorded 21,129 BC deaths (ICD-10: C50) nationwide in 2024 [5]. This pathology exhibits high biological heterogeneity among molecular subtypes defined by overexpression of Estrogen Receptor (ER), Progesterone Receptor (PR), and Human Epidermal Growth Factor Receptor 2 (HER2). This complexity requires individualized therapeutic management regulated by clinical guidelines and anatomical staging protocols, which are systematically integrated into the Brazilian healthcare framework [6], [7]. In this scenario, longitudinal

survival rates in regional cohorts [8]–[10] serve as critical indicators of the efficacy of oncological care, reflecting diagnostic promptness, access to therapy, and health system equity [11], [12]. Automated hospital record analysis via Data Science optimizes resource allocation and point-of-care decisions [13]–[15]. Nationally, Machine Learning (ML) applications gain clinical acceptance when validated on Real-World Data (RWD) [16]. However, deployment faces two main operational barriers: prevalent missing data requiring robust preprocessing [17]–[19], and black-box opacity (e.g., Deep Learning) that hinders clinical auditability [20]. Consequently, explainable AI remains essential for safe clinical validation [21]–[23]. Traditionally, survival analysis relied on the semiparametric Cox Proportional Hazards (CPH) model [24]. However, CPH struggles with high-dimensional data, strict proportional hazard assumptions, and complex non-linear interactions [23], [25], [26]. Conversely, tree-based ensembles and boosting techniques handle non-linear patterns more effectively [27], [28]. Addressing data noise and missingness via advanced preprocessing is vital for model stability [29], [30], while compressive feature selection isolates a parsimonious core that preserves discriminative power [31]–[33]. To address these demands, this study presents a data engineering pipeline to predict 5-year BC survival in a cohort of 559 patients from Zona da Mata Mineira, Brazil [8]–[10]. Our analysis includes longitudinal hospital records covering baseline diagnostic parameters, anatomical staging, clinical treatment variables, and long-term follow-up status. Through this approach, we evaluate how feature engineering and selection isolate routine care predictors to enhance oncological decision-support models using Python's Scikit-survival library [34].

II. MATERIALS AND METHODS

The experimental pipeline follows a structured five-phase data engineering workflow (Figure 1): (i) cohort recruitment and filtering, (ii) stratified train-test partitioning, (iii) leakage-free preprocessing and imputation, (iv) benchmarking feature selection strategies, and (v) model training, validation, and uncertainty quantification. All routines were implemented in Python using Scikit-learn [35] and Scikit-survival [34] for right-censored time-to-event data.

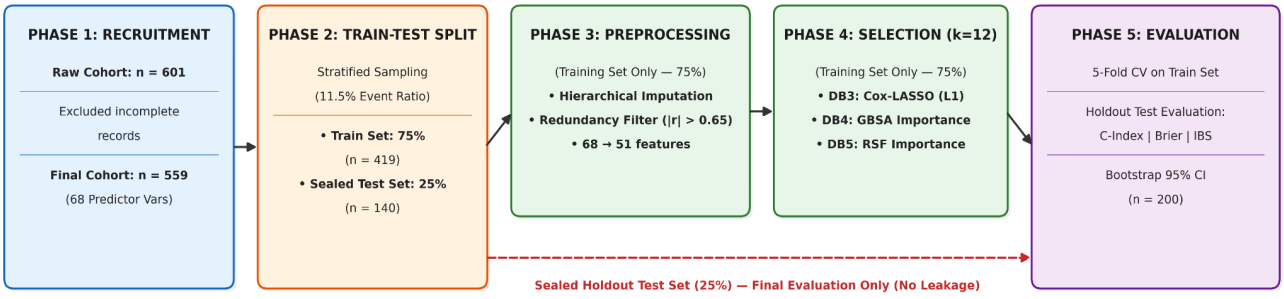

Figure 1. Methodological workflow of the 5-phase data engineering pipeline for 5-year female BC survival prediction, highlighting train-isolated preprocessing and the sealed holdout test set evaluation.

1. Study Population and Cohort Design

Clinical data derived from a retrospective hospital cohort of women with invasive BC (ICD-10: C50) in Zona da Mata Mineira, Brazil, were approved by the UFJF Ethics Committee (no. 5,533,296). Recruitment spanned three prior phases [8]–[10]: Phase 1 (2009–2010) extracted 601 records diagnosed in 2003–2005; Phase 2 (2010–2011) excluded cases without therapeutic follow-up; Phase 3 tracked vital status via SIM/DATASUS and telephone contact, establishing 563 patients. During the preprocessing phase of the present study, records with incomplete administrative or clinical data were excluded, yielding a final analytical cohort of 559 patients

[14], [31]. The feature matrix includes baseline diagnostic parameters (age, grade, molecular subtype, TNM) and longitudinal treatment trajectories (surgery, chemotherapy, radiotherapy) [8]–[10]. Time-to-event was the interval from diagnosis to BC death or 5-year right-censoring (1,825 days).

2. Leakage-Free Data Partitioning and Imputation

To eliminate data leakage, the dataset was partitioned at the onset into a 75% training set (n = 419) and a 25% holdout test set (n = 140) using stratified random sampling to preserve the 11.5% event-to-censoring ratio. The test set was frozen and sealed during all subsequent processing steps:

- **Baseline Raw Data (Database 1 - DB1):** Standardized time fields and removed attributes with missingness exceeding 40%, yielding 68 predictor variables.
- **Train-Isolated Imputation (Database 2.1 - DB2.1) & Filtering (Database 2 - DB2):** Missing values were imputed strictly within training boundaries using hierarchical clinical rules ($|r| > 0.65$) and statistical imputation (mode/median). Bivariate association analysis eliminated 17 redundant attributes ($|r| > 0.65$), reducing the matrix from 68 to 51 features.

3. Parsimonious Framework for Feature Selection

To identify clinically interpretable prognostic cores, selection algorithms were executed exclusively within the training partition:

- **Database 3 - DB3 (Cox-LASSO):** Selected via strict L_1-penalized shrinkage (l1_ratio = 1.0, alpha_min_ratio = 0.01).
- **Database 4 - DB4 (GBSA):** Tree-based Gradient Boosting ranked by Out-Of-Bag (OOB) permutation importance (15 repetitions).
- **Database 5 - DB5 (RSF):** Non-parametric Random Survival Forest (RSF) ranked by OOB permutation importance (15 repetitions).

Data-Driven Parsimony Criterion (k = 12): The cutoff was set by the sparsity boundary of Componentwise Gradient Boosting Survival Analysis (GBSA), which identified 12 active predictive attributes. Consequently, the *top 12* variables were standardized across DB3 through DB5 to enable a homogeneous comparison.

4. Predictive Models and Parameterization

Mathematical modeling integrated right-censorship [34] across linear, regularized, and ensemble paradigms. All models were initialized with a fixed seed (SEED = 42) and evaluated via 5-fold cross-validation strictly within the training partition (n = 419):

- **Regularized Cox Models:** Based on the classical CPH framework [24], regularized variants incorporate penalty terms to manage multicollinearity and stabilize coefficient estimation [36].
    - **Cox Proportional Hazards (CPH):** Configured with a light Ridge L_2 penalty ($\alpha = 10^{-4}$) to guarantee matrix inversion stability, using Breslow's baseline hazard estimator (ties = 'breslow', n_iter = 100) [36].
    - **Cox Elastic Net (CPH-EN):** Evaluated over a cross-validated path of 100 α values (alpha_min_ratio = 0.01) with an equal penalty balance (l1_ratio = 0.5) via coordinate descent (max_iter = 1000, fit_baseline_model = True) [36].
- **Ensemble Models:** Ensemble approaches capture non-linear relationships and complex interactions without relying on proportional hazards assumptions [37]–[42].
    - **Gradient Boosting Survival Analysis (GBSA):** Leverages Friedman's additive boosting framework [37], [38] adapted for Cox's partial likelihood loss function [39]. The model was built

using 250 decision trees (max_depth = 3) with regularization constraints (min_samples_split = 10, min_samples_leaf = 5) and a conservative learning_rate = 0.05.

- **Random Survival Forest (RSF):** Extends random forests to right-censored outcomes [40], constructing using 250 non-parametric survival trees (min_samples_split = 10, min_samples_leaf = 15, max_features = 'sqrt') guided by log-rank split criteria and Nelson-Aalen hazard estimation [40]–[42].

5. Model Evaluation and Uncertainty Quantification

Model performance was validated using *Scikit-survival* [34], across the 25% untouched holdout test set (n = 140) to evaluate both discriminative capacity and probability calibration:

- **Discriminative Capacity:** Longitudinal discrimination was measured using Harrell's and Uno's Concordance Index (C-index) [43]. The metric evaluates the application of Inverse Probability of Censoring Weighting (IPCW) to eliminate censoring bias (0.5 = random chance; 1.0 = perfect ordering).
- **Calibration and Prediction Error:** Calibration accuracy was assessed via the time-dependent Brier Score (BS) at the 5-year threshold (t = 1,825 days) and the Integrated Brier Score (IBS) evaluated across the continuous trajectory horizon ($t \in [0; 1{,}825]$ days) [44]. These metrics compute the IPCW mean-squared error between the actual status and the predicted survival probabilities, with values near zero indicating optimal global calibration.
- **Uncertainty Quantification:** Discriminative accuracy on training (C_{train}) was paired with nonparametric bootstrap resampling (nbootstraps = 200, SEED = 42) on the test partition (C_{test}) to calculate empirical 95% Confidence Intervals (95% CI) [CI_{lower}, CI_{upper}].

III. RESULTS AND DISCUSSION

The experimental evaluation benchmarked four survival modeling paradigms across five dataset configurations (k = 68, 51, 12) on the sealed n = 140 holdout test partition (20.0% event rate, 28 deaths in 5 years).

1. Cohort Characteristics and Feature Selection Dynamics

The curated cohort (n = 559) recorded 111 BC-related deaths over 5 years (79.75% right-censored rate), aligning with regional epidemiological indicators [8], [10]. Initial filtering (>40\% missingness) yielded 68 prognostic covariates (DB 1). Bivariate correlation mapping ($|r| > 0.65$) eliminated 17 redundant attributes, reducing the predictor space to 51 variables (DB 2) to prevent coefficient variance inflation [18], [36].

Feature selection algorithms compressed the operational space to distinct k = 12 attribute cores (Figure 2):

- **Cox-LASSO/Elastic Net Core (DB 3):** Exhibited 100% feature overlap (12/12) between both methods. The top 5 predictors were primary tumor size, post-surgical pathologically involved lymph nodes, semi-quantitative ER status (graded in crosses), distant metastasis (TNM M-category), and time to radiotherapy onset **(Figure 2A)**.
- **GBSA Permutation Core (DB 4):** The top 5 key drivers included treatment sequence modality (1-neoadjuvant, 2-adjuvant, 3-neoadjuvant and adjuvant, 4-palliative), tumor size, post-surgical pathologically involved lymph nodes, ER status (graded in crosses), and age at diagnosis **(Figure 2B)**.
- **RSF Permutation Core (DB 5):** The top 5 predictors were tumor size, immunohistochemical subtype (0-Luminal A, 1-Luminal B, 2-HER2+, 3-Triple-Negative, 4-Unknown), ER status (graded in crosses), post-surgical involved lymph nodes, and Ki-67 proliferation index **(Figure 2C).**

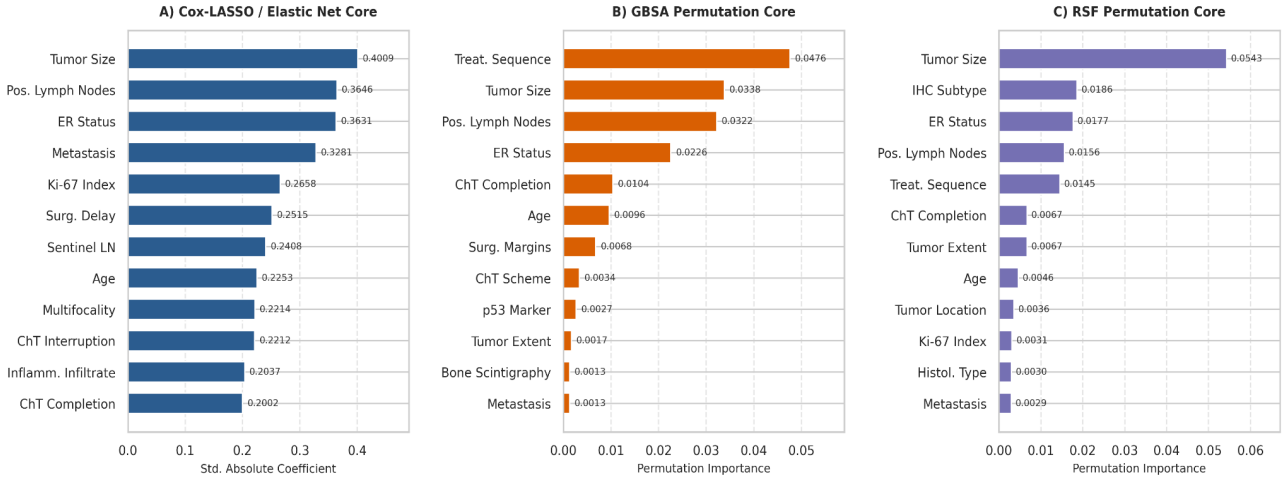

Figure 2. Relative importance ranking for the top k = 12 selected attributes across (A) Cox-LASSO, (B) GBSA, and (C) RSF feature selection paradigms (n = 140). Abbreviations: ER = Estrogen Receptor; ChT = Chemotherapy; LN = Lymph Node; Pos. = Positive; IHC = Immunohistochemical.

2. Comparative Analysis and Key Findings

The overall predictive performance and discrimination metrics across all dataset configurations and survival algorithms are summarized in Table 1. RSF achieved maximum overall discrimination on unrefined data (DB 1; k = 68, Ctest = 0.8879, 95% CI [0.8381, 0.9418]). On the other hand, standard CPH showed a moderate drop in discriminative ability on DB 1 (Ctest = 0.7647; BS = 0.1319), illustrating how high-dimensional clinical noise adversely affects traditional Cox regression [15], [24]. Feature filtering to k = 12 using GBSA permutation importance (DB 4) substantially improved CPH performance, raising its Ctest from 0.7647 to 0.8718 (95% CI [0.8219, 0.9195]) and reducing its 5-year BS to 0.0975 (IBS = 0.0823). Within this subset, GBSA achieved the best performance (Ctest = 0.8740, 95% CI [0.8206, 0.9261]). On the RSF permutation core (DB 5; k = 12), RSF demonstrated superior parsimonious generalization (Ctest = 0.8753, 95% CI [0.8214, 0.9268]), maintaining time-dependent Brier Scores well below the standard 0.25 clinical threshold (Table 1) [28], [44].

Table 1. Model Performance Across Feature Selection Strategies (n = 140 Holdout Test Set)

Paradigm	Model	*K*	C_{train}	C_{test}	95% CI Test	BS (5Y)	IBS

	RSF		0.8519	**0.8753**	[0.8214, 0.9268]	0.1017	0.0865

Note: DB 1: Unfiltered Raw Data; DB 2: Correlation Filtered; DB 3: Cox-LASSO / Elastic Net Core; DB 4: GBSA Permutation Core; DB 5: RSF Permutation Core. k = Active Features; C_{train} and C_{test} = Uno's Concordance Index on train (n=419) and test (n=140) sets; CI TEST = Confidence Interval (200 bootstrap resamples); BS (5Y) = Brier Score at t = 1,825 days; IBS = Integrated Brier Score over 5 years. Models: CPH = Cox Proportional Hazards; CPH-EN = CPH with Elastic Net Penalty; GBSA = Gradient Boosting Survival Analysis; RSF = Random Survival Forest. Bold indicates optimal metrics per dataset.

Reducing the feature space from k = 68 to k = 12 demonstrated that a compact core of variables retains the essential clinical signal for 5-year survival prediction. While RSF achieved maximum discrimination on raw data (Ctest = 0.8879 on DB 1), feature selection enabled highly accurate parsimonious models, such as GBSA on DB 4 (Ctest = 0.8740) and RSF itself on DB 5 (Ctest = 0.8753), while restoring the predictive capacity of classical CPH (Ctest = 0.8718), all while maintaining time-dependent calibration errors well below clinical validation thresholds [28], [44].

3. Discussion and Clinical Interpretation

The transition from classical biostatistics to ML survival algorithms on RWD is pivotal for precision oncology [14], [26]. The proportional hazards assumption inherent to standard CPH regression explains its baseline limitations on unrefined data (DB 1; Table 1), as such assumptions are frequently violated in real-world registries characterized by heterogeneous treatment courses and time-varying covariates [23]. In contrast, non-parametric tree ensembles and boosting methods dynamically capture complex non-linear clinical interactions [28], [44]. Our top-performing models on compact subsets (Ctest = 0.8753 for RSF on DB 5; Ctest = 0.8740 for GBSA on DB 4) consistently outperform benchmark models reported in recent literature. For instance, Kang et al. achieved a maximum C-index of 81.23\% (95% CI [80.34–82.12]) for RSF and 81.73\% (95% CI [81.73–81.73]) for Cox-Elastic Net in their older cohort, while dropping to 74.91\% (95% CI [72.47–77.36]) and 72.61\% (95% CI [72.61–72.61]) in younger patients. Similarly, Cai et al. [20] evaluated performance across varying subsets of variables (k = 8 to 16), reporting test-set C-indices ranging from 0.785 to 0.787 for RSF, 0.796 to 0.803 for CoxPH, and 0.767 to 0.794 for DeepSurv. Notably, DeepSurv exhibited clear overfitting in their evaluation, peaking at a training C-index of 0.845 but dropping to 0.769 on the test set (k = 14). In contrast, our pipeline maintained high discriminative performance (0.8753) and stability on the held-out test set using a parsimonious core of 12 clinical attributes, while deliberately avoiding deep learning architectures that lack clinical interpretability [18], [20]. Model stability and calibration were robust. In contrast to studies showing high metric values during training (e.g., Li et al. [33], where RSF reached a training C-index of 0.920 and a 3-year AUC of 0.947), our primary models maintained generalizability on the sealed holdout test partition (n = 140), with Ctest $\geq$ 0.8694. Time-dependent calibration errors remained low (BS $\leq$ 0.1033; IBS $\leq$ 0.0878 over 5 years; Table 1). This performance aligns with our previous baseline (Carvalho et al. [27]), which reported IBS values of 0.0547 for RSF and 0.0437 for GBSA with 70 predictors. It compares favorably with recent reports such as [30], in which the best model for overall survival (GB) achieved a C-index of 0.68 (95% CI [0.57–0.79]) and an IBS of

0.17. Feature selection grounded in clinical consensus mitigated optimism bias while preserving temporal calibration within clinical validation thresholds.

Importantly, automated feature selection converged with core biological domains (Figure 2) [7], [10]:

- **Anatomical and Pathological Staging:** Tumor size, positive lymph nodes, tumor extent, and distant metastasis reflect disease burden within the standard TNM framework (**Figure 2A-C**) [8], [9].
- **Biomarkers and Molecular Subtypes:** ER status, Ki-67 proliferation index, p53 marker, and immunohistochemical subtypes capture endocrine responsiveness and biological aggressiveness (**Figure 2A, 2C**) [6], [7].
- **Care Trajectories:** Treatment sequence, surgical delays, chemotherapy schemes, and cycle completion highlight the direct clinical impact of healthcare delivery timelines and therapeutic continuity on 5-year survival outcomes (**Figures 2A and 2B**) [6], [33].

IV. CONCLUSION

This study validates the use of supervised ML to predict 5-year overall survival in an invasive BC cohort. Non-parametric ensemble algorithms, led by RSF on the unrefined dataset (DB 1: *C*-index = 0.8879) and on the reduced permutation core (DB 5: *C*-index = 0.8753), demonstrated superior discrimination and robust temporal calibration (BS ≤ 0.1017, IBS ≤ 0.0865), outperforming standard CPH regression. Crucially, compressing the operational space from $k = 68$ to $k = 12$ clinical attributes preserved 98.2% of peak performance while recovering CPH calibration (BS = 0.0975 on DB 4). This confirms that accurate, interpretable prognostic tools can be built using routine clinical parameters, offering a scalable decision-support alternative for resource-constrained healthcare systems [6], [31]. Limitations include the retrospective single-center design and the lack of external validation. However, this risk is mitigated by the study site's representativeness: a major tertiary oncology center serving both the public (SUS) and private sectors that closely reflects the demographics of the broader Brazilian population. Additionally, historical registries underrepresent recent therapeutic advances, which may shift baseline survival [28]. Future work will focus on multi-institutional validation, dynamic imputation techniques, and local Explainable AI frameworks (SHAP and LIME) to enhance point-of-care interpretability [14].

ACKNOWLEDGEMENT

This study was supported in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior – Brasil (CAPES) – Finance Code 001, through a Doctoral Fellowship and the Institutional Sandwich Doctorate Program Abroad (PDSE) Grant. The authors thank the Faculty of Engineering of the University of Porto (FEUP) and the Graduate Program in Computational Modeling at the Federal University of Juiz de Fora (PGMC/UFJF) for their academic support; Prof. Dr. Maximiliano Ribeiro Guerra and Dr. Jane Rocha Duarte Cintra for their valuable collaboration and for providing the clinical database; and Hospital 9 de Julho and Instituto Oncológico for their institutional support.

Abstract
Dental implants are a widely used treatment modality for replacing missing teeth. The implant placement procedure requires accurate positioning, which should be supported by precise, detailed dental imaging analysis. This study aims to perform automatic dental implant segmentation using YOLO (You Only Look Once)-based deep learning models and to compare their performance. Compared with manual analysis, automatic segmentation enables faster, more consistent assessment while reducing clinicians' workload and potentially allowing care to be provided to more patients. In this study, YOLOv8, YOLOv9, YOLOv11, and YOLOv12 were trained and tested on dental images. Model performance was evaluated using accuracy, precision, recall, and processing-time metrics. YOLOv8 demonstrated a balanced performance, achieving a mask mAP@0.50:0.95 of 96.7% with an inference time of 10.309 ms per image. YOLOv9 yielded the highest mask segmentation performance, reaching 97.0% mAP@0.50:0.95, although its inference time was longer at 25.072 ms per image. YOLOv11 achieved a comparable mask mAP@0.50:0.95 of 96.9% with an inference time of 24.825 ms per image. YOLOv12 attained a mask mAP@0.50:0.95 of 93.9%, 99.9% precision, 100% recall, an inference time of 10.831 ms per image, and an approximate throughput of 92.3 FPS. This comparative analysis is expected to help identify the most effective and reliable deep learning model for dental implant segmentation.

Keywords: YOLO, Dental Implant, Deep Learning, Artificial Intelligence, Segmentation

I. INTRODUCTION

Dental implants constitute a widely adopted and effective therapeutic approach for the rehabilitation of missing teeth in contemporary dentistry. Implants, typically manufactured from biocompatible materials such as titanium, are placed into the jawbone and subsequently restored with a prosthesis, thereby providing both functional and esthetic outcomes. Nevertheless, because the success of implant therapy depends on accurate implant positioning and appropriate osseointegration with the surrounding bone, precise and detailed analysis of dental images at the initial stage of treatment planning is of critical importance [1]. In dental implant planning, although panoramic radiography provides a two-dimensional overview for general assessment, it may be insufficient for precise measurement of parameters such as bone density, width, and height due to magnification, geometric distortion, and inherent resolution limitations [1]. Therefore, Cone-Beam Computed Tomography (CBCT) is often preferred for more comprehensive anatomical evaluation; by enabling three-dimensional visualization of the jawbone, CBCT facilitates more accurate assessment of bone quality and

critical structures such as the mandibular canal and the maxillary sinus, thereby supporting the optimization of surgical planning [1]. Nevertheless, manual analysis of CBCT data is time-consuming due to the large volume of information; moreover, it may lead to inconsistencies arising from subjective variability influenced by clinician experience, attention, and fatigue, as well as human error. Given these constraints, deep learning (DL)–based approaches offer substantial advantages by enabling faster analysis of CBCT images, enhancing standardization, and yielding reproducible outcomes. Segmentation, one of the fundamental applications of DL, enables the automatic delineation of teeth, jawbone, and related anatomical structures in dental images, thereby facilitating the identification of suitable regions for implant placement and contributing to a more objective surgical planning process [2]. In recent years, automatic segmentation applications have provided clinical decision support in areas such as implant site localization, prediction of grafting requirements, and reduction of the risk of nerve injury by producing faster and more consistent results compared with manual assessment [3].

In CBCT-based analyses, the YOLO (You Only Look Once) family offers substantial potential for high performance and real-time efficiency in object detection and segmentation tasks owing to its single-stage architecture, making it a suitable candidate for precision-demanding applications such as dental implant segmentation. In this study, YOLOv8, YOLOv9, YOLOv11, and YOLOv12 were compared for dental implant segmentation, and their performance was evaluated using metrics including precision, recall, F1-score, mean average precision, and processing time. The findings reveal the respective strengths and limitations of the different YOLO versions and thereby help identify the most effective and reliable model for implant segmentation. Furthermore, deep learning-based segmentation is clinically valuable because of its potential to reduce clinicians' workload and provide safer decision support throughout surgical workflows.

II. LITERATURE REVIEW

[4] - For breast cancer mass segmentation in digital mammography, the YOLO-LOGO model was proposed by integrating YOLOv5 with Transformer-based Local–Global (LOGO) components. Evaluated on the CBIS-DDSM and INBreast datasets, the approach was reported to achieve superior detection/segmentation performance compared with prior methods while also reducing computational requirements. [5] - YOLOv2 and YOLOv3 were compared for object detection in aerial imagery, with analyses conducted on classes such as vehicles, aircraft, harbors, and ships using the DOTA dataset. The results indicated that YOLOv2 performed better on large objects, whereas YOLOv3 performed better on small objects. In addition, YOLOv3 demonstrated an advantage in inference speed (~2.5 s on average); however, for certain classes, YOLOv2 maintained higher accuracy. [6] - INSTA-YOLO was developed for real-time instance segmentation and operates in a single stage, in contrast to conventional two-stage approaches. By using a contour-based 2D point representation instead of pixel-wise masks, the method aimed to improve computational efficiency; across the Carvana, Cityscapes, and Airbus datasets, it was reported to achieve competitive accuracy while providing approximately a two-fold increase in speed. [7] - For segmentation in prostate cancer histopathology images, Mamba-, SAM-, and YOLO-based models were compared and evaluated on the Gleason 2019 and SICAPv2 datasets. The results indicate that the Mamba approach employing the H-vmunet architecture achieved superior performance in terms of the Dice coefficient. [8] - For the automated assessment of fish freshness, YOLO and Mask R-CNN were compared for segmenting fish head and tail regions. Using the Fish-gres dataset, YOLO was reported to achieve higher precision (98.96%) and recall (80.93%), yielding superior mAP values. [9] - The CNN family and the YOLO family were discussed in terms of architectural framework, computational speed, and object recognition effectiveness. It was emphasized that Faster R-CNN achieves strong detection performance, and that combining an RPN with Faster R-CNN is more advanced than the Selective Search + Faster R-CNN approach. In addition, YOLO was described as a CNN-based method capable of detecting multiple targets with a certain level of accuracy through end-to-end training and inference.

[10] - Two representative algorithm families for object detection, namely CNN-based and YOLO-based approaches, were presented and discussed along the accuracy–speed–cost trade-off. In particular, YOLOv3 has been reported to strike a balance between inference speed and detection accuracy.

[11] - A hybrid YOLO + GrabCut approach was proposed for skin cancer lesion segmentation; after localizing the lesion with YOLO, segmentation was completed using GrabCut. Evaluated on the ISBI 2017 and PH2 datasets, the method was reported to yield competitive results with approximately 90% precision. [12] - For real-time detection and classification of apple surface defects, a BiSeNet V2 + YOLOv4 framework was employed: BiSeNet V2 segmented the defective regions. At the same time, YOLOv4 served as a verification module to reduce the error rate. The results were reported as 92.42% accuracy and 94.31% F1-score.

[13] - For brain tumor segmentation, Inception-V3 and YOLO were integrated; homomorphic wavelet filtering was applied as a preprocessing step, and tumor localization was performed using a YOLOv2–InceptionV3 framework. On the BRATS 2018/2019/2020 datasets, IoU values of 97%, 98%, and 100% were reported, respectively.

[14] - The evolution of YOLO and its performance in real-time detection/segmentation were examined; YOLO versions from v1 to v8 were compared in terms of speed and accuracy on the COCO dataset. It was noted that each successive release introduced optimizations that led to performance improvements.

[15] - A cloud-based CNN was developed for the automatic segmentation of dental implants and associated prosthetic crowns in CBCT images. Training/validation/testing were conducted using 280 CBCT scans; the automated segmentation (AS) method was found to be approximately 60× faster than the semi-automatic approach (SS) (<30 s). Moreover, high segmentation accuracy for implants (DSC: 0.92 ± 0.02; 0.91 ± 0.03) and low error (at the RMSE level) were reported.

[16] - A hierarchical, multi-stage method was developed for fully automatic 3D individual tooth segmentation and identification from dental CBCT. To reduce complexity, panoramic-derived representations were generated for the maxilla and mandible; subsequently, 2D detection/segmentation was performed, followed by 3D segmentation using a coarse-to-fine ROI strategy. Reported performance included an F1-score of 93.35% for tooth detection and a Dice score of 94.79% for 3D tooth segmentation.

[17] - A CNN-based method was proposed to automate tooth segmentation required for the reconstruction of 3D dental models. The approach employed multi-stage training using different sub-volumes; to enhance compatibility across CBCT scanners, histogram-based preprocessing and a posterior probability function were applied. It was reported that performance was further improved by using spatial dropout and dense convolutional blocks.

[18] - In a systematic review evaluating AI applications in dental implant planning, it was emphasized that the automatic detection/segmentation of anatomical structures improves both accuracy and efficiency. Use cases such as automated identification of bone density, the maxillary sinus, neural structures, and teeth were discussed; however, the need for high-quality training data and the lack of protocol standardization were highlighted as major limitations.

[19] - A ResUNet-based model was developed for tooth segmentation and automated implant planning from panoramic and tangential images. PCA and linear regression were employed to detect missing teeth and recommend the implant axis; segmentation performance was 97.85% accuracy (IoU: 84.83%), and the mean implant site deviation was 0.36 mm.

[20] - A U-Net–based model was trained for the segmentation of teeth, restorations, implants, fillings, caries, root canals, and residual roots in OPG images. The reported performance included DSC values of 85% for teeth, 88% for caries, 87% for restorations, 93% for bridge restorations, and 94% for implants; the potential clinical contribution in terms of speed and accuracy was highlighted.

[21] - For implant planning in edentulous mandibles, a U-Net/MONAI-based automated segmentation approach was developed to delineate bone volume in CBCT images. Training and testing were performed using 43 CBCT scans; DSC values of 0.89 for the training set and 0.78 for the test set were reported. Higher performance was observed in unilateral cases, whereas limitations were noted for bilateral cases.

[22] – For segmenting implants and peri-implant crestal bone in radiographic images, a pipeline was proposed in which noise reduction, morphological operations, and histogram thresholding were followed by final segmentation using an Active Shape Model (ASM). Compared with manual measurements, an ICC of 0.75 and 95% agreement in the Bland–Altman analysis were reported, with a mean difference of 0.049 mm.

[23] – For implant (titanium rod) segmentation in CBCT, a three-stage automated method was developed, comprising (i) Tmin pre-thresholding, (ii) edge enhancement using the Sobel operator, and (iii) thresholding with a fixed Tedge of 7.5%. Validated on a phantom across 17 CBCT device protocols with sub-millimeter accuracy, the approach was reported to detect all rods except on one device correctly.

III. MATERIALS AND METHODS

This study aims to compare the performance of the YOLO-based deep learning models YOLOv8, YOLOv9, YOLOv11, and YOLOv12 for dental implant segmentation. These approaches are used for multi-object detection and instance segmentation and are optimized differently with respect to the accuracy–speed trade-off because of differences in their core architectures. The study was conducted using an ethically approved dental CBCT dataset. The images were curated in Roboflow to meet YOLO training requirements, and the corresponding TXT and YAML annotation files were generated. During preprocessing, Auto-Orient was applied, and all images were resized to 640 × 640 pixels. Training and evaluation were performed in a CUDA-enabled PyTorch environment. Performance assessment was based on bounding-box and mask precision, recall, F1-score, mAP@0.50, mAP@0.50:0.95, and preprocessing, inference, and postprocessing times.

1. Data Set

The dataset used in this study comprises dental images obtained from Medipol University Faculty of Dentistry and Dental Hospital (Ankara, Türkiye). Using the Roboflow platform, the images were partitioned into training (70%), validation (10%), and test (20%) sets; the training set was used to learn implant segmentation, and the final performance evaluation was conducted on the test set. The dataset includes 305 images from 9 individuals (7 females, 2 males). The training subset consists of 214 images and covers all 9 individuals (7 females, 2 males), while the test subset contains 91 images from 8 individuals (6 females, 2 males) and was used to assess model outputs objectively.

2. YOLOv8 Segmentation Model

YOLOv8 (You Only Look Once, v8) is an advanced deep learning architecture developed for object detection and segmentation tasks, optimized for both speed and accuracy [24]. In this study, the model was implemented in PyTorch and trained specifically for dental implant segmentation, with performance evaluated using metrics such as accuracy and inference time. Within the architectural context summarized in Figure 1, the main components of YOLOv8 can be highlighted as follows: (i) an anchor-free detection paradigm that directly predicts object centers, (ii) updates to the Backbone/Neck design, including replacing the initial 6×6 convolution with a 3×3 convolution and adopting the C2f module instead of C3 (where Bottleneck outputs are aggregated in C2f), and (iii) the management/disabled setting of the mosaic augmentation mechanism, which is part of the online augmentation strategies used during training [25]. Moreover, YOLOv8's strong performance on benchmark datasets such as COCO and Roboflow 100 (e.g., 50.2% mAP on COCO for

YOLOv8m), its developer-friendly CLI/Python package structure, and extensive community support are key factors explaining its broad adoption in practical applications [25].

3. YOLOv9 Segmentation Model

YOLOv9 is a deep learning model optimized for object detection and segmentation tasks, and, in this study, it was adapted for dental implant segmentation [26]. Computational processes were accelerated using a CUDA-enabled GPU; to enhance data-adaptive learning during training, hyperparameters were set to batch size = 8, IoU threshold = 0.7, and confidence threshold = 0.5. Upon completion of training, YOLOv9 demonstrated high accuracy in implant segmentation. Among the principal architectural contributions that distinguish YOLOv9 from earlier versions are Programmable Gradient Information (PGI), which aims to reduce information loss in deep networks by promoting reliable gradient formation and improving training efficiency, and the Generalized Efficient Layer Aggregation Network (GELAN), which maximizes parameter utilization and computational efficiency. In addition, it has been reported that multi-level features are effectively fused within the Neck component via RepNCSPELAN4, which integrates CSPNet- and ELAN-like paradigms [27]. Collectively, these characteristics help explain why YOLOv9 establishes a competitive standard in real-time applications in the accuracy–speed–parameter efficiency trade-off and why it demonstrates strong performance on complex tasks such as dental implant segmentation [27].

4. YOLOv11 Segmentation Model

YOLOv11 is a recent YOLO variant used for dental implant segmentation in this study [28]. Training used a batch size of 16, with AMP (automatic mixed precision) disabled and the remaining hyperparameters kept similar to those of YOLOv9. Architecturally, YOLOv11 incorporates C3K2 blocks in the Backbone/Neck, SPPF (Spatial Pyramid Pooling Fast) for multi-scale contextual representation, and C2PSA (Channel and Spatial Attention) in the Head. These components improve parameter efficiency and small-object detection while maintaining a favorable speed–accuracy balance [29], supporting effective segmentation of complex dental images [29].

5. YOLOv12 Segmentation Model

YOLOv12 is an attention-centric YOLO variant that integrates attention mechanisms into the real-time object detection framework. The model employs Area Attention to capture broad spatial dependencies at reduced computational cost and a Residual Efficient Layer Aggregation Network (R-ELAN) to improve feature aggregation efficiency [30]. In this study, the YOLOv12n-seg configuration was adapted to a single-class dental implant segmentation task. The fused model comprised 172 layers, 2,809,339 parameters, and a computational complexity of 9.6 GFLOPs. Final testing was performed using Ultralytics 8.4.104, Python 3.11.9, and PyTorch 2.11.0+cu128 on an NVIDIA GeForce RTX 3060 12-GB GPU with CUDA 12.8 and cuDNN 9.1.9. The best-performing trained weights were evaluated on the 61-image test set, and bounding-box, segmentation-mask, and runtime metrics were calculated.

IV. MODEL PERFORMANCE EVALUATION METRICS AND COMPARATIVE ANALYSIS

In this study, YOLOv8, YOLOv9, YOLOv11, and YOLOv12, trained for dental implant segmentation, were evaluated on an independent test set for object detection and segmentation performance. Segmentation quality, localization sensitivity, and runtime profiles were considered jointly. The evaluation metrics included mAP@0.50 (Boxes/Masks), which represents mean average precision at an IoU threshold of 0.50; mAP@0.50:0.95 (Boxes/Masks), which reflects generalized performance over IoU thresholds ranging from 0.50 to 0.95; precision, which indicates the capacity to limit false-positive predictions; recall, which represents the capacity to avoid missed implants; and the F1-score, which summarizes the precision–recall balance. Runtime performance was assessed using preprocessing, inference, and postprocessing times. The resulting metrics are presented in Table 1.

Table 1. Performance metrics and durations of the models

Metric	**Models**			
	YOLOv8	***YOLOv9***	***YOLOv11***	***YOLOv12***
mAP@0.5 (Average Sensitivity at 0.5 IoU Threshold) (Boxes)	0.995	0.995	0.995	0.995
mAP@0.5:0.95 (Average Sensitivity in the Range of IoU 0.5–0.95) (Boxes)	0.963	0.961	0.945	0.931
Precision (Boxes)	0.999	0.998	0.999	0.999
Recall (Boxes)	1.000	1.000	1.000	1.000
F1-Score (Boxes)	1.000	0.999	1.000	1.000
mAP@0.5 (Masks)	0.995	0.995	0.995	0.995
mAP@0.5:0.95 (Masks)	0.967	0.970	0.969	0.939
Precision (Masks)	0.999	0.998	0.999	0.999
Recall (Masks)	1.000	1.000	1.000	1.000
F1-Score (Masks)	1.000	0.999	1.000	1.000
Preprocessing Time (ms) (test)	2.13 ms	2.10 ms	4.87 ms	6.39 ms
Inference Time (ms) (test)	10.31 ms	25.07 ms	24.82 ms	10.83 ms
Post-processing Time (ms) (test)	3.51 ms	3.05 ms	4.29 ms	3.70 ms

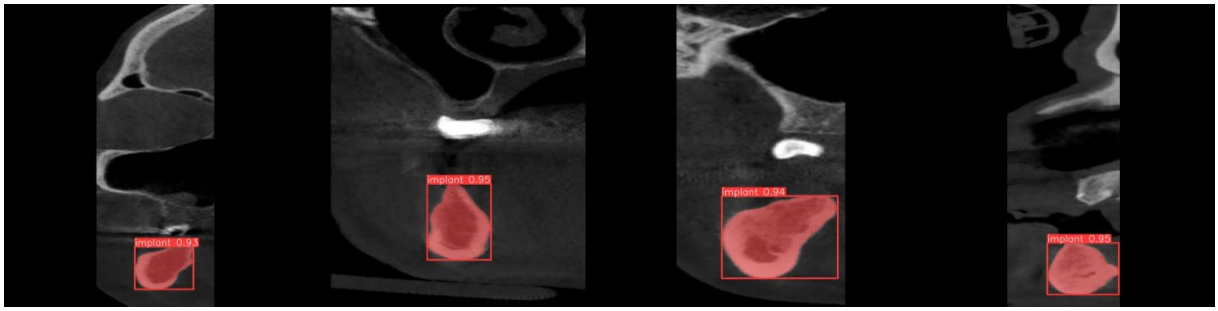

Figure 1. Sample dental implant segmentation results.

Figure 1 presents the results of the dental implant segmentation study. The figure illustrates the detection and masking of implants in different dental tomography slices using a YOLO-based segmentation model. The red boxes denote the bounding boxes of the detected implants, whereas the red overlay mask represents the segmented implant regions. The numerical values displayed on the boxes (e.g., 0.93) indicate the confidence scores corresponding to the model's predictions. Overall, these outputs demonstrate that the model achieves successful performance in both detection and segmentation.

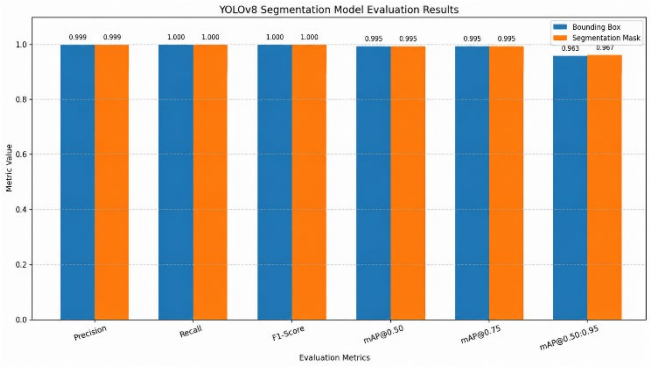

Figure 2. YOLOv8 segmentation results.

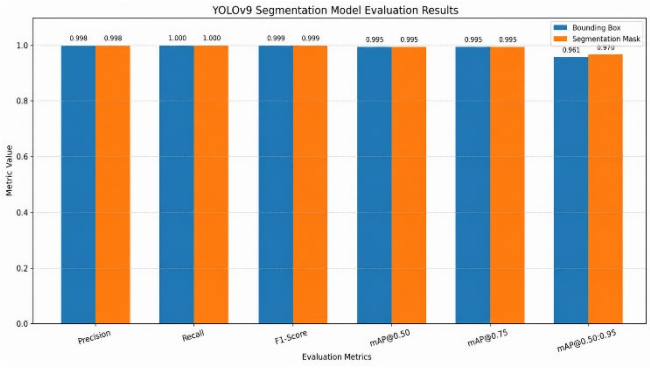

Figure 3. YOLOv9 segmentation results.

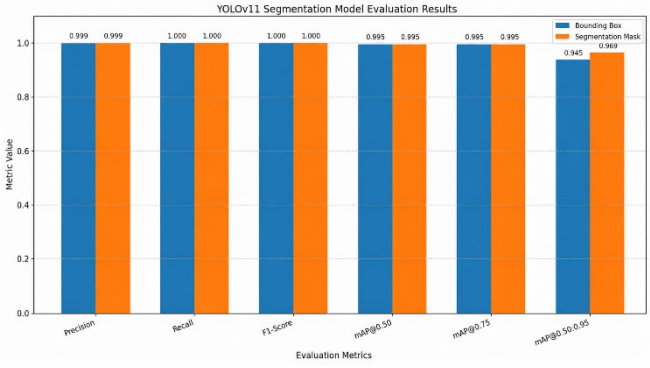

Figure 4. YOLOv11 segmentation results.

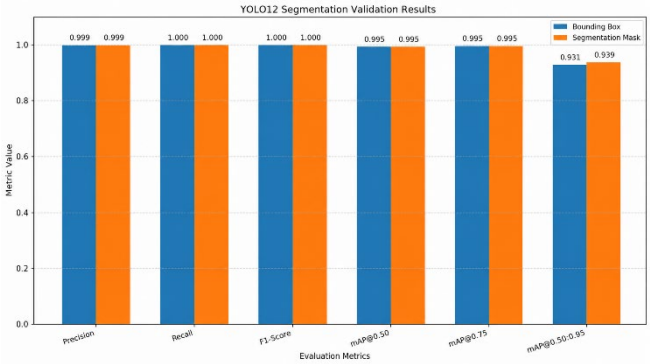

Figure 5. YOLOv12 segmentation results.

Figures 2–5 present the bounding-box and segmentation-mask metrics obtained by YOLOv8, YOLOv9, YOLOv11, and YOLOv12, respectively, on the independent test set. All models achieved similarly high precision, recall, F1 Score, and mAP@0.50. The principal differences between the models emerged for mAP@0.50:0.95, which incorporates more stringent overlap thresholds. Figure 2 shows that YOLOv8 achieved the best localization performance, with a bounding-box mAP@0.50:0.95 of 0.962750, while also providing the highest processing speed. Figure 3 demonstrates that YOLOv9 achieved the highest segmentation performance, with a mask mAP@0.50:0.95 of 0.970460. Figure 4 shows that YOLOv11 attained a mask mAP@0.50:0.95 of 0.969176, closely approaching YOLOv9, although its inference time was longer. Figure 5 indicates that YOLOv12 preserved high precision and perfect recall and operated at a speed comparable to YOLOv8; however, its bounding-box and mask mAP@0.50:0.95 values of 0.930811 and 0.938581, respectively, reflect lower localization performance under stringent overlap thresholds than the other evaluated models.

V. CONCLUSION

In this study, a comparative performance analysis of YOLOv8, YOLOv9, YOLOv11, and YOLOv12 was conducted for dental implant segmentation, and the findings demonstrated that each model offers distinct advantages in terms of accuracy and computational speed. The fact that all four models achieved an mAP@0.50 of 0.995 for both bounding boxes and segmentation masks and a recall of 1.000 indicates highly reliable implant detection on the test set. For the more discriminative mAP@0.50:0.95 metric, YOLOv8 achieved the highest bounding-box localization performance (0.962750), whereas YOLOv9 achieved the highest pixel-level segmentation performance for masks (0.970460). YOLOv11 attained a mask mAP@0.50:0.95 of 0.969176, closely approaching YOLOv9, but remained slower, with an inference time of 24.824682 ms and a total processing time of 34.000603 ms per image. YOLOv12 achieved a precision of 0.999062, a recall of 1.000, an F1-score of 0.999531, and approximately 92.324 FPS with an inference time of 10.831413 ms; however, its bounding-box and mask mAP@0.50:0.95 values were lower at 0.930811 and 0.938581, respectively.

YOLOv8's inference time of 10.309349 ms, total processing time of 15.968530 ms per image, and throughput of approximately 96.999 FPS indicate that it provides the most balanced option for clinical scenarios in which accuracy and real-time operation must be optimized jointly. Accordingly, YOLOv9 may be preferred in research and detailed analytical applications where maximum mask segmentation accuracy is prioritized, whereas YOLOv8 is more suitable when speed, bounding-box accuracy, and overall computational efficiency

must be considered together. From clinical and academic perspectives, the study contributes to strengthening decision-support systems, reducing variability associated with manual analysis, and providing a methodological framework that can be adapted to other medical imaging problems.

Abstract
This study presents the development and implementation of a data-driven physiotherapy recommender system empowered by machine learning. The system serves as a clinical decision-support tool for patients with arthritis, providing personalized exercise recommendations based on structured clinical parameters. The dataset was sourced from MIMIC-IV (Medical Information Mart for Intensive Care, Version 2.2), a large de-identified electronic health records database. It comprised 25,225 arthritis-related clinical encounter records representing 15,160 distinct patients. Diagnosis-based severity classification was applied to derive patient profiles, and exercise recommendation labels were assigned using evidence-based guidelines adapted from the American College of Rheumatology (ACR) and the Centers for Disease Control and Prevention (CDC). The resulting labeled dataset was partitioned into a training set of 20,180 records (80%) and a held-out test set of 5,045 records (20%) using stratified random sampling. A Random Forest Classifier with 200 decision trees was trained using six clinical features: age, sex, arthritis type, pain severity, mobility limitation, and use of a walking aid. The model achieved 100% accuracy and a macro AUC-ROC of 1.0000 across four exercise recommendation classes on the held-out test set. In addition, 20 representative system-generated recommendations were independently reviewed by a rehabilitation expert, and all were judged clinically appropriate. The system was deployed as a responsive Flask web application that provided personalized recommendations incorporating exercise type, frequency, intensity, and safety guidance. The high classification performance primarily reflects the deterministic nature of the rule-based label assignment and demonstrates the model's ability to reproduce the predefined recommendation logic rather than clinical effectiveness. Future work should validate the recommendations using prospectively collected, independently clinician-assigned labels and patient outcomes.

Keywords: Physiotherapy, Recommender System, Arthritis, Machine Learning, Electronic Health Records, MIMIC-IV, Healthcare, Personalized Exercise Recommendation

I. INTRODUCTION

Physiotherapy is a crucial component of rehabilitative healthcare, employing tailored exercise programs and specialized tools to address abnormal physical function. It addresses various health issues, including back pain, arthritis, osteoporosis, and nerve-related ailments [1]. Globally, approximately 2.4 billion people require rehabilitation [2], yet there is a substantial unmet need for these services, particularly in regions such as Nigeria, where the density of physiotherapists is alarmingly low [3], [4]. In Nigeria, the need for qualified physiotherapists, combined with economic constraints, limits access to quality physiotherapy services. The ratio of physiotherapists per population is critically low compared to developed countries, exacerbating the problem [3]. As a result, many individuals with potentially manageable conditions do not receive timely and effective treatment, leading to worsening health outcomes and increased healthcare costs. Arthritis is a disease that causes damage to your joints [5]. It is a common and debilitating condition that affects millions of people worldwide and significantly impairs quality of life. Effective management of arthritis often requires personalized exercise regimens tailored to alleviate specific symptoms [6], [7], [8], [9]. The current approach to physiotherapy in Nigeria typically relies on manual assessments and generalized treatment plans, often lacking the customization needed to address individual patient needs effectively. This traditional method is hampered by a lack of data-driven solutions, making it challenging to provide personalized care. Without integrating advanced technologies and data analytics, physiotherapy services remain largely one-size-fits-all, which may be ineffective for all patients, particularly those with complex or chronic conditions such as arthritis [10]. The development of a physiotherapy recommender system can bridge this gap by offering personalized exercise recommendations based on structured clinical parameters derived from patient health records [11], [12], [13], [14]. By leveraging machine learning and data analysis, such a system can enhance the precision and effectiveness of physiotherapy, ensuring that patients receive the most appropriate exercises for their specific conditions [15], [16], [17], [18]. The goal of this project is to create and implement a data-driven recommendation system for physical therapy, especially suited to people with arthritis. The technology uses machine learning algorithms trained on large-scale electronic health records to evaluate patient clinical profiles and provide tailored exercise recommendations. Enhancing patient outcomes, expanding access to efficient physiotherapy, and making the best use of the limited resources available to the healthcare industry are the goals of this research. To ensure the system meets the needs of both patients and healthcare providers, the study focuses on its design, development, and evaluation. This strategy not only addresses the immediate needs of arthritis patients but also advances broader initiatives to improve healthcare delivery in resource-constrained settings.

II. RELATED WORKS

By providing personalized exercise plans, Physiotherapy Recommender Systems (PRSs) have become increasingly significant in improving the care of patients with arthritis. These systems incorporate technologies such as fuzzy logic [17], [19], machine learning [15], [18], [20], [21], [22], and sensor data analysis [23], [24] to make such recommendations. Several important strategies and limitations are highlighted by a review of previous research, which is what this study aims to address. Fuzzy logic was employed in the early PRS implementations to suggest physical rehabilitation activities for stroke victims [17]. When dealing with uncertainty in patient-reported data—where symptoms aren't always well-defined—fuzzy logic was especially well-suited. These systems are difficult to create and improve, and the accuracy of their data is highly dependent on its quality. Inaccurate or incomplete patient profiles frequently led to inadequate exercise recommendations and unsatisfactory outcomes. Exercise recommendations are becoming increasingly personalized thanks to the growing use of machine learning techniques. For example, one study developed exercise programs using a multi-output regression model based on clinical information and patient-reported symptoms [18]. Although this approach made workouts more personalized, it faced challenges with scalability and real-time feedback. Subjectivity further affected the

consistency of the suggestions in patient-reported data. Another study used clinical evaluations and physical activity logs to create personalized exercise regimens for people with osteoarthritis using machine learning algorithms [15]. The method was constrained by a small sample size and a lack of long-term evaluation, despite showing improvements in pain management and physical function. To enhance real-time feedback and adherence tracking, some PRSs have combined machine learning with wearable sensor data [23]. These technologies provide real-time feedback on patient activities and tailored workout recommendations by evaluating sensor data. This strategy increased adherence rates and reduced pain. Still, it was difficult to fully evaluate its long-term effectiveness due to the studies' short intervention periods and the absence of control groups. Drug Recommender Systems (DRSs), which incorporate feedback mechanisms and characteristics relevant to individual patients, have also added to the body of knowledge. To deliver prescription recommendations based on patient profiles, DRSs frequently use machine-learning techniques like sentiment analysis and clustering [16]. Nevertheless, many DRSs fall short of incorporating real-time user feedback or considering age and prior medical conditions. As a result, more patient-centric PRSs with real-time symptom monitoring and feedback systems have been created. This work aims to overcome these constraints by creating a PRS that uses a Random Forest model to provide arthritis patients with tailored exercise recommendations. Compared to previous models, Random Forest has numerous advantages: it combines multiple decision trees to improve accuracy; it is robust by minimizing overfitting; and it handles missing data well. The flexibility of Random Forest enables reliable predictions and rankings of feature importance, which help identify the most influential clinical variables for exercise recommendations. This study directly addresses the scalability and data quality challenges that have hampered earlier systems by training and evaluating the model on a large-scale, real-world EHR dataset of 25,225 clinical records sourced from the MIMIC-IV database, substantially exceeding the sample sizes reported in prior work.

III. MATERIALS AND METHODS

This section describes the development process for the Physiotherapy Recommender System for patients with arthritis. It discusses the machine learning model's development, the datasets used, the system design, and the implementation environment. The strategy used ensures the system's dependability and functionality while providing precise exercise recommendations tailored to each patient's needs. Every part of the system, including data collection, preprocessing, model training, and evaluation, is covered in detail.

1. System Design

The study follows a well-defined architecture, as depicted in Figure 1, to provide exercise recommendations for patients with arthritis efficiently. The central components of this architecture include the User Interface (UI), Web Application, Machine Learning Model, and Data Management.

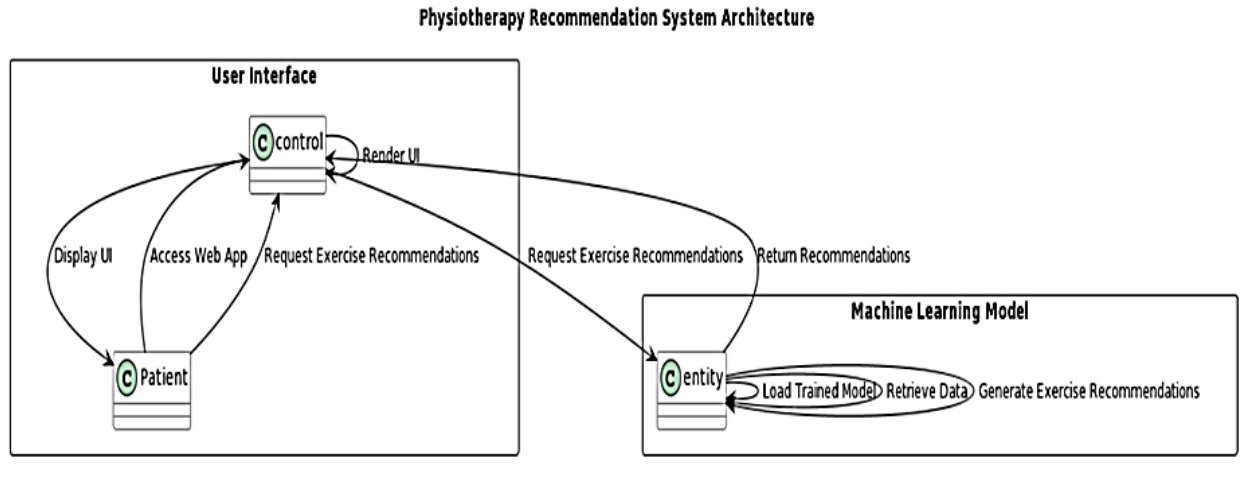

Figure 1. General Architecture for the Physiotherapy Recommender System

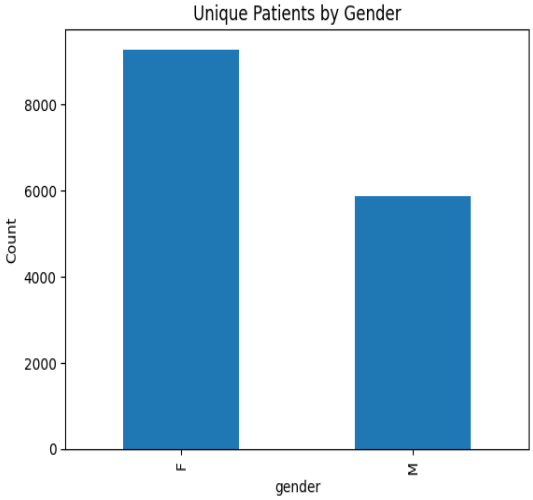
The User Interface serves as the front-end platform through which users interact with the system, presenting a structured clinical parameter input form and displaying personalized exercise recommendations. The Web Application serves as the intermediary, receiving user input and passing it to the Machine Learning Model. The core of the system is the Machine Learning Model, which uses a trained Random Forest Classifier to process clinical parameters and generate personalized exercise recommendations. The Data Management component ensures that model artifacts are efficiently persisted and loaded at application startup. This architecture harmonizes user interaction, data processing, and machine learning capabilities to deliver tailored exercise recommendations for individuals with arthritis, streamlining the process from clinical input to meaningful output.



2. Dataset

The dataset used in this study was sourced from MIMIC-IV (Medical Information Mart for Intensive Care, Version 2.2), a large, de-identified electronic health records (EHR) database maintained by the Beth Israel Deaconess Medical Center (BIDMC) and publicly available through PhysioNet [25]. MIMIC-IV contains records for patients admitted to the BIDMC emergency department and intensive care units. Version 2.2 of the dataset used for this study comprises 431,231 records from patient admissions. These records are for 299,712 distinct patients with various ailments such as arthritis, diabetes, hypertension, peptic ulcer disease, mental disorders, neoplasms, etc. From this study, 25,225 admission records corresponding to 15,160 distinct patients with arthritis-related diagnoses were extracted. These records span 20 distinct arthritis variants, with the most prevalent being unspecified osteoarthritis (n = 7,879), rheumatoid arthritis (n = 7,029), and primary osteoarthritis of the knee and hip (n = 4,549). Exercise recommendation labels were not natively available in MIMIC-IV; they were derived using evidence-based labeling rules adapted from the Osteoarthritis Initiative (OAI) guidelines published by the ACR and CDC. Data Collection: Records were extracted from MIMIC-IV for all patients carrying a primary or secondary arthritis diagnosis. Each record provided patient age, sex, and ICD-10-coded diagnosis strings. The dataset comprised 25,225 arthritis-related clinical encounter records obtained from 15,160 distinct patients. Because the data were collected during routine hospital visits, some patients contributed multiple records for different clinical encounters. Each record was treated as an individual clinical encounter for the recommendation modeling task. The analysis of the dataset for patients diagnosed with arthritis is as follows:

i. Gender Distribution: A total of 9,279 females and 5,881 males were admitted for arthritis. The total number of admissions was 16272, with 8953 for females and 7319 for males. The numbers of males and females diagnosed with arthritis are shown in Figure 2.

ii. Age Distribution: Figure 3 shows that the average patient age is approximately 66 years, consistent with literature indicating that arthritis is elderly-dominated [5]. The standard deviation of the age distribution is approximately 15, indicating that patients are moderately spread across age groups. Not every patient is elderly, but most are clustered around older adults. The youngest patient in the dataset is 18 years old, and the oldest is 91 years old. This further indicates that the dataset includes only adults (no pediatric patients). The figure also shows that most patients are over 50 years of age, with the largest number in the 66-80 age range. This strongly aligns with the clinical prevalence of arthritis and related musculoskeletal conditions in older adults.

iii. Length of Hospital Stay (Admission Length): Table 1 shows information regarding the length of stay (LOS) per hospital admission. The LOS calculated is for 25,225 admissions. Therefore, every hospital record has a stay duration. The average length of hospital stay is approximately 5 days. This suggests that mostly short-to-moderate hospitalizations.

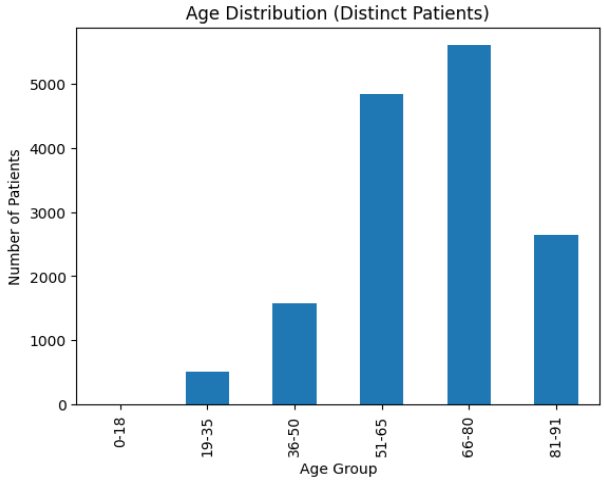


Figure 2. Unique diagnoses by gender, Figure 3. Age Distribution (For Distinct Patients)

Table 1. Length of Hospital Stay

	Length of Hospital Stay
count	25,225
mean	5.35
std	7.69
min	1
25%	1
50%	3
75%	6
max	200

The LOS standard deviation of approximately 8 is quite high relative to the mean. This means that the LOS is highly variable, as some patients stay very short while others stay very long.

25% of patients stay 1 day or less. This can be due to many short admissions, including emergency or observation cases. Half of the patients stay 3 days or less. 75% of patients stay 6 days or less. So most admissions are under a week.

The maximum number of days of stay is 200. This means that some patients stayed approximately 6–7 months. This can be as a result of severe chronic illness, complications, long-term hospitalization in ICU or recovery, etc.

iv. Number of Deaths: 3,450 of the patients diagnosed with arthritis died according to the dataset. This accounts for 22.76% of all arthritis patients. Some of these patients died during admission, others after discharge, and some during home healthcare or at a skilled nursing facility. Figure 4 is a bar chart showing patient survival vs. death. The first bar has the label Alive/Unknown because some of the patients might have died after discharge without the hospital being aware.

To assign exercise labels, each diagnosis was classified into one of five severity tiers—at risk, mild, moderate, moderate-severe, and severe—using keyword-based rules applied to the diagnosis text. Exercise labels, frequency prescriptions, intensity levels, and safety notes were then assigned according to four evidence-based labeling rules (R1–R4) adapted from OAI-style guidelines, as summarized in Table 2. Each rule maps a severity tier to an exercise recommendation, frequency, and intensity prescription.

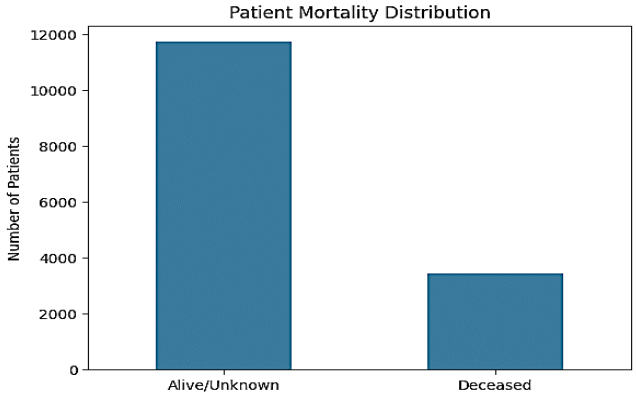

Figure 4. Survival Vs Death Plot

Table 2. Evidence-based exercise labeling rules

Rule	Severity Tier	Input Conditions	Recommended Exercise	Frequency	Intensity
R1	At risk / Mild	Pain: Mild; Mobility: Low; No walking aid	Walking/brisk walking + stretching	20–30 min, 3–5 days/week	Low to moderate

R2	Moderate	Pain: Moderate; Mobility: Moderate	Cycling/walking + light strengthening	20 min, 3 days/week	Low
R3	Moderate-Severe	Pain: Moderate-Severe; Mobility: High	Water exercise + tai chi/balance + gentle strengthening	15–25 min, 2–3 days/week	Low
R4	Severe	Pain: Severe or walking aid = Yes	Supervised aquatic/chair-based exercise + physiotherapy review	10–20 min, 2–3 days/week	Very low to low

Data Preprocessing: The following preprocessing steps were applied to the extracted records:

Severity Classification: Each ICD-10 diagnosis string was mapped to one of five severity tiers using priority keyword rules. Diagnoses containing 'rheumatoid' or 'pyogenic arthritis' map to the severe tier. Diagnoses containing 'bilateral' or 'polyosteoarthritis' map to moderate-severe. Diagnoses containing 'unilateral primary osteoarthritis' or 'primary osteoarthritis' of a specific joint map to moderate. Diagnoses containing 'hyperuricemia without signs of inflammatory arthritis' map to at-risk. All remaining osteoarthritis diagnoses default to mild. Where a record carries multiple diagnoses, the highest-priority tier takes precedence.

Feature Derivation: Six model input features were derived from the MIMIC-IV records: patient age (continuous, years); sex (binary: F/M); arthritis type (categorical: Knee OA, Hip OA, Rheumatoid Arthritis, Other OA, Other), derived from diagnosis keywords; pain severity (ordinal: Mild, Moderate, Moderate-Severe, Severe), derived from severity tier; mobility limitation (ordinal: Low, Moderate, High), derived from severity tier; and use of a walking aid (binary: Yes/No), inferred as 'Yes' for severe-tier patients aged 70 years or above and for moderate-severe-tier patients aged 75 or above, and 'No' otherwise.

Label Assignment: Exercise recommendation labels were assigned using four evidence-based rules (R1–R4). R1 assigns 'Walking/brisk walking + stretching' (20–30 min, 3–5 days/week, low to moderate intensity) to at-risk and mild-tier patients. R2 assigns 'Cycling/walking + light strengthening' (20 min, 3 days/week, low intensity) to moderate-tier patients. R3 assigns 'Water exercise + tai chi/balance + gentle strengthening' (15–25 min, 2–3 days/week, low intensity) to patients in the moderate-to-severe tier. R4 assigns 'Supervised aquatic/chair-based exercise + physiotherapy review' (10–20 min, 2–3 days/week, very low to low intensity) to severe-tier patients. Each rule also specifies a tailored safety note.

The exercise recommendation labels were not directly available in the MIMIC-IV database and were therefore generated using predefined evidence-based rules (R1–R4). These rules derive the recommendation class from clinical characteristics such as pain severity, mobility limitation, and walking-aid status. Several of these characteristics are also included among the model input features. Therefore, the resulting machine-learning task evaluates the Random Forest's ability to reproduce the predefined rule-based recommendation logic rather than predict independently observed clinical outcomes.

Feature Encoding: Categorical features were encoded using a deterministic ordinal scheme: pain severity (Mild = 0, Moderate = 1, Moderate-Severe = 2, Severe = 3), mobility limitation (Low = 0, Moderate = 1, High = 2), sex (F = 0, M = 1), and walking aid use (No = 0, Yes = 1). Age was retained as a continuous numeric feature. The exercise label was encoded as an integer class index (0–3) corresponding to rules R1–R4, respectively.

Data Partitioning: The full dataset of 25,225 clinical encounter records (admissions records) was partitioned into a training set of 20,180 records (80%) and a held-out test set of 5,045 records (20%) using stratified random sampling to preserve the distribution of the four exercise recommendation classes. The partitioning was performed at the clinical encounter-record level, consistent with the modeling unit used in this study. Because some patients contributed multiple hospital encounter records, records belonging to the same patient could potentially occur in both the training and test subsets. Therefore, the held-out test set represents unseen clinical encounter records rather than exclusively unseen patients. This distinction is important when interpreting model performance, particularly with respect to generalization to new patients.

The four exercise classes in the training set are distributed as follows: Walking/brisk walking + stretching (n = 7,680), Supervised aquatic/chair-based exercise + physiotherapy review (n = 7,398), Cycling/walking + light strengthening (n = 3,914), and Water exercise + tai chi/balance + gentle strengthening (n = 1,188). Class-weight balancing was applied during model training to account for this imbalance.

This stratified partitioning ensures that the model is evaluated on genuinely unseen patient records and that minority exercise classes are adequately represented in both training and evaluation.

3. Exercise Recommender Model Formulation

The Random Forest Classifier [26], which forms the machine learning component, is encapsulated in the PhysioPredictor class. This model is well-suited to multi-class classification problems such as mapping a patient's clinical profile to an appropriate exercise recommendation. During training, the algorithm builds an ensemble of 200 decision trees, each trained on a random bootstrap sample of the data with a random subset of features considered at each node split. The majority vote across all trees determines the final class prediction, reducing variance and improving generalization relative to a single decision tree.

Mathematical Method:

Given a set of training examples $(x1,y1),(x2,y2),\ldots,(xn,yn)$ where xi represents the feature vector (symptoms) and yi represents the output, which is the exercise recommendation:

Bootstrap Sampling: Randomly select a subset of the training data with replacement.

Decision Tree Construction: For each bootstrap sample, a decision tree hk(x) is grown using a random subset of features at each node.

Voting: Each tree hk(x) in the forest gives a prediction, and the final output f(x) is determined by majority voting:

$$f(x) = \text{mode}\{h1(x), h2(x)\ldots, hB(x)\}$$

where B is the total number of trees in the forest.

The PhysioPredictor class encapsulates the machine learning component. Upon instantiation, it loads the serialized model artifact from disk. The class exposes a single predict() method that accepts six clinical parameters—age, sex, arthritis type, pain severity, mobility limitation, and use of a walking aid—encodes them deterministically, and returns the predicted exercise label together with its associated frequency, intensity, and safety note.

IV. RESULTS AND DISCUSSION

The updated Physiotherapy Recommender System features a structured clinical input form through which users enter six parameters: age, sex, arthritis type, pain severity, mobility limitation, and use of a walking aid. Based on these inputs, the system generates a personalized exercise recommendation in real time, along with the recommended frequency and intensity level, and a safety note tailored to the patient's severity profile. The updated interface replaces the original symptom-checkbox approach with validated clinical dropdowns, improving clinical relevance and enabling use of the substantially larger MIMIC-IV dataset. The system is deployed as a live web application accessible at: https://kareemadesola-physio-recommender.hf.space. By presenting inputs in structured clinical terms and providing multi-faceted recommendations, the system supports both patients and caregivers in selecting appropriate exercise regimens. The real-time recommendation engine, combined with severity-stratified safety guidance, ensures that users receive clinically aligned advice appropriate to their condition severity. The user-friendly design ensures that patients, regardless of technical literacy, can interact effectively with the system. Inputs such as walking aid use and mobility limitation help stratify patients accurately, and the system's output explicitly includes frequency and intensity alongside safety warnings, promoting safe adherence to the prescribed exercise plan.

1. System Interface

The system presents users with a structured clinical input form comprising six patient parameters: age (in years), biological sex (Female/Male), arthritis type (Knee OA, Hip OA, Rheumatoid Arthritis, Other OA, or Other), pain severity (Mild, Moderate, Moderate-Severe, or Severe), mobility limitation (Low, Moderate, or High), and use of a walking aid (Yes/No). Each parameter maps directly to an input feature of the trained Random Forest Classifier. Dropdown menus and radio buttons are used for categorical inputs to ensure data entry consistency and minimize user error. Upon form submission, the system immediately returns a personalized exercise recommendation comprising the exercise type, recommended frequency, intensity level, and a severity-stratified safety note. The interface is built with Bootstrap 5 and is fully responsive on desktop and mobile devices. Figure 5 shows the clinical input form, and Figure 6 shows a sample recommendation output for a 72-year-old female patient with Rheumatoid Arthritis (severe pain, high mobility limitation, uses a walking aid), for whom the system recommends supervised aquatic/chair-based exercise at 10–20 minutes, 2–3 days per week, at very low to low intensity.

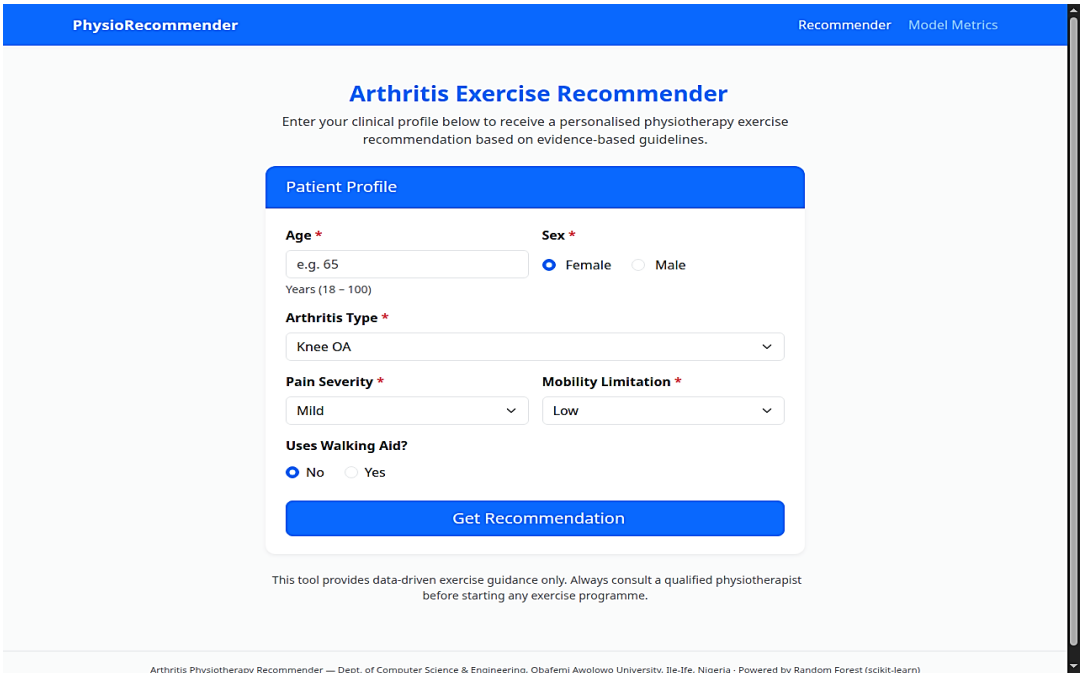

Figure 5. The PhysioReco clinical input form

2. System Output

The system generates exercise recommendations based on the six clinical inputs provided, as seen in Figures 5 and 6. For example, a 72-year-old female with Rheumatoid Arthritis, severe pain, high mobility limitation, and use of a walking aid receives a recommendation for 'Supervised aquatic/chair-based exercise + physiotherapy review' at a frequency of 10–20 minutes, 2–3 days per week, at very low to low intensity, with a safety note advising clinical review before initiating an independent program. A 55-year-old male with Knee Osteoarthritis, mild pain, and low mobility limitation receives 'Walking/brisk walking + stretching' at 20–30 minutes, 3–5 days per week, at low to moderate intensity. A 63-year-old female with Hip Osteoarthritis, moderate pain, and moderate mobility limitation receives 'Cycling/walking + light strengthening' at 20 minutes, 3 days per week. A 70-year-old female with bilateral Knee OA, moderate-to-severe pain, and significant mobility limitation receives 'Water exercise + tai chi/balance + gentle strengthening' for 15–25 minutes, 2–3 days per week. These examples demonstrate the system's capacity to distinguish among four clinically meaningful exercise classes along the OA severity spectrum. The results confirm the system's capacity to map structured clinical inputs to appropriate, severity-stratified exercise recommendations. The four exercise classes reflect a clinically ordered spectrum from low-impact aerobic activity for mild cases to fully supervised aquatic and chair-based therapy for severe cases. Transitioning from symptom-checkbox input to structured clinical parameters substantially improves the specificity, clinical interpretability, and scalability of the recommendation pipeline.

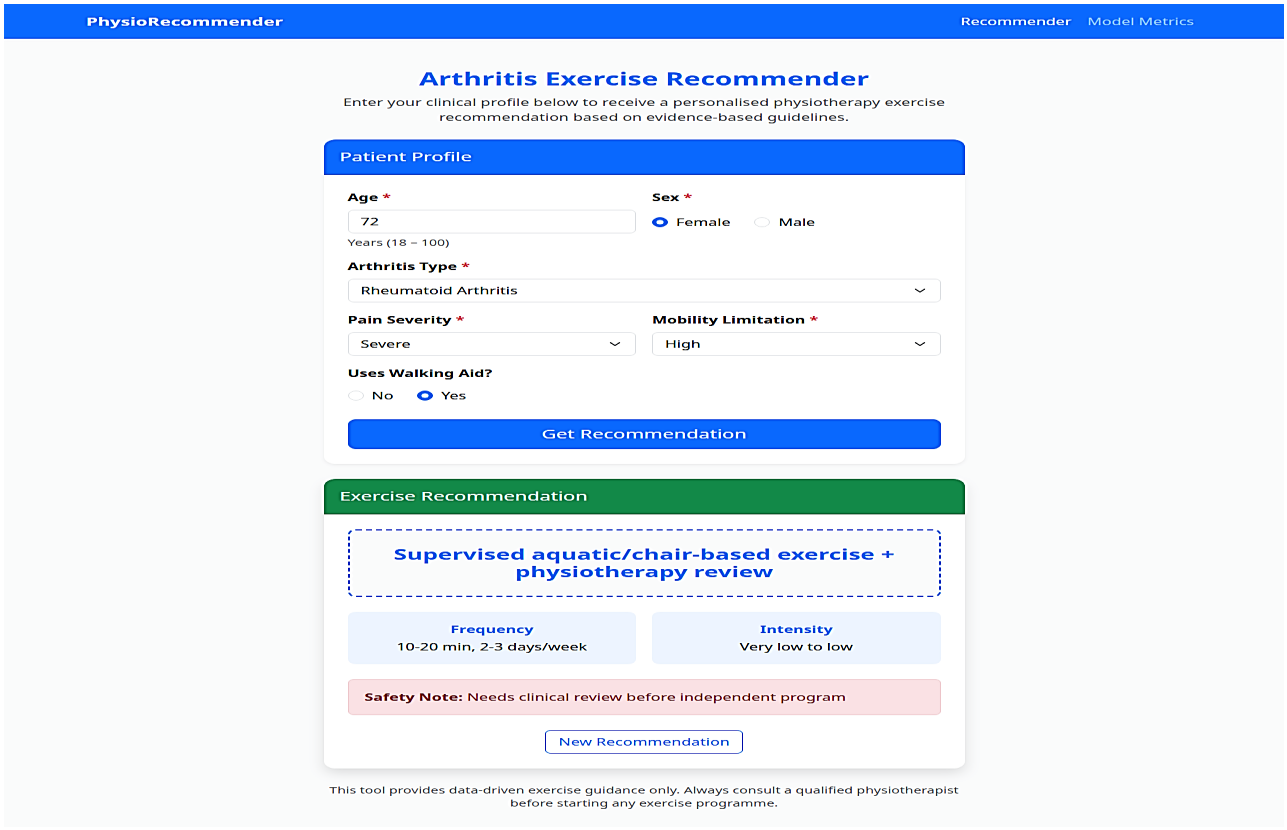

Figure 6. PhysioReco Output

3. System Testing and Validation

The system was evaluated on a held-out test set of 5,045 records (20% of the total 25,225-record dataset), selected using stratified random sampling to maintain the class distribution of the training data. A confusion matrix was computed across all four exercise recommendation classes [27], and AUC-ROC was computed using a one-vs-rest macro-averaged approach, as recommended for multi-class classification [28]. The normalized confusion matrix is presented in Figure 7. The rows represent the actual classes, while the columns represent the classes predicted by the Random Forest model. All diagonal entries have a value of 1.00, whereas all off-diagonal entries have a value of 0.00. This indicates that every test record was assigned to its correct exercise class, with no misclassifications across the four categories. The per-class classification report is summarised in Table 3. The per-class test support was: Walking/brisk walking + stretching (n = 1,920), Cycling/walking + light strengthening (n = 978), Water exercise + tai chi/balance + gentle strengthening (n = 297), and Supervised aquatic/chair-based exercise + physiotherapy review (n = 1,850). The model achieved 100% accuracy, with a precision, recall, and F1-score of 1.0000 across all four recommendation classes. However, this result must be interpreted in the context of the label-generation procedure. The exercise recommendation labels were deterministically generated using predefined evidence-based rules, and several variables used in these rules were also included as model input features. Therefore, the classification task primarily assesses the Random Forest's ability to reproduce the predefined recommendation logic. The 100% accuracy demonstrates complete agreement between the model predictions and the rule-derived labels in the held-out evaluation records. Still, it does not establish that the model can predict independently observed clinical outcomes with perfect accuracy or that the recommendations are clinically effective.

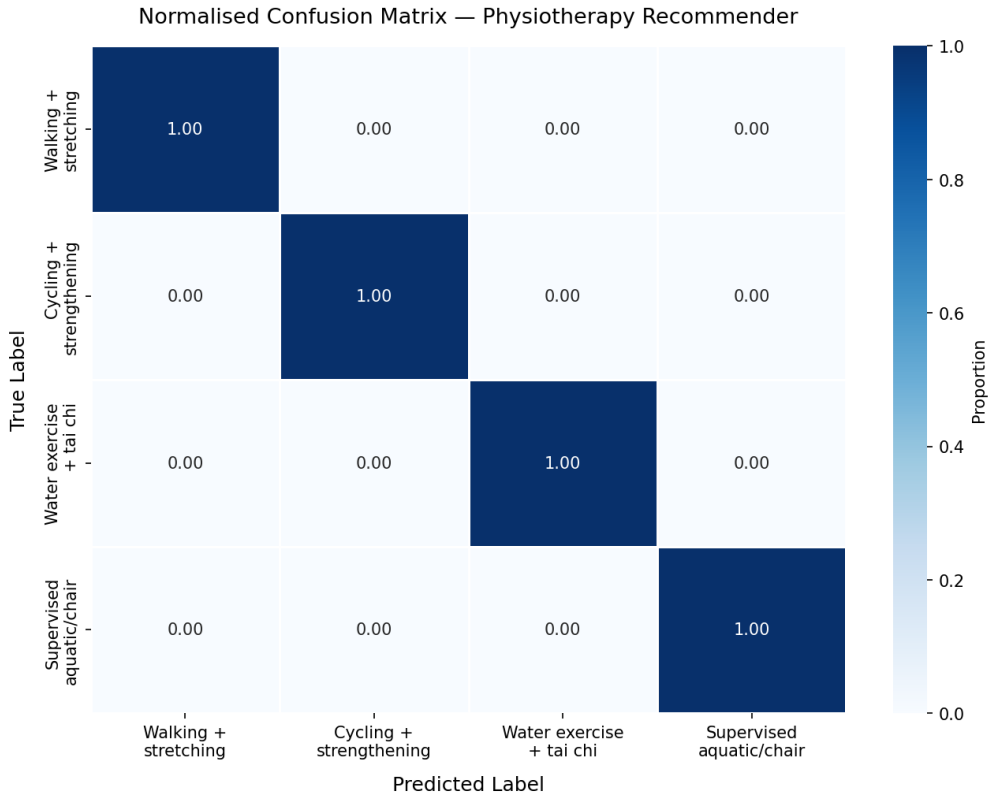

Figure 7. Normalized Confusion Matrix

Table 3. Exercise classification report evaluated

Exercise Class	Precision	Recall	F1-Score	Support (n)
Walking/brisk walking + stretching	1.0000	1.0000	1.0000	1,920
Cycling/walking + light strengthening	1.0000	1.0000	1.0000	978
Water exercise + tai chi/balance + gentle strengthening	1.0000	1.0000	1.0000	297
Supervised aquatic/chair-based exercise + physiotherapy review	1.0000	1.0000	1.0000	1,850
Macro Average	1.0000	1.0000	1.0000	5,045

4. Clinical Validation of Exercise Recommendations

To provide an independent clinical assessment of the recommendations generated by the PhysioReco system, an author with expertise in medical rehabilitation conducted a clinical validation exercise. The purpose of the validation was to determine whether the exercise recommendations generated by the system were clinically appropriate and consistent with established rehabilitation principles for patients presenting with different arthritis characteristics and levels of functional limitation. This assessment was conducted separately from the machine-learning performance evaluation because the 100% classification accuracy reported in the preceding section reflects agreement with rule-derived labels and does not, by itself, establish clinical appropriateness or effective-

ness. Twenty representative patient profiles were generated from the system using combinations of the six clinical input variables: age, sex, arthritis type, pain severity, mobility limitation, and use of a walking aid. The profiles were selected to cover the range of arthritis types and severity categories represented by the four exercise recommendation classes. Each profile was entered into the deployed PhysioReco system, and the rehabilitation expert independently reviewed the resulting recommendation, frequency, intensity, and safety guidance. The clinical validation results are presented in Table 4. Each recommendation was assessed as either clinically appropriate or inappropriate, with the option to provide comments when modification was deemed necessary. The rehabilitation expert judged all 20 reviewed recommendations to be clinically appropriate, corresponding to an expert agreement rate of 100% (20/20). The expert assessment, therefore, provided preliminary evidence that the system-generated recommendations were clinically plausible and appropriately aligned with the severity and functional characteristics of the reviewed cases. This assessment is complementary to the computational evaluation. Whereas the latter assesses reproduction of the rule-derived labels, the clinical review assesses the appropriateness of the resulting recommendations from a rehabilitation perspective.

Table 4. Clinical Validation of PhysioReco Recommendations by a Rehabilitation Expert

Case	Age	Sex	Arthritis Type	Pain Severity	Mobility Limitation	Walking Aid	System-Generated Recommendation	Expert Assessment
1	55	Male	Knee OA	Mild	Low	No	Walking/brisk walking + stretching; 20–30 min, 3–5 days/week; low–moderate intensity	Appropriate
2	61	Female	Knee OA	Mild	Low	No	Walking/brisk walking + stretching; 20–30 min, 3–5 days/week; low–moderate intensity	Appropriate
3	58	Female	Hip OA	Mild	Low	No	Walking/brisk walking + stretching; 20–30 min, 3–5 days/week; low–moderate intensity	Appropriate
4	66	Male	Other OA	Mild	Low	No	Walking/brisk walking + stretching; 20–30 min, 3–5 days/week; low–moderate intensity	Appropriate
5	63	Female	Knee OA	Moderate	Moderate	No	Cycling/walking + light strengthening; 20 min, 3 days/week; low intensity	Appropriate
6	68	Male	Hip OA	Moderate	Moderate	No	Cycling/walking + light strengthening; 20 min, 3 days/week; low intensity	Appropriate
7	59	Female	Other OA	Moderate	Moderate	No	Cycling/walking + light strengthening; 20 min, 3 days/week; low intensity	Appropriate
8	72	Female	Knee OA	Moderate	Moderate	No	Cycling/walking + light strengthening; 20 min, 3 days/week; low intensity	Appropriate
9	70	Female	Knee OA	Moderate-Severe	High	No	Water exercise + tai chi/balance + gentle strengthening; 15–25 min, 2–3 days/week; low intensity	Appropriate

10	74	Male	Hip OA	Moder-ate-Se-vere	High	No	Water exercise + tai chi/balance + gentle strengthening; 15–25 min, 2–3 days/week; low intensity	Ap-pro-priate
11	67	Fe-male	Other OA	Moder-ate-Se-vere	High	No	Water exercise + tai chi/balance + gentle strengthening; 15–25 min, 2–3 days/week; low intensity	Ap-pro-priate
12	75	Fe-male	Knee OA	Moder-ate-Se-vere	High	Yes	Water exercise + tai chi/balance + gentle strengthening; 15–25 min, 2–3 days/week; low intensity	Ap-pro-priate
13	72	Fe-male	Rheu-matoid Arthritis	Severe	High	Yes	Supervised aquatic/chair-based exercise + physiotherapy review; 10–20 min, 2–3 days/week; very low–low intensity	Ap-pro-priate
14	78	Male	Rheu-matoid Arthritis	Severe	High	Yes	Supervised aquatic/chair-based exercise + physiotherapy review; 10–20 min, 2–3 days/week; very low–low intensity	Ap-pro-priate
15	70	Fe-male	Rheu-matoid Arthritis	Severe	High	Yes	Supervised aquatic/chair-based exercise + physiotherapy review; 10–20 min, 2–3 days/week; very low–low intensity	Ap-pro-priate
16	81	Fe-male	Knee OA	Severe	High	Yes	Supervised aquatic/chair-based exercise + physiotherapy review; 10–20 min, 2–3 days/week; very low–low intensity	Ap-pro-priate
17	76	Male	Hip OA	Severe	High	Yes	Supervised aquatic/chair-based exercise + physiotherapy review; 10–20 min, 2–3 days/week; very low–low intensity	Ap-pro-priate
18	64	Fe-male	Rheu-matoid Arthritis	Severe	High	Yes	Supervised aquatic/chair-based exercise + physiotherapy review; 10–20 min, 2–3 days/week; very low–low intensity	Ap-pro-priate
19	69	Male	Knee OA	Moder-ate-Se-vere	High	No	Water exercise + tai chi/balance + gentle strengthening; 15–25 min, 2–3 days/week; low intensity	Ap-pro-priate
20	73	Fe-male	Hip OA	Moder-ate	Moder-ate	No	Cycling/walking + light strength-ening; 20 min, 3 days/week; low intensity	Ap-pro-priate

5. Model Performance and Recommendations

The Random Forest Classifier was configured with 200 decision trees, balanced class weights (to account for the imbalanced distribution across exercise classes), and a fixed random seed (42) for full reproducibility. The model was trained on 20,180 records using six input features: age, sex, arthritis type, pain severity, mobility limitation, and use of a walking aid. Feature importance analysis (Figure 8) reveals that pain severity was the

most influential feature in reproducing the rule-based exercise recommendation classes, accounting for approximately 47% of the total feature importance, followed by mobility limitation at approximately 34%. Arthritis type contributed approximately 16%, while walking-aid use had a comparatively small contribution. Age and sex had minimal influence on the classification outcome. These findings indicate that the model primarily distinguished among the four exercise recommendation classes using the severity and functional-status variables. This pattern is consistent with the labeling framework, in which pain severity and mobility limitation were the principal factors used to allocate patients to progressively more supported exercise interventions. The dominance of pain severity and mobility limitation is clinically understandable because these variables directly reflect a patient's capacity to participate safely in physical activity. Patients with mild pain and low mobility restrictions were generally assigned walking, stretching, and low- to moderate-intensity exercises. In contrast, those with severe pain or high mobility restriction were assigned supervised aquatic or chair-based exercises. Their high feature-importance values therefore confirm that the Random Forest reproduced the predetermined labeling logic rather than proving that these variables are independently the strongest predictors of successful physiotherapy outcomes. The model's performance on the MIMIC-IV-derived dataset represents a substantial advance over the original 30-record prototype, which was too small for statistically meaningful evaluation. The current model was trained on 20,180 clinical encounter records and evaluated on 5,045 held-out encounter records, providing an assessment of classification fidelity at the clinical encounter level. The shift from symptom-severity weights to structured clinical features (arthritis type, pain severity, mobility limitation) also improves the clinical interpretability of the model's decision boundaries. It aligns the recommendation logic with internationally recognized arthritis management guidelines.

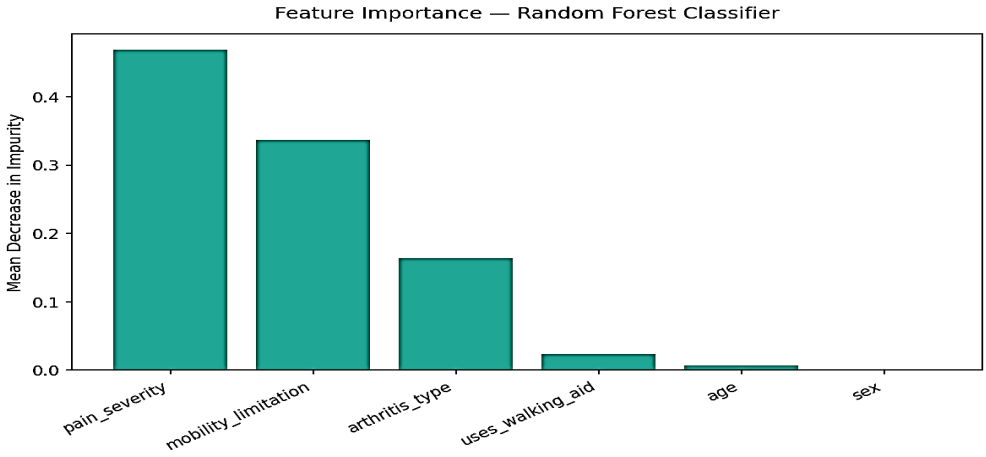

Figure 8. Feature Importance scores

V. CONCLUSION AND RECOMMENDATION

The Arthritis Physiotherapy Recommender System presents a scalable, data-driven tool for personalized exercise guidance for patients with arthritis. Built on 25,225 de-identified clinical records (distinct admission records) from the MIMIC-IV database and trained using evidence-based exercise labeling rules adapted from ACR and CDC guidelines, the system demonstrates that a Random Forest Classifier can reliably learn and replicate structured clinical decision logic for exercise prescription across four clinically ordered recommendation classes. The model achieved perfect accuracy and AUC-ROC on a 5,045-record held-out test set, and the system is deployed as a responsive Flask web application that provides real-time recommendations, including exercise type, frequency, intensity, and safety guidance. While the deterministic nature of the rule-based labeling scheme limits

the independence of the current evaluation, the architecture—which uses a large, real-world EHR dataset and validated clinical guidelines—provides a robust foundation for future work that incorporates prospectively labeled clinical data, richer feature sets, and real-world validation in clinical practice. The result confirms that the implementation correctly captures the intended decision rules, but further evaluation using prospectively collected, clinician-labeled data is required to establish external validity and clinical effectiveness. A limitation of the current study is that the dataset was partitioned at the admission record level rather than at the patient level. As a result, when patients contributed multiple hospital visits, records from the same patient could appear in both the training and evaluation subsets. Therefore, the reported performance should be interpreted as performance at the admission-record level rather than as authoritative evidence of generalization to completely unseen patients. Future studies should employ patient-level partitioning and external validation to provide a more stringent assessment of generalizability. Also, although the model achieved 100% accuracy in reproducing the evidence-guided recommendation labels, the labels were derived from predefined rules rather than independently observed physiotherapy outcomes. As a result, the predictive evaluation cannot establish clinical effectiveness. The expert-based evaluation provides preliminary evidence of clinical appropriateness but does not constitute prospective clinical validation or demonstrate improved patient outcomes. Future studies should evaluate the system prospectively with multiple physiotherapists and arthritis patients and compare recommendations with longitudinal treatment outcomes. Future improvements to the system should include: (1) collection of prospectively labeled datasets with physiotherapist-assigned exercise labels to enable independent clinical validation; (2) integration of additional variables such as Body Mass Index (BMI), WOMAC pain and function scores, and Kellgren-Lawrence (KL) grade to enrich the clinical feature space; (3) incorporation of patient feedback and exercise adherence tracking to support continuous model refinement; (4) deployment in a clinical pilot study, with physiotherapist oversight, to establish clinical validity, real-world utility, and patient outcomes in an African healthcare context, (5) prospectively labeled patient data should be collected where exercise labels are assigned by certified physiotherapists—to enable a rigorous, independent assessment of model generalization to real clinical populations. Since age is continuous and the other variables are encoded categorically, permutation importance or SHAP analysis could be explored in future work to provide a more reliable and clinically interpretable explanation of model predictions.

AI DISCLOSURE

During manuscript preparation, generative artificial intelligence tools were used only for language refinement, organization of ideas, grammar correction, and readability improvement. The tools were not used to generate or alter the study data, perform statistical analysis, train or evaluate the machine-learning models, create clinical interpretations, or make authorship-level contributions. All authors reviewed, verified, and approved the final manuscript and take full responsibility for the accuracy, integrity, originality, and scientific content of the work.

Abstract

This paper presents a blockchain-based evaluation system built on Ethereum smart contracts and the InterPlanetary File System (IPFS) to address the structural vulnerabilities of the associate professorship evaluation process in Turkey. The current system suffers from four problems: unverifiable jury selection, risk to document integrity, opaque appeal mechanisms, and a lack of accountability. The proposed framework addresses all four. The system provides on-chain deterministic jury assignment, IPFS-backed hybrid document storage, automated rule-based scoring using a simplified weighting model abstracted from the UAK Associate Professorship Application Criteria, and a transparent state machine governing the full application lifecycle: Pending, JuryAssigned, Accepted, Rejected, Appealed, and Canceled. Implemented on the Ethereum Sepolia testnet using the Truffle v5.11.5 development framework, the system is evaluated through gas cost analysis, comparative system benchmarking, and a security assessment. The evaluation reports gas costs for all core contract functions and a functional comparison against the current process and related blockchain systems. Off-chain identity verification for data entry is included in future development plans.

Keywords: blockchain, smart contract, Ethereum, IPFS, associate professorship, academic evaluation, transparency

I.INTRODUCTION

Academic career advancement in higher education systems rests on formal evaluation processes that weigh research output, teaching experience, and scholarly impact. In Turkey, the associate professorship (doçent) evaluation is a critical milestone in academic career progression, marking the transition from assistant professor to associate professor. The process is coordinated by the Higher Education Council (YÖK) and consists of document submission, jury assignment, multi-criteria scoring, and an appeal mechanism [1]. Despite its institutional importance, the current system carries structural vulnerabilities that undermine stakeholder confidence. Centralized document repositories create a single point of failure, leaving data susceptible to loss or unauthorized modification. Jury selection procedures are not grounded in externally verifiable criteria, which makes the process opaque to candidates and independent observers. Evaluation outcomes are communicated with limited justification, and appeal mechanisms do not offer adequate transparency into the review process. These problems echo broader concerns raised in the blockchain literature about transparency and accountability in centralized systems [2], and in blockchain-in-education research about the gap between credential verification and procedural fairness [3]. Blockchain technology offers an alternative architecture for addressing these structural issues. The defining properties of blockchain (decentralized consensus, cryptographic immutability, and programmable smart contracts) enable trust among multiple stakeholders without relying on any central

authority [4], [5]. Prior research has demonstrated blockchain's effectiveness in academic credential verification [6], [7], multi-actor evaluation and grant management [8], and academic research integrity monitoring [9]. Existing solutions, however, address document issuance and single-institution verification rather than the multi-actor evaluation workflow examined here.

This paper introduces a blockchain-based associate professorship evaluation system built on Ethereum smart contracts and the InterPlanetary File System (IPFS). The proposed framework establishes an auditable record of the evaluation process by recording every step (application submission, jury assignment, voting, and appeal) on an immutable ledger. The principal contributions of this work are listed below:

- On-chain jury assignment: A contract function that selects three jurors from a managed pool using on-chain pseudorandomness, so that every assignment is deterministically reproducible and can later be audited.
- IPFS-backed document integrity protocol: A hybrid storage model in which the full content of credential documents is stored on IPFS. At the same time, only cryptographic hash values are anchored to the blockchain [10].
- On-chain automated scoring model: A calculateScore() function that deterministically computes weighted scores from a parameterizable weighting model abstracted from the UAK Associate Professorship Application Criteria [1] at the time of submission, removing discretionary weighting from the scoring step.
- Transparent state machine and appeal workflow: A formal model that implements the full application lifecycle (Pending, JuryAssigned, Accepted, Rejected, Appealed, Canceled) entirely through smart contract state transitions, supplemented by an on-chain appeal recording mechanism that extends the same procedural guarantees to the secondary independent review.

II.RELATED WORK

Blockchain-based academic credentialing began with Blockcerts [11], which anchors cryptographically signed diplomas to the Bitcoin chain but is constrained by public-chain fees and throughput [2], [4]. EduCTX [12] moves credit transfer onto a consortium blockchain built on the open-source Ark platform and addresses cross-institutional interoperability, while Cerberus [7] mitigates diploma fraud at the accreditation and degree-verification layer; neither model shows how multiple evaluators reach a collective decision. Dash et al. [6] pair Hyperledger Fabric with IPFS for certificate authentication (300–900 ms latency, ~250–280 TPS), and VeritasChain [9] extends Fabric-based credentialing with research-integrity monitoring and zero-knowledge proofs (reported 182 TPS, 1.2 s verification). Both remain single-decision verification systems with no jury layer. On the governance side, Hjalmarsson et al. [13] demonstrate Ethereum-based e-voting without addressing voter identity verification, and Erturk et al. [14] illustrate the on-chain-hash/off-chain-content pattern [10] in a non-credentialing setting. Closest to this work is the fellowship management system of Gupta et al. [8], which combines eligibility verification, attribute-based encryption, and zero-knowledge proofs at a reported $0.39–$1.31 per operation, but is specific to funding allocation and provides no application scoring, jury pool management, or appeal handling. Across these works, blockchain research has concentrated on single-institution document verification or isolated voting decisions [3], [11–14]. No existing system integrates a multi-actor evaluation workflow, pool-managed jury assignment, weighted scoring against an institutional standard such as the UAK criteria, and an on-chain appeal mechanism in a single contract architecture. The proposed system is designed to close this gap.

III.SYSTEM MODEL

1. System Actors and Roles

Four actors interact with the system, each with authority boundaries encoded in the contract. The Candidate uploads supporting documents to IPFS, submits the resulting content identifier (CID) via createApplication(), and may appeal a rejection by writing the grounds on-chain. The YÖK Administrator (yokAdmin), a single Ethereum address fixed at deployment, maintains the jury pool and triggers assignment. Jury Members evaluate an assigned application and cast one irrevocable vote each. The Auditor/Institution is any external observer who can query application histories, jury assignments, and voting outcomes without prior authorization [2].

2. Layered Architecture

The system comprises three layers. The application layer is a single-page JavaScript application with role-based panels for candidate, jury member, and administrator roles, authenticated via MetaMask and interacting with the contract via Ethers.js v6. The smart contract layer holds all business logic in DocentlikSistemi.sol (Solidity 0.8.20), deployed to the Ethereum Sepolia testnet with Truffle v5.11.5. The storage layer holds document content on IPFS via Pinata, with only the CID persisted on-chain [10].

3. Application Lifecycle (State Machine)

Each application in the system progresses through a six-state state machine enforced by the smart contract (Table 1). Every state transition can be triggered only by the authorized actor when the specified conditions are satisfied; the transition logic is enforced at runtime by require() checks within the contract.

Table 1. Application State Machine

State	Triggering function	Authorized actor	Successor state(s)
Pending	createApplication()	Candidate	JuryAssigned, Canceled
JuryAssigned	assignJury()	YÖK administrator	Accepted, Rejected, Canceled
Accepted	castVote() – 2/3 for	Jury members	Terminal
Rejected	castVote() – 2/3 against	Jury members	Appealed; Terminal if appealCount = MAX_APPEAL
Appealed	appeal()	Candidate	JuryAssigned
Cancelled	cancelApplication()	YÖK administrator	Terminal

Transitions are guarded on-chain: castVote() requires the JuryAssigned state and appeal() requires Rejected, so these constraints hold regardless of front-end behavior [5].

IV. SMART CONTRACT DESIGN

1. Data Structures

The contract is built on three core data structures. The Application struct below consolidates all evaluation data for a given candidate into a single record:

```
struct Application {
address candidate; uint256 score; string ipfsHash; Status status; uint256 adminYears;
```

string rejectionReason; uint256 submissionTime; uint256 pubCount; uint256 citeCount;}

Three mappings hold auxiliary state: applicationJuries (id → three juror addresses), juryDecisions (id → juror → vote, where 0 = not voted, 1 = accept, 2 = reject), and appealCounter (id → number of appeals filed). Vote tallies are not stored; castVote() recomputes them from juryDecisions on each call.

2. Scoring Model

The calculateScore() function deterministically computes a weighted score from the three-parameter model summarized in Table 2, which abstracts the publication, citation, and teaching categories of the UAK Associate Professorship Application Criteria [1]. Declared as pure, the function neither reads nor modifies chain state, so it consumes no gas when queried externally via eth_call; when invoked internally during createApplication(), its cost is included in the gas reported for that function:

The total score is expressed as $P = 8 \cdot n_pub + \lfloor n_cite/2 \rfloor + 5 \cdot n_admin$, where n_pub is the declared publication count, n_cite is the international citation count, and n_admin is the number of administrative or teaching years. The prototype applies a single publication weight; differentiating SCI/SSCI-indexed and nationally indexed publications is left to future work. Solidity has no fixed-point type, so the citation weight is implemented as integer division that truncates toward zero: two citations contribute one point. The contract enforces the UAK weighting deterministically, but does not verify the declared counts themselves, which are supplied by the candidate at submission; automated validation against YOKSIS records is required before the scoring step can be considered trustless (Section VIII).

Table 2. Score Weights Based on UAK Associate Professorship Application Criteria

Criterion	Contract parameter	Weight	Contribution
SCI/SSCI-indexed publication	PubCount	× 8	8·n_pub
International citation	citeCount	÷ 2	⌊n_cite/2⌋
Administrative / teaching year	adminYears	× 5	5·n_admin

A minimum score threshold can be defined as a contract constant; applications falling below that threshold can be automatically rejected during the required check in submitApplication(), thereby directing jury capacity exclusively toward qualified candidates [8].

3. Jury Assignment Mechanism

Jury assignment is the core mechanism that makes the system independent of a central decision body. Algorithm 1 presents the pseudocode for the assignJury() function:

Algorithm 1: assignJury(applicationId)

1. require(status == Pending or Appealed)
2. require(activeJuryCount >= 3)
3. seed ← keccak256(blockhash(block.number-1), applicationId, timestamp)
4. active ← array of active jury addresses
5. for i ← 0..2: swap actives[i] ↔ actives[i + keccak256(seed,i) mod (n−i)]
6. selected[0..2] ← actives[0..2]

7. applicationJuries[id] ← selected; status ← JuryAssigned

The current prototype derives randomness from blockhash(block.number - 1). This makes each assignment deterministically reproducible from public chain data, and therefore auditable, but not verifiably random in the cryptographic sense. Two weaknesses follow. A miner can, in principle, influence the block hash. More practically, because blockhash(block.number - 1) is already known to the caller when the transaction is composed, the administrator can compute the resulting panel in advance and withhold the call until a favorable draw appears. Replacing this layer with Chainlink VRF [15] removes both and is a prerequisite for production deployment.

4. Voting and Consensus Mechanism

Jury members cast their votes independently via the castVote() function. When the third vote is recorded, the contract automatically applies a 2/3 majority rule. The voting mechanism enforces three security properties: the jury decisions mapping prevents a jury member from voting on the same application more than once; votes are irrevocable; and the 2/3 decision threshold is hard-coded in castVote() with no setter exposed, so no one, including the administrator, can alter it.

5. Appeal Process

A rejected candidate can invoke the appeal() function to write their grounds for appeal directly to the chain. The contract records the appeal and updates the status to Appealed. Every appeal step is written to an immutable record, so initial and appeal decisions are equally auditable [6], [9]. The MAX_APPEAL constant, set at contract deployment, prevents an infinite appeal loop from being opened against the same rejection decision. The post-appeal process carries the same procedural guarantees as the initial evaluation: assignJury() is called again, a new panel is drawn from the same active pool with a fresh seed, and the voting process restarts from scratch. The current implementation does not prevent the original panel from being reselected; enforcing panel disjointness is left to future work.

V.DOCUMENT MANAGEMENT AND IPFS INTEGRATION

Application documents such as CVs, publication lists, diplomas, and project reports range from a few hundred kilobytes to several megabytes. Persisting such content on-chain is impractical: under the EVM storage schedule, a newly written 32-byte slot costs 20,000 gas, about 640,000 gas per kilobyte, and blocks are additionally bounded by the block gas limit [5]. The system therefore adopts the hybrid pattern used in comparable work [6], [9]: content is pinned to IPFS through Pinata, and only the resulting CID is written to Application.ipfsHash by createApplication(), holding on-chain state at 1–2 KB per record regardless of document size [10]. Because an IPFS CID is the root hash of a Merkle DAG built over SHA-256 chunk hashes, any single-byte modification yields a different CID; assigned jurors read documents directly from IPFS, and any third party can verify post-submission integrity against the on-chain CID without an intermediary. By comparison, an off-chain server with a URL pointer costs only ≈40,000 gas but offers no integrity guarantee, since the target content remains mutable. Pinata provides primary pinning, and Filecoin archiving is planned as a second tier. The on-chain CIDs remain valid identifiers even in the event of a storage-layer failure, but their retrievability depends on at least one node continuing to pin the content. Because the CID is public, any observer can also retrieve the underlying documents. The prototype, therefore, assumes that submitted material is disclosable; handling personal data under KVKK and GDPR, including the conflict between ledger immutability and the right to erasure, would

require encrypting content before pinning and anchoring, with decryption entitlements on-chain only, as in [8]. This is outside the present scope (Section VIII).

VI.IMPLEMENTATION AND EVALUATION

1. Implementation Environment

The proposed system was developed for the Ethereum Sepolia testnet, then compiled and deployed using the Truffle v5.11.5 development framework. The smart contract is written in Solidity 0.8.20; the front-end is built with JavaScript and the Ethers.js v6 library. Wallet connectivity is provided via the MetaMask extension, and document storage is handled through the Pinata IPFS pinning service [10].

2. Gas Cost Analysis

Gas consumption on the Ethereum Virtual Machine (EVM) is deterministic for a given EVM version and storage state, so local measurements under Ganache agree with Sepolia values for the operations reported here; the figures in Table 3 were taken from the Sepolia deployment identified in Section VI-E. The US-dollar equivalents in Table 3 are derived from two explicitly stated parameters: a gas price of 1 Gwei and an ETH/USD rate of 1,940, the spot rate on 26 July 2026. The 1 Gwei assumption is deliberately conservative, so the dollar figures should be read as upper bounds rather than typical costs. Table 3 summarizes both quantities for the core functions. assignJury() is the only function whose cost scales with system size, since it enumerates the active jury pool in memory before sampling (Table 3, note b); extrapolated to the thousand-reviewer pool a national board would maintain, it approaches the block gas limit. Indexing the pool rather than enumerating it is therefore a prerequisite for production deployment, and is the principal scaling constraint of the present design.

Table 3. Smart Contract Function Gas Costs

Function	Gas used	Cost (USD)[a]
createApplication()	196,852	0.382
assignJury()[b]	186,236	0.361
castVote()	63,178	0.123
appeal()	81,695	0.158
calculateScore()	0 (external call)	0.000

[a] A dollar equivalent assumes a gas price of 1 Gwei and ETH/USD = 1,940 (26 July 2026); at the sub-1 Gwei averages typical of 2026 mainnet conditions, the corresponding costs are proportionally lower. calculateScore() is declared pure; it consumes no gas when queried externally via eth_call, while its cost during on-chain submission is contained in the createApplication() figure. [b] Measured for a pool of 10 jury members. The cost rises to 437,324 gas for 50 members and 751,194 gas for 100 members, an increase of approximately 6,277 gas per additional pool member, confirming linear scaling with pool size.

The calculateScore() function incurs no gas since it is declared as pure [5], making frequent score queries cost-free. Under the assumptions above, per-transaction costs fall in the $0.12–$0.38 range, below the $0.39–$1.31 reported for the comparable smart contract system in [8]. The comparison is indicative rather than exact, since the figures in [8] were priced under different market conditions; the underlying gas measurements, being independent of token price, provide the more durable point of comparison.

3. System Comparison

Table 4 presents a comparison of the proposed system with the existing YÖK-centric evaluation process and the most closely related works across six functional criteria. The comparison methodology follows a similar structure to related permissioned-blockchain credential studies [6]. Because the reviewed systems were not designed for the same task, the comparison is qualitative. Each cell records whether a capability is claimed in the corresponding publication, not how well it performs.

Table 4. Functional Comparison Across Six Criteria

System	C1	C2	C3	C4	C5	C6
Current YÖK process	M	N	N	N	P	P
Blockcerts [11]	N	N	P	N	N	Y
EduCTX [12]	N	N	P	N	N	Y
Cerberus [7]	N	N	N	N	N	Y
Dash et al. [6]	N	N	Y	N	N	Y
VeritasChain [9]	N	N	P	N	N	Y
Gupta et al. [8]	P	N	N	N	N	Y
Proposed system	Y	Y	Y	Y	Y	Y

C1 multi-actor evaluation workflow; C2 verifiable jury assignment; C3 hybrid document integrity (on-chain hash, off-chain content); C4 automated scoring against an institutional standard; C5 on-chain appeal mechanism; C6 third-party auditability. Y = supported, P = partially supported, N = not supported, M = supported but performed manually and off-record. Cell values characterize the functional scope that each system reports in its own publication, as summarized in Section II; they are not performance measurements.

4. User Interface

The system provides three separate role-based panels for the candidate, jury member, and YÖK administrator. Following MetaMask authentication, each panel is accessible only to the Ethereum address associated with the relevant role; interface-layer role restrictions are independently validated by require() checks at the smart contract level [5]. As a worked example of the scoring model end-to-end, an application declaring two publications, three international citations, and five administrative years returns $2 \cdot 8 + \lfloor 3/2 \rfloor + 5 \cdot 5 = 42$ points, which is the value written on-chain and displayed in the panel (Figure 1).

The prototype's front-end was implemented in Turkish for the pilot deployment shown in Figure 1 (e.g., "Aday Paneli", "Yeni Başvuru Oluştur", "Jüri Atandı"); these interface labels map directly onto the English contract functions and fields used throughout this paper (createApplication(), pubCount, citeCount, adminYears) and do not affect on-chain behavior.

The Jury Member panel surfaces only the IPFS-linked application documents and the castVote() control for applications currently assigned to that address; no scoring or administrative controls are exposed at this interface, mirroring the on-chain role restriction enforced by require(). The YÖK Administrator panel is limited to jury-pool management and the triggering of assignJury(). It does not expose any control that can alter a submitted score or vote once cast, consistent with the immutability guarantees described in Section VII. Each panel queries the contract directly through Ethers.js v6 rather than through an intermediary backend, so the data displayed to every role is read from the same on-chain state that any external observer can independently verify via a public block explorer such as Etherscan.

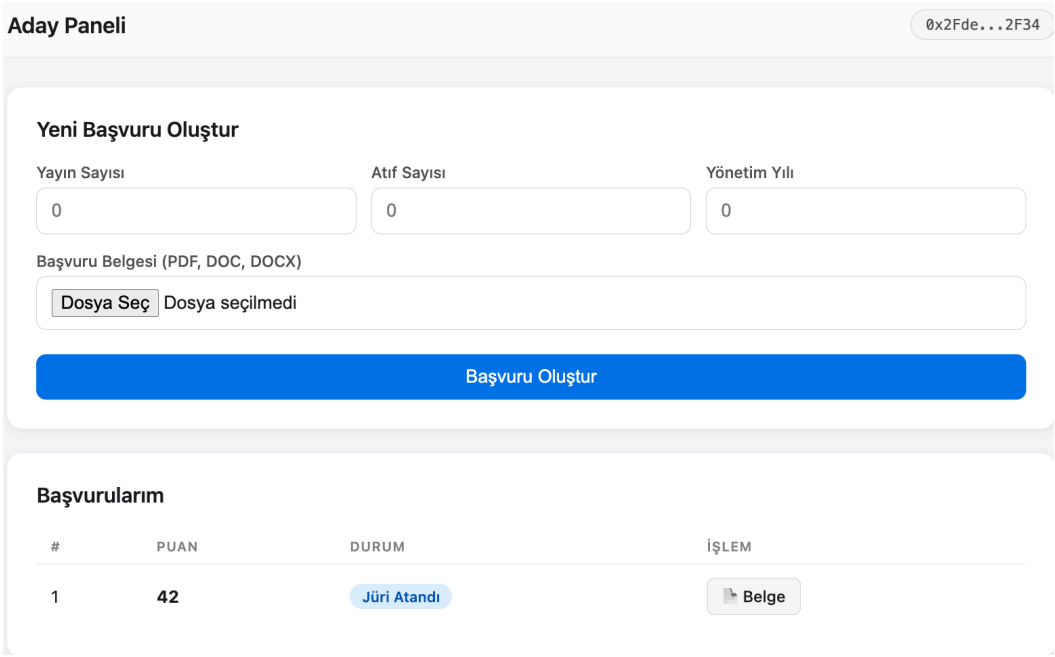

Figure 1. Candidate application interface and IPFS document upload.

5. Reproducibility and Artifact Availability

The gas figures in Table 3 were obtained with eth-gas-reporter against a local EVM instance of DocentlikSistemi.sol. These figures carry over to any EVM-compatible network, since gas consumption is deterministic for identical bytecode and inputs; the contract was also deployed to the Sepolia testnet, where the deployment cost of 2,040,811 gas matches the local measurement exactly. The contract source, migration scripts, and the 49-case Truffle test suite are available in the source repository, and the deployed contract, together with its complete transaction history, is publicly queryable on Etherscan. Deployed contract: 0xD3936E8639b4862F4DB2a33Cab69b50B38c1c9eE (Sepolia). Source repository: github.com/MuhittinTanoba/doc.

VII. SECURITY ANALYSIS

The analysis framework draws on the threat-countermeasure structure used in related permissioned-blockchain credential work [6] and the Ethereum smart contract vulnerability literature [16].

1. Tamper Resistance and Access Control

Modifying data committed to the Ethereum blockchain is computationally infeasible. Once an application record is created and its fields are written to the applications[id] mapping, they are protected by an immutability guarantee [5]. Document contents are guaranteed by IPFS content-addressed structures, as described in Section V [10].

Every critical function in the contract verifies the message. sender address through either the onlyAdmin modifier or a require() check. The assignJury() function can only be called from the YokAdmin address set at

deployment; castVote() is restricted to one of the three addresses registered in the applicationJuries[id] array. The EVM evaluates these constraints at call time, so unauthorized calls revert before any state is written.

2. Double Voting and Replay Resistance

The jury decisions [id][msg.sender] mapping deterministically ensures that each jury member may cast only one vote per application. When a member calls castVote() a second time, the require(juryDecisions[id][msg.sender] == 0) condition fails, and the transaction is reverted.

Replay resistance follows from record identity: each application is timestamped with a block. timestamp and applicationId increments monotonically with every new record, so an earlier submission cannot be resubmitted as a new one. Repeated appeals against the same rejection decision are bounded by the MAX_APPEAL check described in Section IV-E.

3. Insider Threat Mitigation

The YÖK administrator can assign jury members but cannot alter the voting outcome, modify a candidate's score, or delete an appeal rationale, as these data become immutable once written to the contract. All transactions are publicly queryable via Etherscan. A multi-signature scheme for critical administrative functions is left to future work.

4. Smart Contract Vulnerabilities

Reentrancy attacks, classified by Atzei et al. as the most critical vulnerability category in Ethereum smart contracts [16], are structurally eliminated in the proposed contract by the absence of any function that transfers ETH to an external address. Before deployment, 49 unit tests were executed under the Truffle test suite, covering key boundary conditions and invalid state transitions. Independent formal verification and a smart contract audit are planned steps before any production release.

VIII. CONCLUSION AND FUTURE WORK

This paper presented a blockchain-based framework for evaluating associate professorships that addresses four structural weaknesses in the current process: unverifiable jury selection, document integrity risks, opaque appeals, and weak accountability. These are addressed through on-chain deterministic jury assignment, IPFS-anchored document integrity, automated UAK-based scoring, and a six-state transparent lifecycle with an on-chain appeal path. Deployed on the Sepolia testnet, the system executes its core functions at 63,178–196,852 gas, corresponding to $0.12–$0.38 under the pricing assumptions stated in Section VI-B, below the $0.39–$1.31 range reported for the closest comparable system [8]. Several limitations remain. Blockhash-based pseudorandomness is theoretically susceptible to miner influence and, more practically, to pre-computation by the caller; it will be replaced by Chainlink VRF [15]. The declared publication and citation counts are not validated against an external register: the system is not yet integrated with YOKSIS or the e-Government identity infrastructure. Hence, data entry still requires an off-chain verification step, which constrains the trustless model. Document CIDs are written in the clear, so confidentiality of candidate material and compliance with KVKK and GDPR require an encryption layer that the prototype does not implement. Finally, assignJury() scales linearly with the size of the jury pool, and the evaluation was confined to a testnet; therefore, institutional-scale deployment requires further validation. Future work will additionally explore ZK-SNARK-based confidential voting [17] and a DAO-based governance model [18].

Abstract
In medical image classification, features are usually computed inside a region of interest (ROI) drawn by an expert. This assumes that the information needed to separate the classes lies within the annotated structure. We tested this assumption directly on a brain Magnetic Resonance Imaging (MRI) classification task, treating the region rather than the feature set or the classifier as the experimental variable. From 80 subjects with expert annotations of a small nerve structure, we extracted the same intensity and texture descriptors from seven spatially distinct regions: the annotated interior; concentric shells of 4, 6, 8, and 10 mm around it; a 40 mm enclosing box; and a fixed-geometry spherical shell control. All regions were evaluated with an identical pipeline and identical repeated cross-validation. Interior features showed an Area Under Curve (AUC) of 0.555 ± 0.136. Shell regions achieved an AUC of 0.743–0.800, whereas the enclosing box achieved an AUC of 0.545 ± 0.114. To test whether shell performance was inherited from the geometry of the annotation, we repeated the experiment with a fixed-radius spherical shell placed at the annotation centroid, identical in shape for every subject; this reached 0.633 ± 0.137, above chance, but noticeably below the mask-derived shells. The discriminative content, therefore, lies in a narrow band just outside the annotation. Annotation location alone carries some of this signal, but most of it depends on proximity to the annotation boundary itself, and the effect is destroyed by enlarging the region. This effect reflects genuine image content rather than annotation shape. In this task, the location of the features mattered more than which features or which classifier were used.

I. INTRODUCTION

Trigeminal neuralgia (TN) is a chronic facial pain disorder. Patients experience sudden, brief, extremely severe electric-shock-like pain on one side of the face, typically triggered by ordinary actions such as chewing, speaking, or touching the skin. Diagnosis rests primarily on clinical criteria [1], [2]. The relevant anatomy is the trigeminal nerve, a structure only a few millimeters across that runs from the brainstem through a fluid-filled space toward the skull base. The prevailing explanation for the disorder is mechanical: a nearby blood vessel

presses on the nerve, gradually damaging its insulating sheath. This mechanical injury is associated with measurable nerve volume loss, which has also been linked to outcomes after surgical decompression [3]. Because the fluid surrounding the nerve appears bright on heavily T2-weighted Magnetic Resonance Imaging (MRI) while the nerve and vessels appear dark, this region can be imaged at sub-millimeter resolution, and high-resolution T2-weighted MRI is the established imaging protocol when the diagnosis is suspected [4]. From an engineering standpoint, however, this is an unusually difficult classification problem, for three reasons. First, the target structure is very small, on the order of a few hundred cubic millimeters, so the number of voxels available per subject is limited and partial-volume effects are substantial. Second, and more importantly, the imaging finding is not decisive. Vascular contact between the nerve and a vessel is common even in individuals without the condition, whereas findings severe enough to distort or compress the nerve are comparatively rare [5]. Distinguishing between these degrees of contact from a radiological read alone is subjective, which is precisely the situation in which automated quantitative analysis is attractive. Third, cohorts are small. TN is uncommon, and datasets with expert annotations typically number in the tens to low hundreds, a regime in which conventional handcrafted predictors remain competitive with, and easier to interpret than, end-to-end deep learning models.

II. RELATED WORK

Extracting a large vector of quantitative descriptors from a region of interest (ROI) and mining it for diagnostic or prognostic signal is known as radiomics [6], [7]. It was originally developed for oncologic imaging but has since been applied broadly across anatomical targets, including small non-tumoral structures such as peripheral nerves. In this study, we also utilized radiomics as the general framework. Several groups have applied this framework specifically to TN. Wang et al. [8] extracted a large radiomic feature vector from MRI in a cohort of 350 patients and 100 controls, reduced dimensionality with principal component analysis followed by LASSO, and compared regularized logistic regression, support vector machines, and boosting, reporting high accuracy with prospective validation on an additional small set. A study published in [9] combined automatic segmentation of the nerve using a U-Net with the extraction of 216 descriptors, and related them to symptom presence in patients treated with radiosurgery. A more recent nomogram study [10] extended the region definition by extracting features from two adjacent anatomical compartments, along with hand-measured anatomical parameters, and reported that the combined model outperformed image descriptors alone. Deep learning approaches have also been reported. A 2025 study using convolutional networks on plain radiographs [11] achieved 87.2% accuracy on an internal test set but 71.0% on external data, a 16-point drop that illustrates how fragile reported figures in this area can be. A separate line of work [12] segmented both the nerve and the adjacent vessels and, notably, cropped a fixed cube around the nerve centroid rather than masking to the nerve itself.

III. MOTIVATION

Across most of this literature, one design choice is shared and rarely examined: descriptors are computed inside the expert annotation. This encodes the assumption that the class-discriminative information is contained within the annotated structure. For a condition defined by the relationship between a structure and its immediate surroundings, that assumption is not obviously correct, and the fixed-cube cropping used in [12] implicitly departs from it, though without a direct comparison. We therefore keep the feature set, the classifier, and the evaluation protocol fixed, and vary only the region from which features are computed. We report an ablation across four regions derived from the same annotation, and a control experiment that separates image content from annotation geometry. The contribution of this study is an empirical result on where the signal lives and a control procedure we recommend for any study using annotation-derived context regions.

IV. METHOD

1. Dataset

Ninety-two subjects (45 patients, 47 controls) were retrospectively collected at the Ankara Training and Research Hospital. This retrospective study was approved by the Ankara Training and Research Hospital Ethics Committee (approval no. E-23-1363, decision dated 07.09.2023). For every subject, an experienced neuroradiologist manually delineated the region containing the course of the trigeminal nerve on the axial volume. Annotations were bilateral in most subjects. Acquisition was heterogeneous. Twelve patients, and no controls, had been imaged with a 3D steady-state sequence (constructive interference in steady state, CISS) rather than T2-weighted imaging. This imbalance arises naturally in retrospective archives, since that sequence is typically ordered only when the condition is clinically suspected. Because such an imbalance could be learned by the model rather than the diagnostic label, these 12 patients were excluded, and all subsequent experiments were restricted to the sequence-homogeneous T2-weighted subcohort (33 patients, 47 controls, n = 80). Demographic characteristics of the patient and control groups are summarized in Table 1.

2. Region Definitions

Four regions were derived per subject from the same expert annotation, denoted M (Figure 1):

- Interior: the annotated region M itself.
- Shell(r): a thin band immediately surrounding M, obtained by expanding M outward by r millimeters and then subtracting the original region, for $r \in \{4, 6, 8, 10\}$ mm.
- Box: a 40 mm cube centered on the midpoint of M.
- Fixed spherical shell (control): all voxels lying between 3 and 7 mm from the midpoint of M.

The fixed spherical shell is the key control. Unlike the other three regions, its shape and size are identical for every subject; the only thing it inherits from the annotation is its location. If the shell effect were caused only by differences in how the masks were drawn, this fixed-shape region would show no effect. It does show the effect, so the result comes from the image, not from the mask shape. For subjects with bilateral annotations, each side was treated as an independent connected component sharing the same diagnostic label; each component was assigned its own centroid when constructing the box and fixed spherical shell regions.

Table 1. Demographic Characteristics of the Study Cohort

Characteristics	Patients	Controls	p
Age, years (mean ± SD)	56.98 ± 15.65	54.46 ± 14.53	0.402
Sex, female (%)	51	67.3	0.096

3. Feature Extraction

Features were computed using PyRadiomics [13] following the Image Biomarker Standardization Initiative (IBSI) conventions [14]. Volumes were resampled to 0.6 mm isotropic spacing with B-spline interpolation, intensity-normalized, and discretized with a fixed bin width of 25. Six descriptor families were enabled: first-order statistics, Gray Level Co-occurrence Matrix (GLCM), Gray Level Run Length Matrix (GLRLM), Gray

Level Size Zone Matrix (GLSZM), Gray Level Dependence Matrix (GLDM), and Neighborhood Gray Tone Difference Matrix (NGTDM), yielding 93 features per region.

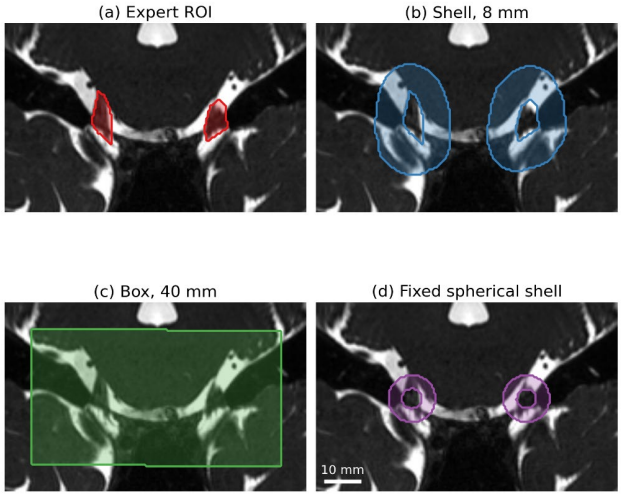

Figure 1. The four regions evaluated in this study are shown on a representative axial slice from a subject with bilateral annotation. (a) the expert-drawn ROI; (b) the shell region, illustrated at r = 8 mm; (c) a 40 mm box; (d) the fixed spherical shell control (radius 3–7 mm from each nerve's own centroid).

Shape descriptors were excluded from all region models. Shape features characterize the geometry of the region rather than the image content within it, and are not comparable across regions with differing construction; for regions 3 and 4, they are constant by design. For reference, the full 107-feature set, including shape, computed on the interior region, gives an AUC of 0.817 ± 0.092, which is noticeably higher than the texture-only result below, since shape descriptors partly encode annotation size and could reflect either genuine anatomical difference or annotator bias, a question we do not attempt to resolve here. From a computational standpoint, each of the six descriptor families summarizes the region through a different mathematical construction. First-order statistics operate directly on the voxel intensity histogram, independent of spatial arrangement. The remaining five families are texture matrices that instead encode spatial relationships between voxel intensities: GLCM tabulates how often pairs of gray levels co-occur at a fixed offset and direction, then averages the result over multiple directions to obtain rotation-invariant descriptors; GLRLM and GLSZM measure the length or size of contiguous runs and zones of constant gray level, capturing coarseness versus fineness of the texture; GLDM quantifies local gray-level similarity within a fixed neighborhood; and NGTDM measures the difference between a voxel's intensity and the average intensity of its neighbors, capturing local contrast. Because these matrices are computed independently within each region mask, their values are sensitive to the number of voxels available: very small or thin regions yield sparser co-occurrence and run-length matrices, which is why a fixed bin width was used for intensity discretization, as recommended by IBSI [14] to keep texture matrices comparable across regions of different sizes.

4. Evaluation

Every region was evaluated with an identical pipeline, implemented with scikit-learn [15]. Four steps were applied in sequence. First, features with near-zero variance across subjects were removed, since a feature that barely changes from one subject to another carries little information for classification. Second, the remaining

features were standardized to zero mean and unit variance, so that no feature would dominate the model simply because it was measured on a larger numerical scale. Third, univariate feature selection was used to retain only the 20 features most strongly associated with the diagnostic label, out of the 93 available; this step reduces the risk of overfitting, which is a particular concern with a sample size of this magnitude. Finally, an L2-regularised logistic regression classifier was trained on these 20 features. Logistic regression was chosen for its simplicity, interpretability, and stable behavior on small datasets, and the L2 penalty discourages the model from assigning excessively large weights to any single feature. All four steps were fitted using only the training fold in each cross-validation split. This is because if feature selection were performed on the full dataset before cross-validation, information from the test fold would leak into the selection process, artificially inflating the reported performance. Performance was estimated using repeated stratified 5-fold cross-validation with 20 repetitions, giving 100 train-test splits per region. Each subject contributed exactly one feature vector per region, computed jointly across both nerves in bilateral cases; cross-validation was therefore inherently performed at the subject level, with no risk of the same subject appearing in both the training and test set within a fold. Results are reported as the mean AUC across these 100 splits, together with the standard deviation and the 2.5th-97.5th percentile range, which shows where the central 95% of the 100 observed AUC values actually fell. Because the 100 splits are not fully independent, each subject contributes to multiple repetitions, the reported percentile range should be interpreted as a description of observed variability across splits rather than a formal confidence interval.

V. RESULTS

Table 2 summarizes classification performance across all seven regions. Four observations were derived from these results (Figure 2). First, features within the annotated region contained no diagnostic information. All 93 descriptors computed inside the expert-drawn boundary performed at the level of random guessing, with an average AUC close to 0.5. In practical terms, texture and intensity patterns measured strictly within the nerve itself did not help separate patients from controls. Second, features from just outside the annotated region did carry useful information. When the same 93 descriptors were computed within a thin band surrounding the annotation, performance rose sharply, reaching 0.743-0.800 depending on how far outward the band extended (4, 6, 8, or 10 mm). Every one of these four distances outperformed both the interior region and the large box. This difference was statistically significant; a Wilcoxon signed-rank test comparing paired fold-level AUC values between the interior region and the 8 mm shell (the best-performing shell radius) confirmed the gap was not attributable to chance ($p < 0.001$). The differences among the four distances themselves were small compared to the normal variability seen from one cross-validation fold to the next. The more important finding is that performance remained consistently high across the entire 4-10 mm range, rather than depending on selecting exactly the right distance. Third, this effect is only partially explained by the annotation's location. A natural concern is that the band surrounding the annotation might only be picking up differences in annotation shape or size between the two groups, rather than any real property of the underlying image. To test this, we repeated the analysis using a region with a completely fixed shape and size, a spherical shell that was identical for every subject, and whose only connection to the original annotation was its center point. This control achieved an AUC of 0.633, which is shown as a reference line in Figure 2. This is clearly above chance, showing that location alone carries some signal, but it remained noticeably lower than the mask-derived shells (0.743–0.800). This gap indicates that shell performance depends not only on being near the annotation, but on being adjacent to its actual boundary. As a further check, we measured how strongly the 4 mm shell features were correlated with the volume of the original annotation; this correlation was weak (median absolute correlation of 0.158), which rules out a purely geometric artifact even though location alone does not account for the full effect. AUC was used as the primary metric because it is threshold-independent and robust to moderate class imbalance. It represents the probability that a randomly selected positive instance receives a higher predicted score than a randomly selected negative instance [16].

Table 2. Classification Performance by Region

Region	AUC (mean ± SD)	[2.5–97.5%]
Interior (expert annotation)	0.555 ± 0.136	0.293–0.830
Shell, 4mm	0.743 ± 0.106	0.496–0.927
Shell, 6mm	0.778 ± 0.101	0.543–0.960
Shell, 8mm	0.800 ± 0.096	0.609–0.969
Shell, 10mm	0.746 ± 0.105	0.553–0.942
Box, 40mm	0.545 ± 0.114	0.348–0.724
Fixed Spherical Shell (control)	0.633 ± 0.137	0.406–0.889

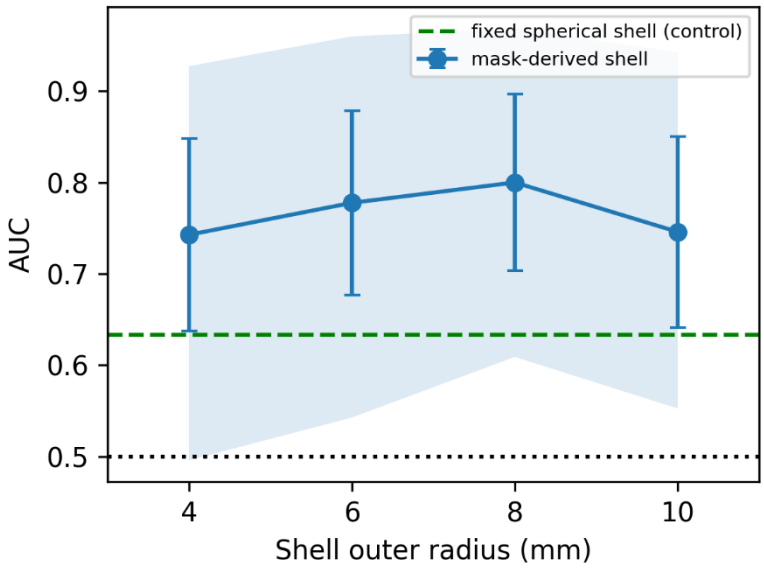

Figure 2. AUC as a function of shell radius (4–10 mm), with the fixed spherical shell control (AUC = 0.633) shown as a horizontal reference line. The control lies below all four shell points, indicating that proximity to the true annotation boundary contributes signal beyond location alone. Error bars show mean ± one standard deviation; the shaded band shows the 2.5th–97.5th percentile range across the 100 cross-validation splits.

VI. DISCUSSION

The main finding is that the choice of features mattered more than the choice of classifier. The same 93 descriptors and the same classifier moved from chance level to an AUC of 0.80 simply by changing the region from which they were extracted. This matters because the common design in this type of study, computing

everything from inside the expert-drawn annotation, is exactly the configuration that failed here. If our results generalize, they suggest that many existing radiomics pipelines may be looking in the wrong place. This result also indicates that patients are distinguished from controls by the relationship between the nerve and the tissue immediately surrounding it, rather than by the property of the nerve in isolation. That relationship is expressed at the boundary between the two, not within the nerve itself, so it is reasonable that features taken from just outside the annotation carried the signal, while features taken from inside it did not. The fixed-cube cropping strategy used in [12] is broadly consistent with this idea, since it also samples a region wider than the nerve itself; however, that study did not directly compare interior and surrounding regions, so this connection remains indirect.

The fixed-geometry control shows that annotation location alone carries some signal (AUC 0.633). Still, the gap between this control and the mask-derived shells (0.743–0.800) indicates that the shell result is not fully explained by location. Proximity to the actual annotation boundary appears to provide information that a region of fixed shape and size placed at the same center cannot capture. This control, therefore, rules out the possibility that the shell effect is purely a geometric artifact of how the annotations were drawn, while showing that location and boundary proximity both play a role. We would still recommend a fixed-geometry control as standard practice in similar studies, since it is the only way to disentangle these two contributions. This study has several limitations. The cohort is small (n = 80 after excluding CISS-acquired patients) and comes from a single center, as reflected in the fairly wide confidence intervals. A single reader produced all annotations, so we cannot yet say whether the shell effect would hold with annotations from a different reader. Because the fixed-geometry control operated below the mask-derived shells, we cannot fully separate content driven by proximity to the annotation boundary from the smaller residual contribution of the annotation shape itself; the control rules out a purely geometric artifact but not a partial one. No external, independent dataset was used to confirm the results. Finally, this study is an ablation experiment comparing regions using a fixed, deliberately simple pipeline, not an attempt to build an optimized diagnostic classifier; the absolute AUC values should therefore be read as a comparison between regions rather than as a claim about real-world diagnostic performance. Within these constraints, the aim of the proposed approach is not to serve as a primary diagnostic method in classical trigeminal neuralgia, which remains a clinical diagnosis. The principal role of imaging is to exclude secondary causes and to characterize neurovascular conflict before intervention. A quantitative peri-nerve marker, i.e., a shell-based feature set, may instead provide additional value for clinical management in the settings where visual assessment is uninformative, such as patients whose examinations are reported as unremarkable despite typical symptoms, and the well-recognized discrepancy in which neurovascular contact is present on the asymptomatic side or absent on the symptomatic one. A natural next step, which the present design cannot address, is a within-patient comparison of the symptomatic and asymptomatic sides, followed by testing whether peri-nerve features relate to response to microvascular decompression or radiosurgery. Until such data are available, the present findings should be interpreted as a methodological result concerning where to look, rather than as evidence that a peri-nerve signature is ready for clinical use.

VII. CONCLUSION

In this paper, we investigated where in a brain MRI the information needed for classification originates, using a small nerve structure as a case study. We compared classification performance across several spatial regions derived from the same expert annotation: the interior of the annotation itself, narrow bands immediately surrounding it, and a large box enclosing it. We also tested a fixed-geometry control region to determine whether the observed effect was due to image content or merely to the shape of the annotation. Intensity and texture predictors computed inside the expert-drawn annotation carried essentially no usable signal, performing no better than chance. The same predictors, computed instead in a narrow band just outside the annotation, reached an

AUC of 0.80. The fixed-geometry control region reached an AUC of 0.633, above chance, but noticeably lower than the shells derived from the annotation, showing that annotation location alone explains part, but not all, of this result; proximity to the true annotation boundary contributes additional signal beyond location alone. The large enclosing box, in contrast, performed poorly, showing that the benefit is specific to a fairly narrow region and is lost once the region becomes too large. These results indicate that, for this task, the region from which features are extracted is not a minor preprocessing choice but a design decision that can determine whether a model succeeds or fails. It deserves the same level of scrutiny and validation as the choice of features or classifier, rather than being fixed by convention to the expert annotation alone.

Abstract
Information Retrieval (IR) has developed over more than seventy years, from lexical indexing and probabilistic weighting models to dense neural retrieval. Large Language Models (LLMs) are now reshaping the field in three ways: as components inside classical IR pipelines (query expansion, reranking); as end-to-end retrieval systems that internalize a corpus (generative and self-retrieval); and as the party that IR serves, through Retrieval-Augmented Generation (RAG), where retrieval becomes external memory for a model rather than a human searcher. A fourth dimension cuts across these: real-world content is increasingly multimodal text, images, audio, and video, which classical lexical IR was not built to index directly, but which the shared embedding space of dense retrieval extends to more naturally. This paper synthesizes recent work on the three integration modes and their multimodal extension. It identifies the open challenges common to all: the lack of standardized joint evaluation for RAG, the limited interpretability of neural matching, precision/recall trade-offs revived by hybrid dense-sparse methods, cross-modal alignment, and the computational and environmental cost of LLM-driven search. We give a structured reading of an active but fragmented area, organized around a single claim: LLMs do not so much replace IR as recompose four of its long-standing assumptions: what is indexed, what counts as a match, who is served, and which modality is retrieved.

Keywords: Information Retrieval; Large Language Models; Retrieval-Augmented Generation; Dense Retrieval; Generative Retrieval; Multimodal Retrieval; Neural Ranking; Evaluation

I. INTRODUCTION

Information Retrieval (IR) was formalized in the 1950s around a deliberately narrow problem: given a large collection of documents and a user query, return the documents most likely to meet the user's information need [1]. Early systems relied on term-overlap indexing [1]. The field then organized itself around three canonical retrieval models: Boolean, Vector Space, and Probabilistic [1],[2] validated through the Cranfield paradigm and, from 1992 onward, through NIST's Text Retrieval Conference (TREC) [1]. Decades of engineering on top of these models, most visibly the Divergence-From-Randomness (DFR) framework in the Terrier platform [3], have produced systems that are still used as reference baselines today. The 2010s brought a neural turn: queries and documents are embedded into continuous vector spaces, and toolkits such as Pyserini made hybrid sparse/dense pipelines reproducible at scale [4], [5].

LLMs are reshaping this trajectory again, but not along a single axis. Reviewing the recent literature, we see them entering IR in at least three structurally different ways:

- as *components* inserted into an otherwise classical pipeline for contextual query expansion, relevance-model extension, or feature-based reranking [6], [7], [8];

- as *end-to-end retrievers* that collapse indexing, matching, and ranking into a single generative model, echoing the broader shift toward generative retrieval [9, 10];
- as the *served party* in Retrieval-Augmented Generation (RAG), where IR becomes an external memory feeding an LLM rather than a human searcher [11-13].

A fourth, cross-cutting dimension compounds these three: real-world content is increasingly multimodal text, images, audio, video, and structured evidence such as tables or document screenshots. Classical lexical IR was not designed to index or match such content directly; it has handled it only indirectly, through manual annotation, captions, or other textual surrogates, rather than over the raw signal itself. The shared embedding-space paradigm of dense retrieval, by contrast, extends to it more naturally [14], [15].

Scope and method. This is a targeted, argument-driven synthesis, not a systematic review under a pre-registered protocol such as PRISMA: the aim is a defensible reading of a fast-moving area, favoring depth of evidence per claim over exhaustive coverage. A source was kept when it offered concrete, verifiable evidence, a quantitative result, an explicit taxonomy, or a foundational definition for at least one of the four dimensions, drawn mostly from peer-reviewed IR/NLP venues (ECIR, SIGIR, ICTIR, TREC, CORIA, IEEE Access), with arXiv preprints admitted only for the most recent work. The 19 sources fall into four strata: (1) foundational IR papers [1],[3]; (2) empirical papers instantiating each convergence mode [4], [6-9], [11]; (3) recent (20232025) surveys giving field-level taxonomies for generative retrieval, LLM-IR, and RAG evaluation [5], [10], [12], [13]; and (4) sources for the multimodal extension [14], [15], plus an expert-workshop report as an independent check [16]. The three-mode organization is not a new taxonomy; it reorganizes distinctions already present across the surveys in stratum (3) [10], [12], [13]; the contribution is the reading in Section 7, whose limitations are also stated in that section. This paper does not propose a new architecture; it offers a structured, literature-grounded reading of these four dimensions. Section 2 revisits the classical foundations later sections build on; Section 3 covers the dense/neural turn and the interpretability question it raised; Section 4 details the three integration modes as an organizing lens rather than a new taxonomy; Section 5 extends the analysis to multimodal retrieval; Section 6 draws together the cross-cutting open challenges; and Section 7 develops the paper's central claim that what is really changing is not a single technique but four of IR's core assumptions: what is indexed, what counts as a match, who the system serves, and what modality is retrieved.

II. CLASSICAL INFORMATION RETRIEVAL FOUNDATIONS

Classical IR rests on three canonical retrieval models that are still the vocabulary of the field: the *Boolean model*, the *Vector Space Model* (Salton), and the *Probabilistic model* of Robertson and Sparck Jones [1], [2]. All three share the same pipeline, summarized in Figure 1: documents are parsed into an inverted index, the query is processed through the same representation, a weighting function scores the document/query overlap, and a ranked list is returned, optionally refined by relevance feedback, which folds information from previously retrieved documents back into the query.

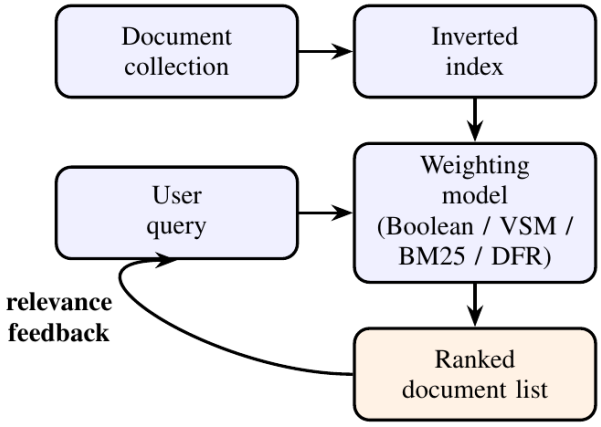

Figure 1. The classical IR pipeline behind the Boolean, Vector Space, and Probabilistic models: a collection is parsed into an inverted index; a query is scored by a weighting model (Boolean, VSM, BM25, or DFR); a ranked list is returned, optionally refined by relevance feedback. Later sections modify the weighting stage (Figure 2) or replace the pipeline (Figure 3). This architecture is not merely historical. The Terrier platform [3] turns the DFR framework, a generalization of Harter's 2-Poisson model, into more than fifty parameter-free document-weighting models alongside tf-idf, BM25, and language-modeling baselines, and it remains in active use (for example, as the retrieval backbone in later TREC Deep Learning submissions [8]). Its efficiency is notable: on the 426 GB TREC.GOV2: A Terabyte collection and a full Terrier index are only about 4.1% of the collection's size, and a long-query-with-expansion run reached a MAP of 0.3075 at the TREC 2004 Terabyte track, more than double the participants' median of 0.1427 [3]. Evaluation in this period is standardized around precision and recall, whose trade-off is already a defining tension of the field [1, 2]: precision-oriented systems were often justified by the observation that most users rarely look past the first results page [1]. That tension between exhaustive recall and user-facing precision returns, in a different guise, in hybrid dense-sparse retrieval (Section 6).

III. THE DENSE AND NEURAL RETRIEVAL TURN

Neural IR reorganizes the weighting stage of Figure 1 rather than the pipeline itself. Hambarde and Proença [5] group neural ranking models into three families: *representation-based* models that encode query and document independently before a shallow comparison (e.g., DSSM); *interaction-based* models that build fine-grained query-document interaction matrices before aggregating a score (e.g., ARC-I/II, MatchPyramid, K-NRM, DUET, PACRR, Conv-KNRM); and *hybrid* models. Pretrained transformers then displaced this generation of models: cross-encoder rankers such as monoBERT and duoBERT, and interaction-aware architectures such as CEDR, became standard second-stage rerankers [5].

Dense retrieval embeds queries and documents in a shared continuous vector space and scores candidates by vector similarity rather than lexical overlap. The Pyserini toolkit [4] made this reproducible at scale by wrapping Lucene-based sparse retrieval (via Anserini) and FAISS-based dense retrieval behind a single interface, along with a HybridSearcher that fuses sparse and dense scores (Figure 2). On the MS MARCO passage ranking dev set, Lin et al. report MRR@10 rising from 0.184 for default BM25 to 0.335 for a dense TCT-ColBERT retriever, 0.3530.365 for sparse-dense hybrids, and up to 0.420 for a multi-stage Expando-Mono-DuoT5 pipeline [4], evidence that dense and sparse signals are complementary rather than interchangeable, a point echoed in Section 6.

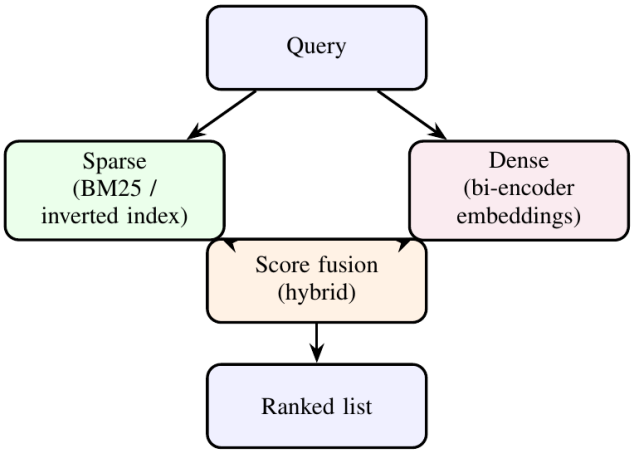

Figure 2. Sparse, dense, and hybrid first-stage retrieval: a query is scored by a sparse path (BM25 over an inverted index), and a dense path (bi-encoder embeddings), and the scores are fused into one ranked list, as in Pyserini's HybridSearcher [4]. On MS MARCO, the two signals prove complementary rather than substitutable (Section 3).

This gain in effectiveness came at the cost of transparency: interaction-based neural rankers are accurate, but their internal matching mechanism is largely opaque. Vast et al. study this directly, ablating attention pathways in monoBERT-style cross-encoders on the TREC Deep Learning 20192022 judgment sets [17]. Ablating the document's self-contextualization (documents that attend to themselves) yields the largest single-pathway drop in ranking quality. At the same time, the [CLS] token seems to aggregate relevance only in the later layers, playing a largely “no-op” role earlier. The same analysis finds that early-to-middle layers capture lexical, word-level correspondence between query and document, whereas later layers match semantically contextualized tokens [17]. This interpretability gap, effective matching without a clear account of why it matches, is one of the threads carried into the LLM era discussed next.

IV. THREE MODES OF LLMIR CONVERGENCE

Across the recent literature, LLMs do not enter IR through a single interface. We organize the convergence into three modes, shown together in Figure 3. These form a spectrum rather than a strict partition: a deployed RAG system (mode (c)) commonly embeds mode (a) components, such as LLM-based query rewriting and reranking, inside its retriever. The modes describe where the LLM does the decisive work; they are not mutually exclusive architectures.

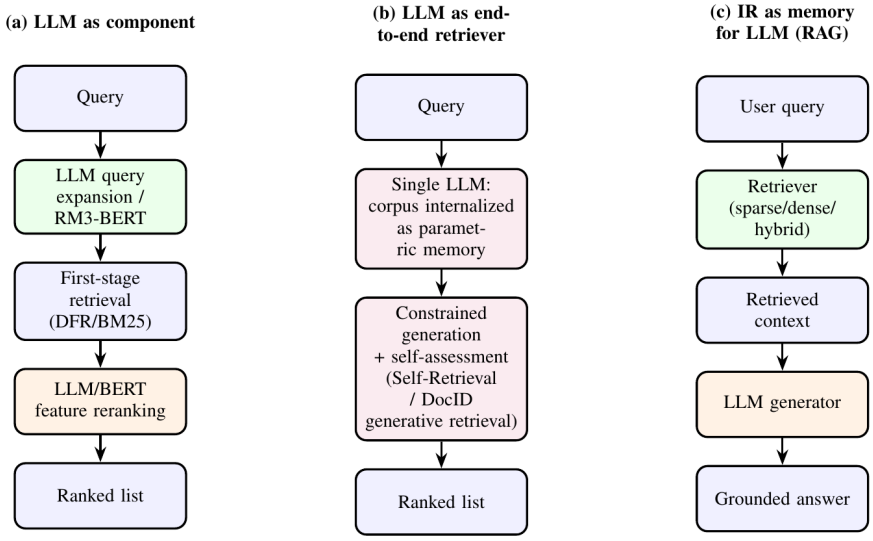

Figure 3. The three modes of LLMIR convergence: (a) LLMs augment a classical pipeline; (b) a single LLM performs indexing, retrieval, and ranking internally; (c) classical or dense IR becomes external memory serving an LLM's generation (RAG).

1. Mode (a): LLMs as Components Inside Classical Pipelines

The least disruptive integration keeps the pipeline in Figure 12 intact and inserts a language model at a single stage. Wang et al. extend pseudo-relevance feedback, classically formulated by Rocchio, to relevance models for multi-representation dense retrievers, refining the query's dense representation from an initial pseudo-relevant set rather than a bag-of-words query [6]. Kheloui et al. take a distinct route: their RM3-BERT model keeps the Relevance Model (RM3) as the backbone and linearly interpolates it with a BERT-based term-weighting component, tuned by a mixing parameter γ [7]. On AP88 and Robust-2004, RM3-BERT clearly outperforms RM3 alone, with MAP gains from 5.73% (short/title queries) up to 20.07% (long/description queries); the best mixture keeps γ=0.7, the lexical RM is weighted *more* than the BERT component, since pure BERT scoring (γ=0) does not beat RM3 on its own [7]. The catch is cost: BERT inference adds roughly 72 seconds per query on commodity hardware, which the authors flag as impractical for real-time search and a reason to move to pre-indexed, ColBERT-style representations. A further instance of mode (a) is feature-fusion reranking. The University of Glasgow Terrier team's TREC 2020 Deep Learning Track submission [8] keeps a three-stage architecture: DFR-based candidate retrieval (DPH) with Bo1 and T5-based query expansion; feature calculation (including BERT-[CLS], ColBERT, and SciBERT scores); and LambdaMART reranking. Notably, their single strongest feature across TREC 2019 and TREC 2020 was the ColBERT MaxPassage score, and their best-submitted run used no learning-to-rank reranking at all, due to the scarcity of training judgments relative to the complexity of the feature-based LTR model [8]. This is a useful counter-example to the assumption that adding more LLM-derived features always improves ranking: the contribution of each component still has to be validated empirically.

2. Mode (b): LLMs as End-to-End Retrievers

A more radical integration folds indexing, matching, and ranking into a single generative model. Generative retrieval recasts search as a sequence-to-sequence mapping from a query directly to a document identifier

(DocID), removing the separate inverted-index and reranking stages [10]. Kuo et al. organize the DocID design space into numerical identifiers (arbitrarily assigned or semantically structured) and string identifiers (substrings, titles/URLs, or pseudo-queries), and survey systems built around each of these, including DSI, DSI++, NCI, GENRE, SEAL, and CorpusBrain [10]. Self-Retrieval [9] goes further: one LLM internalizes the corpus in a self-supervised indexing phase, then retrieves by generate-then-self-assess, playing the role that indexing, matching, and reranking play separately in Figure 1. Mode (b) trades the transparency of an explicit index for the flexibility of a parametric one, at the cost of the interpretability and update guarantees inverted indexes give by construction, a trade-off this paper returns to in Section 6.

3. Mode (c): IR as External Memory for LLMs (RAG)

The third and most widely deployed mode reverses the direction of service. Instead of IR helping a human find documents, IR retrieves context that helps an LLM generate a better answer. Zhu et al. organize LLM-augmented IR around four modules: Query Rewriter, Retriever, Reranker, and Reader, plus an emerging Search-Agent layer that folds retrieval into the generation loop [12]. This raises a new evaluation problem: retrieval quality and generation quality are no longer separable. El-Yagouby et al. address it using a two-phase framework that combines a Longest-Common-Subsequence IR-quality score with an LLM-judge (GPT-4o) correctness rubric on HotpotQA, using a Llama3-8B generator across five retrievers [11]. A plain BM25 retriever gives the best IR score (0.62 at 1000 retrieved tokens), and while an LLM answering *without* any retrieval is fully incorrect 58% of the time, BM25-grounded RAG is fully correct 42% [11]. Two thresholds on the IR score (h=0.105, k=0.670) are then used to estimate answer quality without running the LLM, with roughly 56% of BM25 examples in the intermediate "hallucination risk" zone [11]. Gan et al.'s survey formalizes this joint problem, separating *internal* evaluation (retrieval and generation quality) from *external* evaluation (safety and efficiency), and catalogs metric families from MRR/NDCG/MAP and ROUGE/BLEU/BERTScore to LLM-as-judge protocols [13].

Table 1. The three modes of LLMIR convergence compared by strengths, limitations, and best-fit use cases: (a) an LLM inside a classical pipeline; (b) a single generative retriever; (c) IR as external memory for an LLM (RAG). Cited figures come from the studies in Section 4.

Mode	Strengths	Limitations/use cases
(a) Component	Keeps an auditable, updatable inverted index; incremental, measurable per-component gains (MAP +5.720% for RM3-BERT) [7]	Added latency (e.g., ~72 s/query for BERT-based RM3) [7]; gains not guaranteed best TREC 2020 run used no LTR at all [8]. Best suited to systems that already operate an inverted index.
(b) End-to-end	Unifies indexing, matching, and ranking in one model; flexible DocID design space [9], [10]	No explicit, inspectable index; unclear incremental-update story when new documents arrive [10]. Best suited to closed or slowly-changing corpora, and to research prototypes.
(c) RAG	Decouples parametric knowledge from external, up-to-date facts; even a plain BM25 retriever sharply reduces fully-incorrect answers, raising the fully-correct rate to 42%	Retrieval and generation quality are not yet jointly and consistently measured [13]; ~56% of BM25-based answers still fall within an ambiguous risk zone [11]. Best suited to open-domain QA and knowledge

Mode	Strengths	Limitations/use cases
	where the same LLM with no retrieval is fully incorrect 58% of the time [11]	bases that change faster than any model can be retrained.

V. THE MULTIMODAL EXTENSION

The three modes were formulated for text, but real content is rarely text-only, and the same structure reappears across modalities. Mei et al. frame this as an evolution from *MRAG1.0*, a "pseudo-multimodal" setting where non-textual content is first converted to text and then run through a standard text pipeline, to MRAG2.0, where the original content is kept, and a multimodal LLM (MLLM) interprets and generates directly on it [14]. Abootorabi et al. give a finer-grained taxonomy organized around retrieval strategies, fusion mechanisms, augmentation and generation techniques, and training strategies [15]. Concrete systems fill each branch: ColPali retrieves directly over page images, bypassing OCR; MuRAG and RA-CM3 jointly retrieve and generate across text and images; ColBERT/PreFLMR extend late interaction to multimodal retrieval; and CRAG adds retrieval-quality-aware correction inside the RAG loop [15].

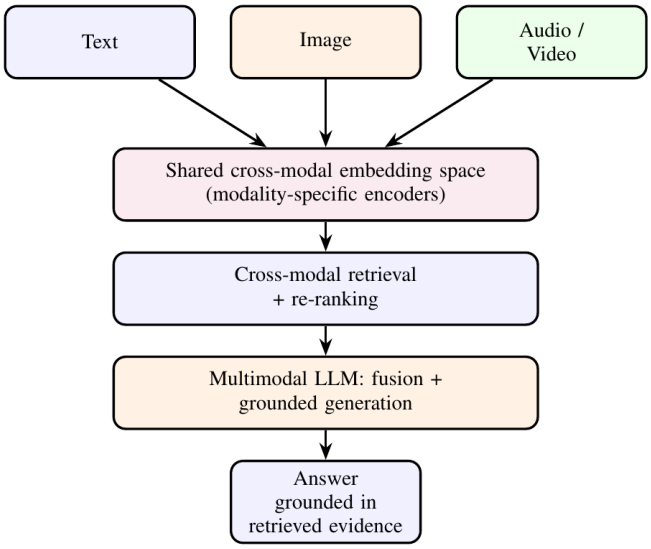

Figure 4. Multimodal RAG (MRAG2.0-style): modality-specific encoders feed a shared embedding space, from which cross-modal evidence is retrieved and grounded by a multimodal LLM [14], [15].

This extension (Figure 4) inherits the same three-mode structure as Section 4 multimodal encoders as components, end-to-end multimodal retrievers, and multimodal RAG. Still, it introduces cross-modal difficulties: aligning heterogeneous embedding geometries, a relative scarcity of multimodal benchmarks compared with decades of text-only TREC-style collections, and the higher cost of multimodal encoders [14], [15]. Badamasi et al. independently flag heterogeneous, multimodal data as a top-level challenge for information access even outside the RAG literature [2], a sign that this is a broadly recognized difficulty rather than one community's framing.

VI. CROSS-CUTTING OPEN CHALLENGES

Table 2 lists five challenges that recur, in different guises, across the modes and the multimodal extension.

Table 2. Five open challenges recurring across the three modes and the multimodal extension, each with the setting in which it surfaces. Directions and mitigations follow in the text.

Challenge	Where it surfaces
Evaluation standardization	Retrieval and generation quality must be assessed jointly in RAG [11]; no consensus metric set yet, though internal/external taxonomies are emerging [13].
Interpretability of matching	Neural cross-encoders match effectively but opaquely; specific attention heads carry lexical vs. semantic signal, with document self-contextualization the most critical single pathway [17].
Precision/recall trade-offs	Hybrid dense-sparse fusion can raise Recall@10 by up to 580% relative (13.9%→80.8% on MS MARCO) but at a cost in ranking quality (NDCG@10 0.83→0.51), and the gain vanishes on specialized-vocabulary corpora [18].
Cross-modal alignment	Modality-specific embedding geometries and scarce multimodal benchmarks limit generalization of dense-retrieval fusion across text/image/audio/video [14], [15].
Computational/environmental cost	BERT-scale inference can add tens of seconds per query on commodity hardware [7]; data-center energy and cooling for large-scale AI search raise resource-consumption concerns, which have been documented primarily in practitioner sources [19] and are still awaiting authoritative, peer-reviewed empirical quantification for LLM-driven retrieval.

The precision/recall tension is worth expanding on, since it revisits the classical trade-off in Section 2. That sparse and dense signals are complementary is established in peer-reviewed work (Section 3) [4]; the magnitudes below come from a non-peer-reviewed preprint [18] and are best read as illustrative. Weinberg's hybrid method, combining a compact bi-encoder with BM25 through weighted score fusion, reports Recall@10 rising from 13.9% (dense-only) to 80.8% (hybrid) on MS MARCO, ahead of a ColBERT-style baseline (15.0%) and a SPLADE-inspired learned-sparse baseline (4.2%) [18]. Yet NDCG@10 falls from 0.83 to 0.51, the recall/precision-quality tension resurfacing inside one fused score, and the advantage disappears on BEIR NFCorpus, where dense-only and hybrid recall are indistinguishable (17.6% vs. 17.4%), attributed to that corpus's specialized vocabulary and small size [18]. The gain is real but corpus-dependent, and bought at a measurable cost elsewhere in the ranking.

At a community level, the 2024 Computing Community Consortium workshop report [16], convening 44 IR, NLP, HCI, and AI researchers, groups future priorities into eight themes that closely mirror the challenges above: evaluation; training and reasoning; modeling users; social ramifications; personalization; efficiency and scalability; AI agents; and foundation models for information access [16]. That an independent expert workshop converges with the challenges surfaced bottom-up here supports treating them as structural open problems rather than incidental limitations of specific systems.

Directions and mitigations. The challenges of Table 2 and the per-mode limitations of Table 1 are not equally intractable. For *evaluation*, the most actionable near-term direction is automated, reference-free assessment: El-Yagouby et al.'s two-threshold scheme predicts RAG answer quality from a retrieval-quality score [11], and Gan et al.'s internal/external decomposition offers a common reporting vocabulary [13]. Both rely on *LLM-as-a-*

Judge protocols, whose known failure modes, position and verbosity biases, prompt sensitivity, and drift when the judge is updated mean a judge should be calibrated against human labels and reported with its model and version fixed [13]. For the *mode-specific* limitations, three directions recur: a high-recall-then-rerank pipeline mitigates both the ranking-quality cost of hybrid fusion and the RAG "risk zone" [18]; pre-computed ColBERT-style representations cut the per-query latency of BERT-based components in mode (a) [7], [8]; and incremental indexing remains the prerequisite for mode (b) to serve fast-changing corpora [10].

VII. DISCUSSION: RECOMPOSING IR'S CORE ASSUMPTIONS

Reading Sections 25 together, the changes LLMs introduce are not well described as "adding a language model to IR." They are better described as a recomposition of four assumptions that classical IR treated as fixed, summarized in Table 3.

Table 3. The paper's central claim: four assumptions classical IR treated as fixed (middle) and what each becomes under LLM-native and multimodal retrieval (right), what is indexed, what counts as a match, who is served, and what modality is retrieved.

Axis	Classical IR	LLM-native / multimodal IR
What is indexed	Terms in an inverted index [3]	DocIDs in a parametric model [9], [10] or cross-modal embeddings [14]
What counts as a match	Lexical / statistical overlap (BM25, DFR) [3]	Learned semantic similarity, often uninterpretable [5], [17]
Who is served	A human searcher [1]	An LLM consumer, via RAG [11], [12]
What modality	Text [1]	Text, image, audio, video, jointly [15]

Each recomposition carries its own unresolved question. Moving what is indexed from an inverted structure to a model's parameters (mode (b)) trades updateability and inspectability for flexibility. A DocID-generating LLM cannot be updated by appending to an index the way Terrier's structure can [3, 10]. Moving what counts as a match from lexical overlap to learned similarity buys effectiveness (Section 3) at the cost of interpretability, which is only partially recoverable by post hoc analysis [17]. Moving who is served from a human to an LLM (mode (c)) is the most consequential shift, since it changes what "relevance" is optimized for: in the HotpotQA setup above, El-Yagouby et al. find plain BM25 the strongest of five retrievers for downstream answer correctness [11] a single-benchmark result that should not be over-read, but a warning that retrieval metrics tuned for human satisfaction may not carry over to LLM consumption. Finally, moving from a text-only modality to a joint text/image/audio/video space is the least mature axis, constrained more by scarcity of benchmarks and alignments than by any architectural obstacle [14], [15].

A dimension that cuts across all four axes, only partly addressed by the sources here, is language. *What counts as a match* changes most: cross-lingual dense retrieval can align query and document across languages in one embedding space, impossible for lexical overlap, but degrades where training data is thinnest. *What is indexed* depends on a tokenizer and parametric memory covering the target script, which works much better for high-resource languages. *Who is served* inherits the retriever's coverage, so the hallucination-reduction grounding in English need not transfer to low-resource languages. And *what modality is retrieved* compounds the scarcity of benchmark data, since jointly multilingual and multimodal collections are rarer still [15]; heterogeneous,

unevenly resourced content is itself flagged as a first-order challenge [2]. Cross-lingual and low-resource robustness is thus a stress test that the four recomposed assumptions have yet to pass uniformly.

1. Limitations of This Survey

Three limitations bear on how these claims should be read. First, source selection was targeted rather than systematic (Section 4), so this is a reading of the space, not a census. Second, a few sources sit outside mainstream peer-reviewed IR/NLP publishing the hybrid dense-sparse report [18], an industry preprint posted to SSRN, and a practitioner survey of AI-based search [19] kept for their concrete quantitative case studies but carrying less evidentiary weight than the TREC-, SIGIR-, or ECIR-anchored studies, and flagged as such throughout. Third, coverage is skewed over time: most LLM-IR and RAG sources are from 20232025, and pre-2020 neural IR is represented mainly by a 2023 survey [5] rather than by the primary sources it summarizes.

VIII. CONCLUSION

Seventy years after it was formalized, Information Retrieval is not being replaced by Large Language Models so much as recomposed by them, along at least four axes: what is indexed, what counts as a match, whom the system serves, and what modality is retrieved. We organized the recent literature around three integration modes: LLMs as pipeline components, LLMs as end-to-end retrievers, and IR as external memory for LLMs via RAG, and showed that each extends naturally but not painlessly to multimodal content. The open challenges standardized joint evaluation of retrieval and generation, interpretable neural matching, corpus-dependent precision/recall trade-offs, cross-modal alignment, and the computational and environmental cost of LLM-driven search are corroborated both by individual studies and by a community-wide expert workshop [16], which suggests they are structural rather than incidental. Clarifying where classical IR foundations still hold, and where they do not, is a necessary step before the field can agree on shared evaluation practices for this new generation of retrieval systems.

Abstract
Between 2021 and 2025, artificial intelligence (AI) and deep learning (DL) methods came to play a defining role in medical imaging research. This study sets a global publication corpus drawn from Scopus (19,968 records after deduplication) against a Turkey-affiliated subset (4,843 records), mapping research trends, thematic shifts, and the keyword clusters that dominate each at both the thematic-group and individual-keyword levels. The bibliometrix R package and VOSviewer were used to build keyword co-occurrence networks and Sankey-based thematic evolution diagrams. CNN and deep learning still anchor the global literature. That dominance, however, is no longer unchallenged: between 2024 and 2025, vision transformers (ViT), explainable AI (XAI) methods such as Grad-CAM, and the broader push for interpretability reshaped the field's center of gravity. The Turkish dataset tells a different story: machine learning and classification lead the field and, once frequencies are normalized by publication volume, interest in ChatGPT and related large-language-model terms, once grouped into a single category, sits at a markedly higher relative density (26.2×, χ^2=290.2, $p<0.001$) than in the global corpus. A supplementary, ungrouped keyword analysis tentatively identifies clinical decision support as an early point of convergence between the two literatures in 2024-2025.

Keywords: bibliometric analysis, deep learning, medical imaging, VOSviewer, bibliometrix, Turkey, thematic evolution

I. INTRODUCTION

Deep learning's move into medical imaging has been one of the fastest technological shifts of the past five years. Convolutional neural networks (CNNs) outpaced traditional pattern-recognition methods. They gave diagnostic support systems a solid technical foundation [1], [2], with the same architecture continuing to prove effective on general image-classification tasks outside the medical domain, including semantic-communication-based classification pipelines [3], [4]. Residual connections [5], dense connectivity [6], and EfficientNet's compound scaling [7] later enabled CNNs to go deeper and more cheaply without sacrificing trainability. The Vision Transformer (ViT) architecture, proposed in 2021, drew researchers' attention to attention-based approaches that split images into patches and model global relationships among them, rather than relying on CNNs' local, hierarchical receptive fields [8]. Bibliometric analysis offers a way to track which methods are actually setting the agenda. By processing large volumes of publication data with quantitative methods, researchers can map the structure of a field [9]. Donthu et al. [10] note that the method does double duty, measuring performance while also mapping the science itself, and that it travels well across disciplines. Chen et al. [11] examined 562 highly cited WoS articles from 2013–2023 and found CNN, classification, and segmentation dominant, but their window closes before the post-2024 rise of ViT and XAI. Wang et al. [12] reported that breast, lung, and skin cancer dominate cancer-focused DL applications, while Lin et al. [13] identified country-level productivity leaders between 2019 and 2023; neither examined Turkey specifically. This paper fills that gap with four

contributions: a comparative global-versus-Turkey analysis; a mapping of the research agenda through keyword networks, Sankey diagrams; a volume-normalized assessment of where Turkey stands relative to the global agenda, not merely a raw-count one; and a side-by-side look at ViT, XAI/Grad-CAM, and ChatGPT-related terms, supplemented by an ungrouped keyword-level pass that surfaces micro-themes too small to register thematically. The remainder of this paper is organized as follows: Section II reviews related bibliometric studies; Section III describes the corpus construction and analytical methods; Section IV presents the results, including keyword frequencies, co-occurrence networks, and thematic evolution; Section V discusses the findings; and Section VI concludes with limitations and future work.

II. RELATED WORK

Bibliometric studies at the intersection of medical imaging and AI have multiplied quickly (Table 1). Chen et al. [11] used CiteSpace to scan 2013–2023 and confirmed CNN-centered themes, but missed the newer ViT and XAI threads. Wang et al. [12] and Lin et al. [13] contributed findings on cancer applications and country-level productivity, respectively, but neither examined Turkey on its own terms. Litjens et al. [14], Shen et al. [15], and Miotto et al. [16] published broad reviews spanning pathology, radiology, and clinical decision support, while Dosovitskiy et al. [8] showed that ViT could rival or exceed CNNs with large-scale pretraining. Selvaraju et al.'s Grad-CAM method [17] helps explain why interpretability research has accelerated so fast, addressing a transparency gap in the field. Broader application reviews, such as Houssein et al.'s survey of deep and machine learning techniques for breast cancer imaging [18], implicitly highlight this same gap by cataloging the many black-box models now in clinical use. None of the existing literature provides a comparative, volume-normalized look at global and Turkey-affiliated publications across 2021–2025; this is the gap this study addresses.

Table 1: Comparison of Related Studies

Study	Scope	Period	Turkey-specific
Chen et al. [11]	CNN, classification, segmentation	2013–2023	No
Wang et al. [12]	Cancer-focused DL applications	2015–2023	No
Lin et al. [13]	Country-level AI productivity	2019–2023	No
This study	Global vs. Turkey, volume-normalized, ViT/XAI/LLM emergence	2021–2025	Yes

III. MATERIALS AND METHODS

1. Corpus Construction and Sampling

Two publications set the anchor for this study. The global dataset was derived from a Boolean query run in Scopus's TITLE-ABS-KEY field, combining AI-architecture terms with health, medical, clinical, radiology,

pathology, and imaging terms, and restricted to the computer science and medicine subject areas from 2021 to 2025. The exact query used was: TITLE-ABS-KEY(("deep learning" OR "machine learning" OR "convolutional neural network" OR "CNN" OR "transformer" OR "vision transformer" OR "ViT" OR "U-Net" OR "ResNet" OR "LSTM" OR "RNN" OR "GAN" OR "generative adversarial" OR "attention mechanism" OR "transfer learning") AND ("healthcare" OR "medical" OR "clinical" OR "hospital" OR "patient" OR "disease" OR "diagnosis" OR "radiology" OR "pathology" OR "imaging")) AND NOT TITLE-ABS-KEY("plant disease*" OR "plant detect*" OR "crop*" OR "agriculture" OR "soil*" OR "weed*" OR "pest*" OR "livestock") AND PUBYEAR > 2020 AND PUBYEAR < 2026 AND (LIMIT-TO(SUBJAREA, "COMP") OR LIMIT-TO(SUBJAREA, "MEDI")) AND (LIMIT-TO(DOCTYPE, "ar") OR LIMIT-TO(DOCTYPE, "re") OR LIMIT-TO(DOCTYPE, "cp")). The Turkey subset applied the same query with an additional AND (LIMIT-TO(AFFILCOUNTRY, "Turkey")) clause, capturing 4,847 records, 4,843 after deduplication. The global query returned 278,252 records in total, rising steadily from 32,639 in 2021 to 84,720 in 2025. Scopus caps single-query exports at 20,000 records. For the global corpus, the top 4,000 relevance-ranked records per year were therefore retained, yielding a 20,000-record working corpus. After DOI and title deduplication, the working corpora settled at 19,968 global records and 4,843 Turkey records. Processing the full frame was not feasible: Scopus's export interface is capped at 20,000 records in total and offers no random sampling option, and Bibliometrix's own memory ceiling is roughly the same. Together, these fixed the working corpus at 20,000 records, hence the 4,000-record-per-year allocation across the five years (a 50,000-record ceiling would instead have allowed 10,000 per year). This is a relevance-ranked, year-stratified truncation, not systematic sampling: within each year, Scopus's proprietary relevance score, rather than a random interval, determines inclusion, which means highly cited, metadata-complete records are overrepresented relative to low-citation, very recent, or non-English/national-journal records. Although the truncation procedure is non-probabilistic, its empirical regularity was assessed across five sequential 4,000-record slices, using Spearman's ρ and Jaccard's J over the top-20 keyword set (Table 9). Consecutive-slice stability was high (mean $\rho = 0.890$; mean $J = 0.741$), indicating strong thematic consistency despite the non-probabilistic truncation. Cumulative comparison against the first slice showed expected attenuation ($\rho = 0.488$; $J = 0.538$), consistent with gradual thematic drift. A chi-square test was significant at every step, but is known to be oversensitive at this sample size, so Spearman/Jaccard were used as the primary criteria. A Mann-Whitney U test found no difference across the first three transitions but a significant one between the fourth and fifth slices ($p = 0.0028$), consistent with the fifth slice (2025) having had less time to accrue citations. Taken together, these findings suggest the truncation, though not systematic by design, produced a stable and representative working corpus.

Records were included if they were published between 2021 and 2025, indexed in Scopus, written in English, and classified as an original article, review, or conference paper, and referencing the intersection of AI and medical imaging in the title, abstract, or keywords. Duplicates, retractions, non-clinical engineering studies, and records lacking an accessible abstract were excluded. Two independent researchers applied these criteria and resolved disagreements by discussion.

2. Analytical Tools and Parameters

Analysis ran on two platforms. Aria and Cuccurullo's [9] bibliometrix package, version 4.3.x, handled publication-trend analysis, country and institution classification, and keyword frequency counts at two levels, 23 canonical thematic groups such as Deep Learning, CNN, ViT, XAI, and ChatGPT/LLM, plus a supplementary pass across individual, ungrouped Author Keywords meant to catch early-stage micro-themes falling below any single group's detection threshold. Keyword standardization followed a controlled synonym-mapping protocol that unified plural, hyphenated, and near-duplicate variants into a single canonical form, with 10% of mappings cross-checked by a second researcher. Van Eck and Waltman's [19] VOSviewer, version

1.6.20, built keyword co-occurrence networks, clustered them with the Leiden algorithm at a resolution of 1.0, and generated overlay visualizations keyed to the average publication year. The co-occurrence parameters were derived from pilot runs rather than the default settings. These runs settled on a minimum frequency of 10 for the global set, and 5 for the Turkey set, a cap of 150 terms, and association strength as the normalization method. Thematic evolution used Bibliometrix's thematicEvolution(). Supplementary keyword terms needed at least 3 occurrences in the 2024 baseline year to enter the share-growth ranking. Because the global corpus is roughly 4.1 times Turkey's, every comparison is reported as both a raw count and a rate per 1,000 publications. All figures were produced in R 4.4.0. To assess whether Turkey/Global density differences were statistically significant, chi-square tests of independence were additionally computed for each keyword in Table 2, comparing Turkey presence/absence against the Global corpus (α=0.05).

IV. RESULTS

Table 2 reports raw frequencies alongside volume-normalized densities, with the Turkey/Global ratio in the final column (1.0 = equal relative weight; below 1 = Turkey under-use; above 1 = over-use). Two entries dominate that column: a grouped ChatGPT/LLM category at 26.2× (χ^2=290.2, p<0.001) and radiomics at 2.42× (χ^2=40.1, p<0.001), both indicating that Turkey is proportionally more engaged than the global literature. All differences in Table 2 are statistically significant (p<0.05) except Explainable AI (χ^2=3.3, p=0.070), where Turkey's apparent under-use is not distinguishable from the global rate. At the other extreme, the convolutional neural network sits at 0.23×, and the vision transformer at 0.22×. Turkey engages with these foundational architectures at under a quarter of the global rate.

Table 2: Global vs. Turkey Keyword Frequencies, Raw and Volume-Normalized

Keyword	Global f	Global /1000 pub	Turkey f	Turkey /1000 pub	Turkey/ Global ratio	χ^2	p
Deep learning	9,579	479.7	1,422	293.6	0.61x	546.8	<0.001
Convolutional neural network	3,138	157.2	177	36.5	0.23x	488.9	<0.001
Machine learning	2,688	134.6	1,311	270.6	2.01x	532.5	<0.001
Transfer learning	2,286	114.5	258	53.3	0.47x	158.1	<0.001
U-Net	627	31.4	65	13.4	0.43x	45.8	<0.001
MRI	574	28.7	80	16.5	0.57x	22.3	<0.001
Vision transformer	970	48.6	51	10.5	0.22x	142.1	<0.001
Explainable AI	184	9.2	31	6.4	0.69x	3.3	0.070
Grad-CAM	144	7.2	20	4.1	0.57x	5.2	0.023
Artificial intelligence	1,229	61.6	614	126.8	2.06x	240.1	<0.001
Radiomics	133	6.7	78	16.1	2.42x	40.1	<0.001
ChatGPT	3	0.2	57	11.8	78.32x	213.3	<0.001
LLM-grouped	14	0.7	89	18.4	26.20x	290.2	<0.001

1. Co-occurrence Networks

Figure 1, the global co-occurrence network, and Figure 2, the Turkey co-occurrence network, show the cluster-colored VOSviewer maps. Globally, “deep learning” sits at the center, branching to “CNN,” “breast cancer,” “COVID-19,” and “U-Net,” whose segmentation role traces to Ronneberger et al.’s original architecture [20], with the network splitting into an imaging/clinical cluster and a bioelectric-signal cluster. Turkey’s network organizes around four hubs: “deep learning,” “classification,” “transfer learning,” and “artificial intelligence,” with the “U-Net”/“MRI” clusters that loom large globally, barely visible here, matching their sub-1.0 density ratios in Table 2.

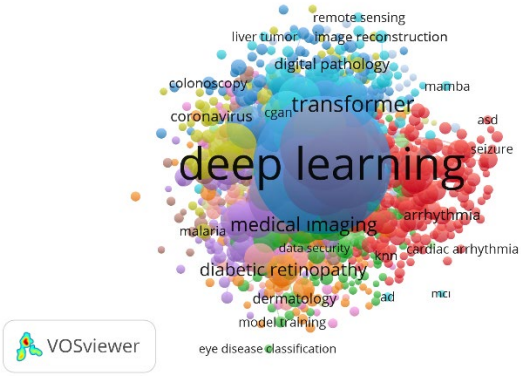

Figure 1. Global co-occurrence network

Figure 2 presents the corresponding network built from the Turkey-affiliated subset.

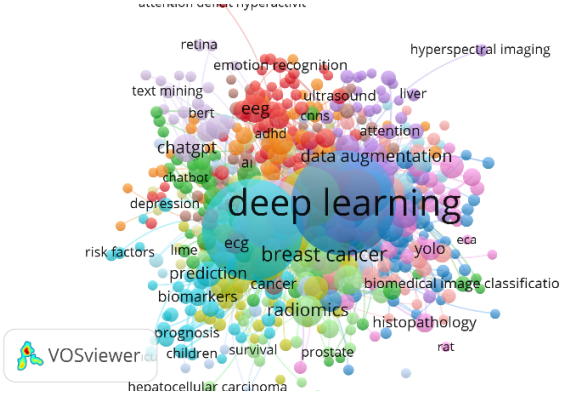

Figure 2. Turkey co-occurrence network

To examine whether architectural choices vary by imaging modality, Tables 3 and 4 cross-tabulate the five leading architectures (CNN, ViT, U-Net, ResNet, GAN) with seven imaging modalities. Globally, CNN-MRI is the dominant pairing (f=482), consistent with CNN's foundational role in neuroimaging. In the Turkish corpus, this pairing drops sharply (f=20). At the same time, ViT-histopathology (f=6) approaches ViT-MRI (f=3) in frequency — a modality distribution not visible in the aggregate architecture and modality counts reported separately in Table 2.

Table 3: Architecture × Modality Crosstab — Global (publication count)

Architecture	MRI	CT	X-ray	Ultrasound	Histopath.	Endoscopy	Dermoscopy
CNN	482	135	264	44	65	22	32
ViT	65	14	48	12	29	5	8
U-Net	58	17	10	6	7	1	1
ResNet	14	6	15	3	5	0	2
GAN	75	34	21	7	9	3	2

Table 4 repeats this breakdown for the Turkey-affiliated subset.

Table 4: Architecture × Modality Crosstab — Turkey (publication count)

Architecture	MRI	CT	X-ray	Ultrasound	Histopath.	Endoscopy	Dermoscopy
CNN	20	7	9	2	9	2	6
ViT	3	0	4	0	6	1	0
U-Net	10	1	0	1	2	0	1
ResNet	0	1	1	0	1	0	0
GAN	3	2	0	1	0	0	0

2. Overlay Visualizations

In Figure 3, the global overlay, and in Figure 4, the Turkey overlay, each node is colored by average publication year. Globally, “vision transformer,” “swin transformer,” and “radiomics” sit in the 2023–2024 band, confirming their recent surge, while older terms like “CNN” and “VGG16” stay in earlier tones. Turkey shows “radiomics,” “ChatGPT,” and “explainable AI” in similarly recent shades, but their clusters are visibly smaller, gaining currency, not yet critical mass. Because the 2024–2025 nodes in both figures overlap too densely to read individually, Tables 5 and 6 list the highest-recency keywords by average publication year for each network, along with their frequencies.

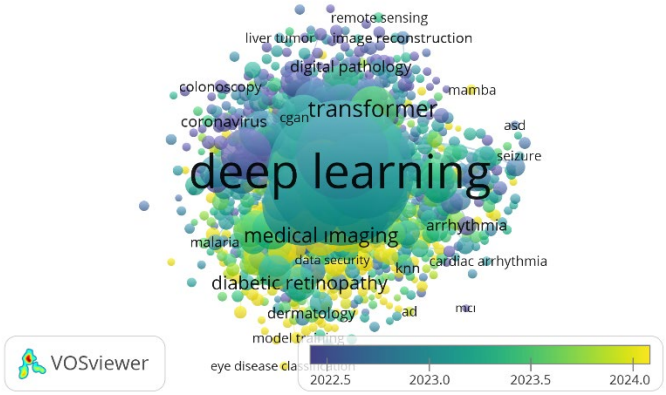

Figure 3. Global overlay network (by average publication year)

Figure 4 shows the same overlay computed for the Turkey-affiliated subset.

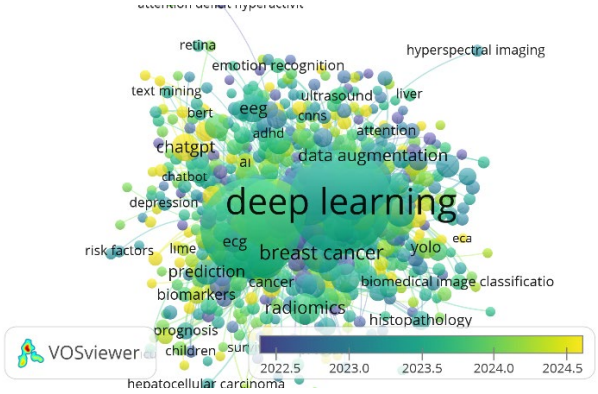

Figure 4. Turkey overlay network (by average publication year)

These frequency and average-publication-year values are reported in Tables 5 and 6 below.

Table 5: Top Recently-Emerging Keywords by Average Publication Year — Global Overlay Network (Figure 3)

Keyword	f	Avg. publication year
ChatGPT/LLM (grouped)	14	2024.2
Vision transformer	1425	2024.1
Swin transformer	126	2024.1
Grad-CAM	159	2024.1
Explainable AI	281	2024.0
Medical imaging	1532	2023.8
Anomaly detection	48	2023.6
VGG16	267	2023.5
Transformer	834	2023.5
ResNet	401	2023.4

Table 6 presents the equivalent ranking for the Turkey overlay network.

Table 6: Top Recently-Emerging Keywords by Average Publication Year — Turkey Overlay Network (Figure 4)

Keyword	f	Avg. publication year
ChatGPT/LLM (grouped)	89	2024.5
Vision transformer	85	2024.5
Swin transformer	15	2024.3
Explainable AI	92	2024.3

Keyword	f	Avg. publication year
Anomaly detection	17	2024.2
Grad-CAM	21	2024.1
Medical imaging	116	2024.1
Transformer	64	2023.9
Artificial intelligence	627	2023.9
Radiomics	78	2023.7

3. Thematic Evolution

Figure 5 shows the global thematic evolution as a Sankey diagram, and Figure 6 shows the same view for Turkey, tracing how themes shifted year by year. Globally, 2021 was dominated by "skin cancer," anchored early by Esteva et al.'s dermatologist-level classifier [21], alongside "deep learning" and "CNN"; "COVID-19" gained visibility in 2022; "transfer learning" and "transformer" emerged in 2023; and 2024 brought "breast cancer" and "vision transformer" to the fore. In Turkey, "deep learning" led every year from 2021 through 2024. Still, in 2025, "machine learning" overtook it for the first time (488 vs. 482 occurrences), a reversal not previously visible under the coarser multi-year binning used in Figure 6. "Classification," "explainable AI," and "anomaly detection" only emerged as distinct themes in 2025, roughly a year behind the global pattern.

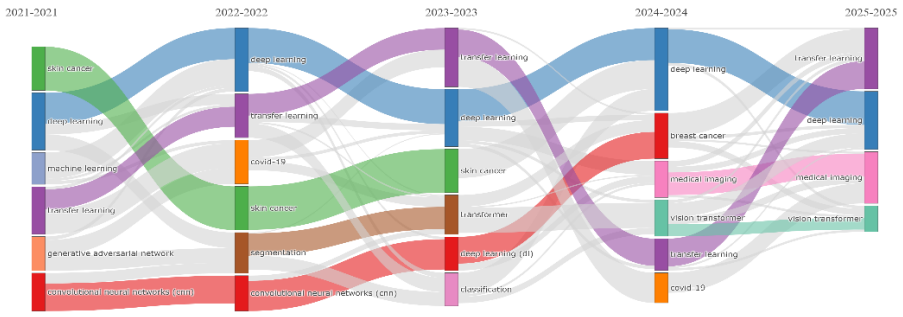

Figure 5. Global thematic evolution (Sankey diagram)

Figure 6 presents the corresponding thematic evolution for the Turkey-affiliated corpus.

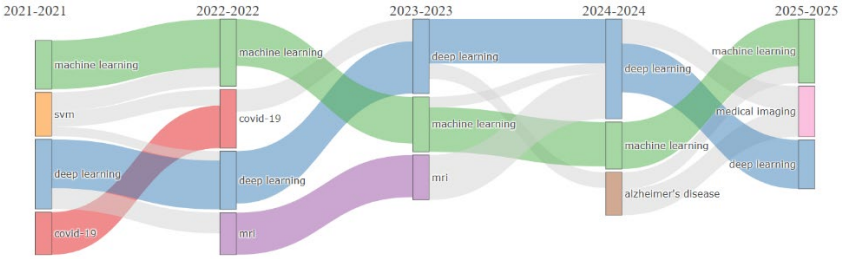

Figure 6. Turkey thematic evolution, 2021-2025, uniform annual bins (Sankey diagram)

4. Supplementary Ungrouped Keyword Trends

Grouping keywords into 23 themes averages out signals that are too small or too new to register at that scale. A supplementary, ungrouped pass ranked by 2024-to-2025 share growth (Tables 7 and 8) shows that globally, the steepest risers by volume were "deep learning," "medical imaging," and "vision transformer," but ranking instead by average citations per paper reorders this list: "vision transformers" (11.5 citations/paper) and "ensemble learning" (8.3) emerge as the highest-impact risers, while high-volume terms like "convolutional neural networks (cnn)" (2.7) rank lowest — indicating that keyword growth and citation impact identify different topics. Turkey's risers ran the other way: clinical decision support, risk prediction, and precision medicine. The clinical-decision-support overlap, arriving from different directions in each corpus, is the closest thing to a convergence signal here. However, the sample sizes are small enough to treat it as a future research lead rather than a settled finding. In the Turkish corpus, "clinical decision support" increased from 1 to 17 mentions between 2024 and 2025 but garnered only 126 citations across both years, suggesting that this signal should be read as an early-stage trend rather than an established finding.

Table 7: Citation-Weighted 2024→2025 Risers — Global

Keyword	2024→2025 f	Avg. citations/paper
Vision transformers	98→193	11.5
Vision transformer	278→414	8.5
Ensemble learning	44→85	8.3
Medical image analysis	108→228	6.9
Grad-CAM	13→86	6.6
Deep learning	1876→2084	5.8
Convolutional neural networks (CNN)	105→181	2.7

Table 8 reports the same ranking for the Turkey-affiliated corpus.

Table 8: Citation-Weighted 2024→2025 Risers — Turkey

Keyword	2024→2025 f	Total citations
Artificial intelligence	138→278	3,536
Machine learning	292→488	5,330
Clinical decision support	1→17	126
Large language models	6→19	434

Table 9 turns from these thematic rankings to the sampling-validity checks described in Section III.

Table 9: Sampling Validity Summary (Global Corpus, 5 Relevance-Ranked Slices)

Comparison	Spearman ρ	Jaccard J	χ^2 (p)
Consecutive slices (mean)	0.890	0.741	66.4–289.4 ($p < 0.001$)
Slice 1 → 5 (cumulative)	0.488	0.538	-

V. DISCUSSION

The dominance of CNNs and deep learning in the global dataset aligns with earlier bibliometric findings (Chen et al. [11]; Litjens et al. [14]). ViT's rapid rise after 2023 tracks the prediction Dosovitskiy et al. [8] made at the outset: with enough pretraining data, its ability to capture long-range dependencies makes it a genuine rival to CNN. Liu et al.'s Swin Transformer [22] reinforces the momentum, demonstrating higher segmentation accuracy on general-purpose vision benchmarks and gains that later motivated its adoption in medical imaging pipelines. The rise in interpretability terms, XAI, Grad-CAM, SHAP, LIME, reads as a direct response to the clinical-trust barrier flagged by Topol [23]; Selvaraju et al.'s Grad-CAM [17] built an early bridge by turning black-box decisions into visible heat maps.

Two structural weak points define the Turkish dataset before anything else does. U-Net occurs at 13.4 per 1,000 Turkish publications, compared with 32.3 globally. MRI shows a similar pattern, with 16.5 against 28.8. Both figures indicate that segmentation and neuroimaging capacity have not yet matured nationally. This is worth naming first because it forms the backdrop against which the more striking ratios below should be read. Turkey is not simply behind across the board. It is specifically thin on the infrastructure-heavy end of the field. The outsized share held by "machine learning" (2.01) and "artificial intelligence" (2.06) suggests many national studies still lean on traditional algorithms rather than deeper architectures. However, keyword data alone cannot distinguish a training gap from a slower architectural transition.

ChatGPT and related LLM terms move in opposite directions. When grouped into a single category (ChatGPT, GPT-4, LLM, large language model), 14 mentions appear globally, compared with 89 in the Turkish corpus, a gap that normalizes to 26.2-fold (χ^2=290.2, $p<0.001$). Grouping addresses the single-term fragility of the raw ChatGPT count: pooling ChatGPT with its generic-term variants absorbs the terminological split, where researchers outside Turkey may favor "large language model" over the branded name. The resulting ratio, still large but now statistically robust, indicates a genuine relative preference among Turkish authors for LLM- and ChatGPT-related terms. However, keyword counts alone cannot establish intent beyond that.

ViT tells a steadier story. Turkey's raw count of 51 against the global figure of 970 looks like a nineteen-fold gap, but once normalized by volume (10.5 versus 48.6 per 1,000), it narrows to about 4.6x, real under-adoption but far short of what the raw count implies. Radiomics presents a partial exception, since its 2.42x ratio is the highest in Table 2 after the grouped ChatGPT/LLM category's 26.2x outlier, despite Turkey's weak infrastructure

numbers on U-Net and MRI noted above, suggesting infrastructure-level and application-level capacity do not move together here. The fast-growing interest in ChatGPT in Turkey since 2024 also shows that the national research community is responding quickly to the generative AI wave. However, how far that interest actually feeds into medical imaging work remains a separate question for future full-text mining to answer.

The 4,000-record-per-year cutoff also introduces a systematic bias, since Scopus's relevance ranking rewards citation history and metadata completeness over recency. The Turkey dataset, processed in full without truncation, is largely free of this bias, which is why normalized densities are reported alongside raw counts throughout. Future work should draw on API access or an institutional license permitting full export.

Despite these limitations, the patterns identified here point to several practical directions. Encouraging ViT- and XAI-focused projects in Turkey would strengthen both the country's contribution to the global agenda and the transparency now expected of clinical decision-support systems under regulations such as the EU AI Act. The thin national footprint in segmentation and neuroimaging also points to opportunities for international collaboration, given Turkey's centralized health databases. Closer ties between medical and engineering departments, as Lin et al. [13] suggest, could help push national output further.

VI. CONCLUSION

This study examined AI-assisted medical imaging research from 2021 to 2025 through a comparative, volume-normalized bibliometric lens. Globally, CNN maintains its dominant position even as ViT, Swin Transformer, XAI, and Grad-CAM enter the thematic landscape after 2023, steering the field toward attention mechanisms and interpretability. Turkey's output still leans on machine learning and classification, with a grouped ChatGPT/LLM density 26.2 times the global rate ($p<0.001$) — a robust signal once single-term fragility is removed by grouping. Normalizing by corpus size reduces ViT's raw 19-fold gap to a 4.6-fold gap. This is a correction to scale, not to direction. Radiomics runs in the opposite direction entirely, with Turkey proportionally ahead of the global literature despite a weaker segmentation infrastructure. Clinical decision support is rising in both corpora, though from different starting points. It remains the only candidate signal worth tracking as the literature moves beyond its current small-sample stage. The relevance-ranked, year-stratified truncation was independently validated through a five-slice rank-stability analysis, supporting the conclusion that the working set reflects the field's dominant thematic structure. The caveats on low-citation and long-tail representation noted above still apply. Future work should extend coverage to WoS and PubMed, apply NLP-based full-text mining by methodology and clinical modality, and encourage Turkey-based research on ViT and XAI through TUBITAK-funded university-industry partnerships. A living bibliometric dashboard tracking individual keywords alongside the 23 thematic groups would also help, since signals like Mamba or clinical decision support surface at the keyword level well before they register thematically.

Abstract
The rapid dissemination of fake news through social media threatens democratic processes and public trust. Although BERT provides a strong foundation for automated detection, its limitations in capturing linguistic, structural, and social dimensions motivate the development of hybrid architectures. This systematic review analyzes 18 peer-reviewed studies published between January 2021 and June 2026, identified through database searches conducted in May–June 2026. It classifies them into eight architectural categories: BERT+CNN, recurrent networks, gradient boosting, graph neural networks, stacking ensembles, multimodal models, GAN-based augmentation, and other approaches. Across studies reporting BERT-only baselines, hybrid models achieved higher performance, with accuracies ranging from 92% to 98%. BBC-FND reported the highest accuracy (98%), while BERT+CNN achieved the highest category mean (97.0%) across two studies. GNN integration provided approximately 2–3% additional improvement through social-contextual signals. Explainability remained limited: three studies (17%) used post hoc methods, six provided partial interpretability, and nine were largely black-box. Key gaps include dataset standardization, English-language dominance, insufficient statistical testing, and limited preparedness for LLM-generated fake news. The findings highlight the need for standardized, rigorous, interpretable, multilingual, and practically applicable BERT-based hybrid frameworks.

Keywords: fake news detection, BERT, hybrid deep learning, explainable artificial intelligence, natural language processing, systematic review

I. INTRODUCTION

The digital transformation of information production and consumption has enabled the rapid proliferation of fake news—content deliberately produced for political, economic, or ideological purposes [1] — and has increasingly framed it as information disorder [2]. Such content can spread up to six times faster than true news on social media [3], threatening democratic processes, social trust, and public health. Moreover, LLM-generated misinformation can be more difficult for humans and automated detectors to identify than semantically equivalent human-written misinformation [4]. At the same time, existing detection methods degrade in the presence of LLM-generated disinformation [5], highlighting the increasingly adversarial nature of fake news detection [6]. BERT's strong benchmark performance [7], enabled by the Transformer self-attention mechanism [8], established a promising foundation through bidirectional attention, pretrained representations, and fine-tuning flexibility. However, BERT alone has limitations in capturing local linguistic patterns and long-range dependencies, incorporating social propagation and metadata, and maintaining computational efficiency. These limitations have motivated hybrid architectures that combine BERT with

convolutional, recurrent, and graph neural networks, as well as gradient-boosting methods. Existing reviews address only specific aspects of this field: Alnabhan and Branco [9] examine deep learning-based detection without synthesizing comparative performance; Athira et al. [10] focus on explainability without systematically evaluating transformer-based hybrids; and Nasser et al. [11] review multimodal approaches without a systematic taxonomy of fusion strategies. Thus, an integrated review that combines architectural taxonomy, cross-category performance analysis, and explainability assessment remains lacking, with only three of the eighteen studies in our corpus incorporating explicit post hoc explainability mechanisms. Accordingly, this review classifies BERT-based hybrid architectures, compares their performance across metrics, datasets, and methodologies, examines explainability, maps methodological gaps, and identifies future research directions. Specifically, it investigates the extent to which hybrid models outperform plain-BERT baselines (RQ1), which architectural combinations achieve the highest accuracy, and how performance varies across datasets (RQ2), how SHAP/LIME integration affects performance and interpretability (RQ3), and which methodological gaps and future directions remain in the field (RQ4). The remainder of the paper is organized as follows: Section II presents the methodology; Section III presents the architectural taxonomy and the reviewed corpus; Sections IV–VI present the performance, dataset, and explainability analyses; Section VII presents the methodological gaps and research directions; and Section VIII presents the conclusions.

II. REVIEW METHODOLOGY

This study was conducted as a systematic literature review in accordance with the PRISMA 2020 guidelines [12]. Searches were performed in Google Scholar, IEEE Xplore, Elsevier ScienceDirect, SpringerLink, Nature Portfolio, MDPI, and Web of Science using three Boolean keyword groups: (i) fake news and disinformation detection, (ii) transformer-based language models, and (iii) hybrid and ensemble learning approaches. Keywords within each group were combined with OR, and groups with AND. A representative query was: ("fake news" OR "disinformation" OR "misinformation") AND ("BERT" OR "RoBERTa" OR "transformer") AND ("hybrid" OR "ensemble" OR "CNN" OR "LSTM" OR "graph neural network"). Database-specific syntax was adapted using title, abstract, and keyword fields where available, and full-text searching otherwise. The search covered peer-reviewed journal articles published between January 2021 and June 2026. Retrieved records were merged and duplicates manually removed by matching titles, authors, and DOIs. Title/abstract screening and full-text eligibility assessment were conducted by the first author, with ambiguous cases resolved through discussion among all authors. The protocol was not publicly registered (e.g., PROSPERO.) Studies were included if they (i) were published between 2021 and 2026, (ii) appeared in peer-reviewed journals, (iii) used a transformer-based language model as the primary text encoder, (iv) addressed fake news or disinformation detection, (v) incorporated at least one additional learning component into a hybrid architecture, and (vi) reported at least one quantitative metric, such as accuracy or F1-score. Studies without an accessible full English text were excluded. One methodological exception was admitted: Truică and Apostol [13], which does not propose an explicit hybrid fusion architecture but provides a systematic and transferable methodological contribution relevant to the review questions. The search and screening process is summarized in Fig. 1. The database and backward citation searches initially yielded 487 records, which were reduced to 18 included studies after screening and full-text assessment. Two studies required particular consideration: Hashmi et al. [14] was included because its transformer encoder is complemented by a FastText embedding layer, satisfying the hybrid framework. At the same time, Truică and Apostol [13] were retained as the methodological exception because they systematically compare embedding methods and report significance using the Wilcoxon signed-rank and McNemar tests.

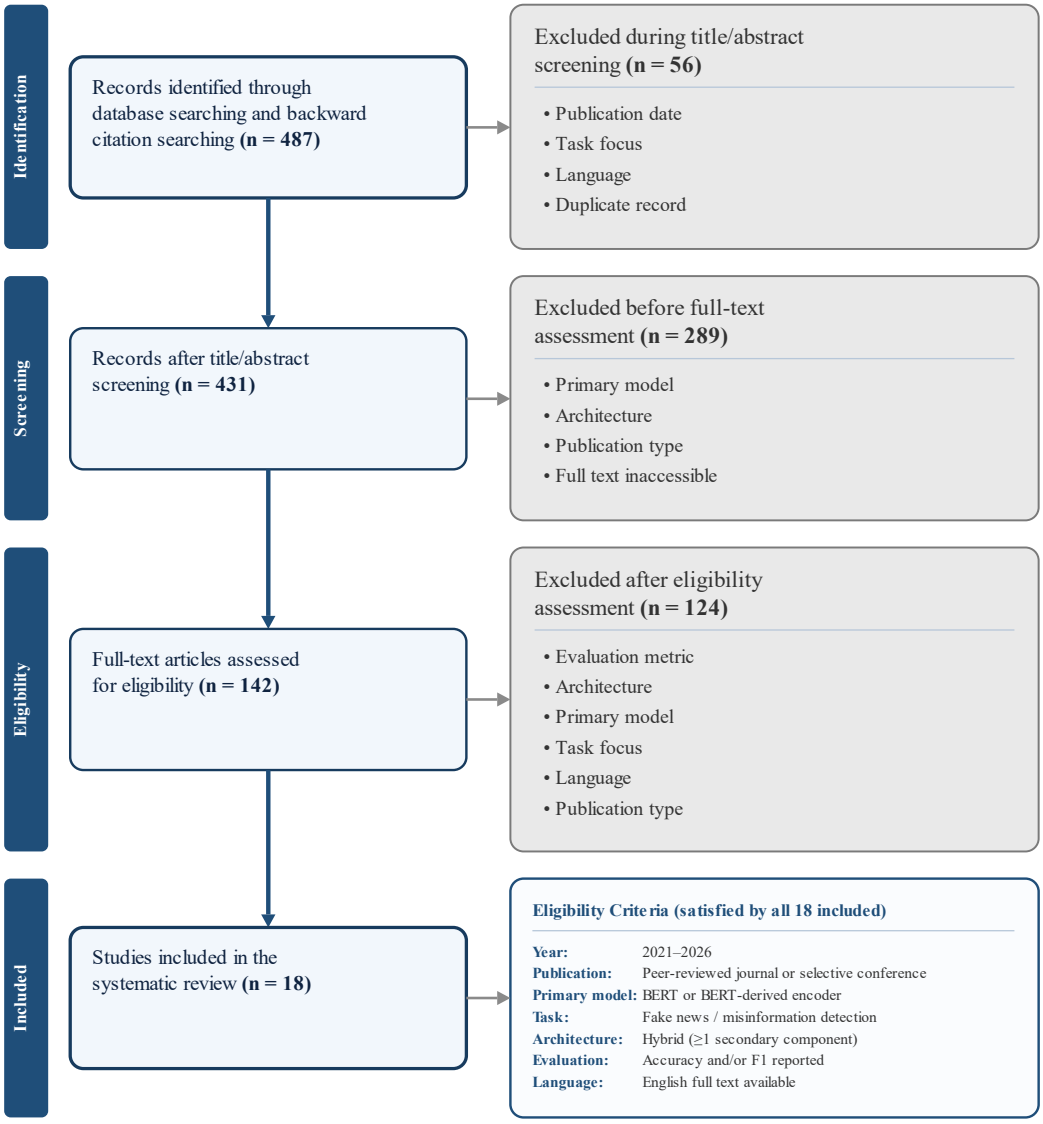

Figure 1. PRISMA-based flow diagram illustrating the literature search, study selection, and eligibility screening process.

III. ARCHITECTURAL TAXONOMY OF BERT-BASED HYBRIDS

As shown in Table 1, 12 of the 18 studies were published in JCR 2024 Q1 journals and five in Q2, while Human-Centric Intelligent Systems is not yet JCR-indexed but is classified as Scopus Q1. Graph neural network approaches, typically implemented using graph attention networks [15] or graph convolutional networks [16], constitute the largest category, with four studies, followed by stacking ensembles, with three.

BERT+CNN, recurrent neural networks, gradient boosting, multimodal, and other approaches each account for two studies, whereas GAN-based augmentation is represented by one study. Representative works include BERT–CNN hybrids [17], [18], multimodal capsule- and CNN–GRU-based models [19], [20], gradient-boosting hybrids [21], [22], a sentiment-aware BERT ensemble [23], and a GANBERT–BiLSTM ensemble [24]. CNNs [25] are the most frequently used complementary component, followed by recurrent layers (LSTM [26], GRU [27]) and gradient-boosting classifiers (XGBoost [28], LightGBM [29]). BERT-base serves as the primary backbone in most studies, while RoBERTa [30] is used in six studies requiring stronger semantic representations. Four main fusion strategies are identified: parallel concatenation, the most common approach; hierarchical sequential feeding, as in FakeStack [31], which sequentially combines BERT, CNN, and LSTM; stacking at the meta-learner level, as in BBC-FND [32], which achieves the highest reported accuracy (98%) through error-complementary predictions; and attention-based fusion, where cross- and co-attention mechanisms [33] provide approximately 1.5% improvement over late fusion. Several studies provide distinctive contributions. GETE [34] reduces computational cost by 60% with only a 0.3% performance decrease through GraphSAGE sampling and provides the only systematic multilingual evaluation. Kukkar and Kaur's adaptive ensemble [35] dynamically adjusts component weights based on entropy, topic, and text length and uniquely combines LIME and SHAP. The dual-stream model of Rama Moorthy et al. [36] jointly processes textual and social-graph streams using cross-attention, representing the most advanced attention-based fusion in the reviewed corpus.

Table 1. Overview of the 18 reviewed studies.

#	Study [ref]	Venue (JCR 2024 quartile)	Hybrid model	Dataset(s) (approx. N)	Validation	BERT-only baseline	Acc/ F1 (%)
1	Kaliyar et al., 2021 [17]	Multimedia Tools Appl. (Q1)	FakeBERT (BERT+CNN)	LIAR (~12.8k), ISOT (~44k), WELFake (~72k)	80/10/10	Reported (n/r)	≥97 / ≥97

15	Brinda et al., 2025 [24]	Knowl. Inf. Syst. (Q1)	EnsembleNet (GANBERT+BiLSTM)	ISOT (~44k), PolitiFact (~3–5k) + GAN synthetic	80/10/10 + imbalance exps.	Reported (n/r)	96 / 96
16	Kukkar & Kaur, 2025 [35]	Expert Syst. Appl. (Q1)	Adaptive ensemble + LIME/SHAP	LIAR, WELFake, ISOT, FNN GossipCop+PolitiFact	5-fold CV	Fixed-weight ens. ~94–94.5	96 / 96
17	Truică & Apostol, 2023 [13]	Mathematics (Q1)	Document embeddings (RoBERTa)	CLEF CheckThat! 2021 (~12–15k)	5-fold CV	Fine-tuned BERT 91.2	92 / 92
18	Xia et al., 2026 [38	Ann. Oper. Res. (Q1)	BERT-LSTM + SHAP	Custom social-media + engagement metadata (N n/r)	75/15/10	Reported (hybrid +2–3)	95 / 95

IV. PERFORMANCE SYNTHESIS

Reported accuracy ranges from 92% to 98%, with the highest value (98%) achieved by the stacking-ensemble BBC-FND model [32]. BERT+CNN (97.0%) and stacking ensembles (96.2%) have the highest category-level means, whereas "other approaches" have the lowest (92.5%). These values are descriptive only, as categories contain one to four studies and involve heterogeneous datasets, class distributions, preprocessing, train–test splits, and evaluation protocols; therefore, no pooled effect size, confidence interval, or between-architecture significance test is justified, and no claim of architectural superiority is made. Ablation results consistently support hybridization: every study reporting a plain-BERT baseline shows improved performance with the hybrid configuration. In FakeStack [31], accuracy increases from approximately 93–94% with BERT alone to 95–96% with pairwise combinations and 97% with the full BERT-CNN-LSTM architecture. GNN integration provides an additional 2–3% improvement through social-context signals, based on within-study ablations [33], [34], [36], [37] rather than a cross-study average; in DANES [37], for example, the social branch increases accuracy from approximately 89–90% to 93%. This advantage is constrained by the lack of propagation data for newly published news. Precision and recall were excluded because of inconsistent reporting, while accuracy and F1 were sufficiently available for synthesis. Reported accuracy values follow the original studies, using lower bounds where no point estimate was provided (≥97% for FakeBERT). Direct numerical comparisons should therefore be interpreted cautiously. Although no formal reporting bias instrument was applied, every study reporting a plain-BERT baseline favors the hybrid model, with no null or negative results. This uniformity suggests potential publication or reporting bias and indicates that the reported gains may represent an optimistic upper bound on hybridization benefits. More than 14 datasets were used, enabling evaluation across diverse content types and platforms but limiting direct comparison. ISOT was used in eight studies, followed by FakeNewsNet, whose GossipCop and PolitiFact subsets each appeared in six. FakeNewsNet uniquely combines textual and social-propagation information, although its approximately 1,000-sample PolitiFact subset may limit statistical reliability and generalizability. LIAR appeared in five studies, while WELFake and Kaggle Fake News appeared in four each; three studies used custom datasets, reducing reproducibility. Other datasets—including PHEME, Fakeddit, Webis Clickbait 2017, CLEF CheckThat! In 2021, Twitter15/Twitter16, BuzzFeed News, and MediaEval VMU were used less frequently. Social-propagation information was available only in FakeNewsNet, PHEME, and Twitter15/Twitter16; the remaining datasets primarily provided textual content and metadata. Because no standardized risk-of-bias instrument exists for machine-learning benchmark studies, dataset and reproducibility risks were assessed using a transparent Low/Medium/High rubric. Dataset risk reflected benchmark availability, while reproducibility risk reflected data accessibility and reporting of model configurations; explainability and statistical significance were assessed separately. Study-level results are presented in Table 2, providing a broader quality assessment than the journal quartile alone.

Table 2. Per-study risk-of-bias and reporting-quality assessment.

#	Study [ref]	Dataset risk	Reproducibility risk	Explainability	Significance testing	Notes
1	Kaliyar [17]	Low	Medium	None	Not reported	High compute cost
2	Lin [23]	Medium	High	None	Not reported	Multi-task (clickbait+FN)
3	Palani (CB-Fake) [19]	Medium (noisy labels)	Medium	None	Not reported	Requires image modality
4	Essa [21]	Low	Medium	Partial	Not reported	Two-stage pipeline

5	Keya (FakeStack) [31]	Low	Medium	None	Not reported	7-config ablation
6	Palani & Elango [32]	Low	Medium	None	Not reported	Highest accuracy (98%)
7	Verma (MCred) [18]	Medium	Medium	Partial	No (author's note of absence)	Text-only in practice
8	Al-Quayed [22]	High (custom)	High	Partial	Not reported	3-stage pipeline
9	Khalil [20]	Medium (small ~12k)	Medium	None	Not reported	Limited rigor
10	Truică (DANES) [37]	Medium (~1k PolitiFact)	Medium (social-data)	Partial	Not reported	Text + social context
11	Hashmi [14]	Medium (undocumented)	High	Full (LIME)	Not reported	Efficiency-focused
12	Zhang (GBCA) [33]	Medium (~1k PolitiFact)	Medium (social-data)	Partial	Not reported	8-config ablation
13	Kumar (GETE) [34]	Medium (~1k PolitiFact)	Medium (social-data)	None	Not reported	Multilingual eval.
14	Rama Moorthy [36]	Medium (rumor task)	Medium (API-dep.)	Partial	Not reported	The task partly differs
15	Brinda (EnsembleNet) [24]	Medium (synthetic)	Medium	None	Not reported	Synthetic representativeness
16	Kukkar & Kaur [35]	Low	Low (5-fold CV)	Full (LIME+SHAP)	5-fold CV (no formal test)	Adaptive ensemble
17	Truică & Apostol [13]	Medium (CLEF)	Low (5-fold CV)	None	Yes (Wilcoxon+ McNemar)	Few reporting significance
18	Xia [38]	High (custom)	High (non-benchmark)	Full (SHAP)	Not reported	Engagement metadata

V. INTERPRETABILITY OF HYBRID DETECTORS

Explainability is the most prominent methodological deficiency in the reviewed literature. Only three of the eighteen studies employ formal post-hoc explainability methods: one explicitly fuses explainable AI with a BERT–LSTM architecture [38], using SHAP [39] or LIME [40] as the underlying techniques; six provide partial interpretability through attention weights or feature importance; and nine remain entirely black-box. Cross-attention visualizations provide diagnostic insight but are classified as having partial interpretability because they do not constitute post hoc explanation methods. A consistent linguistic pattern emerges in the explainability studies [14], [35], [38]. SHAP and LIME identify uncertainty expressions such as "allegedly," "sources claim," and "reportedly" as strong indicators of fake news. In contrast, reference expressions such as "confirmed," "official statement," and "according to" are associated with genuine news. The reported 72%

overlap and 28% divergence between SHAP and LIME stem exclusively from the adaptive-ensemble study by Kukkar and Kaur [35], the only study that jointly applies both methods and measures their agreement; therefore, these values should not be generalized to the full corpus. This finding suggests that explainability methods can support both model transparency and validation of learned linguistic markers. The lower cross-study mean accuracy of explainability-integrating studies should not be interpreted as evidence that interpretability reduces performance. Within-study ablations in the three relevant studies [14], [35], [38] report comparable accuracy with and without the post-hoc explanation layer, with one study [38] reporting a marginal improvement attributed to the removal of noisy features. However, because these studies differ in datasets and backbone architectures, this represents a within-study observation rather than a controlled cross-study comparison. Thus, the reviewed evidence does not indicate a necessary trade-off between explainability and detection performance.

VI. METHODOLOGICAL LIMITATIONS AND RESEARCH GAPS

The reviewed studies demonstrate a clear evolutionary trajectory from BERT+CNN models in 2021 to multimodal and multi-task approaches (2022), stacking and gradient-boosting methods (2023), cross-attention and graph-based models (2024), multilingual graph and GAN-based approaches (2025), and explainability-integrated BERT-LSTM models (2026). Despite this progression, several methodological gaps remain. Dataset standardization and explainability are the most critical limitations. All 18 studies use heterogeneous datasets and evaluation protocols, while 15 lack genuine post-hoc XAI mechanisms. A unified benchmark combining ISOT, WELFake, and FakeNewsNet, along with standardized SHAP/LIME integration, is therefore recommended. The English-only constraint applies to 17 studies, requiring multilingual evaluation using mBERT or XLM-R. Social-data dependency affects four studies, suggesting the need for text-only fallback mechanisms. Other limitations include 512-token truncation across all 18 studies, which motivates long-context models such as Longformer, BigBird, or hierarchical BERT; insufficient statistical rigor in 16 studies, for which significance tests and bootstrap confidence intervals are recommended; and opaque custom datasets in three studies, highlighting the need for transparent collection and labeling protocols. None of the studies evaluates LLM-generated fake news or reports streaming/incremental inference. Given evidence that LLM-generated misinformation can evade existing detectors [4], [5], LLM-authored benchmark corpora and robustness testing should be prioritized [6], alongside streaming APIs and incremental learning for real-time detection. Finally, computational cost affects eight studies, motivating distillation, pruning, and GraphSAGE sampling. These gaps define the main priorities for more standardized, interpretable, multilingual, statistically rigorous, LLM-robust, and deployable BERT-based detection systems.

VII. CONCLUSION

This review systematically evaluated 18 peer-reviewed studies published between 2021 and 2026 across 8 architectural categories, presenting the current state, evolution, and limitations of BERT-based hybrid models for fake news detection within an integrated framework. The findings show that in all studies reporting a plain-BERT baseline, the hybrid configuration is superior, that accuracy values range from 92% to 98%, and that there are modest but meaningful differences among architectural categories. The most striking observation pointing to the field's immature aspects, however, lies in the explainability dimension: only three of the reviewed studies incorporate a genuine explainability mechanism, revealing that the transparency gap is one of the most critical shortcomings in the field. The modest contribution of graph neural network integration via social-context signals, in turn, suggests that structural signals have not yet been sufficiently exploited. The greatest challenge facing the field is moving beyond technical accuracy to develop systems that are explainable,

multilingual, deployable in real time, and statistically rigorous. This review aims to guide future work both by offering a comparative panorama of the current state and by identifying concrete research priorities.

Abstract

The exchange rate of the US dollar against the Libyan dinar is a crucial and influential topic for the Central Bank of Libya. It positively or negatively affects oil and gas revenues, thereby affecting the Central Bank's ability to cover public institutions' expenses in the country, which in turn impacts the lives of Libyan citizens. Speculation in the black market on the official exchange rate of the US dollar against the Libyan dinar is considered a crime against Libyan citizens and is punishable by law. This study employs a Deep Learning framework based on Long Short-Term Memory (LSTM) to detect and prevent speculation in the exchange rate of the US dollar against the Libyan dinar. Based on this, we applied the Long Short-Term Memory (LSTM) algorithm on the historical dataset of the official exchange rate against the dollar to detect speculation in the US dollar against the Libyan dinar. The LSTM algorithm shows promising results by leveraging extensive financial data and economic indicators to detect irregularities and precisely forecast future exchange rate movements in the black market. The experimental results of this paper demonstrate high predictive accuracy, with a root mean squared error (RMSE) of no more than 0.0428 Libyan dinars. By analyzing historical data over a 30-day timeframe, the model projected a potential price rise to 1.3010 Libyan dinars, representing a positive difference of 0.067 from the last actual closing price.

Keywords: Machine Learning, Financial Time Series Forecasting, Central Bank of Libya (CBL), Currency Speculation, Long Short-Term Memory (LSTM).

I. INTRODUCTION

Exchange rate stability is a fundamental element for the economic and financial equilibrium of any country. This importance becomes more pronounced in economies undergoing transition or those facing structural and political obstacles. In the Libyan context, following prolonged periods of political and economic instability, the Libyan Dinar (LYD) has come under severe pressure, leading to intensified foreign-currency black-market activity and aggressive currency speculation. Economic reports indicate that the widening gap between the official and parallel rates in Libya has led to structural distortions in resource allocation and increased import costs [1]. These phenomena not only threaten the Central Bank of Libya's (CBL) efforts toward monetary stability but also undermine citizens' purchasing power, hinder economic growth, and heighten uncertainty in the business environment. The central issue of this research is that the escalation of speculation in the foreign currency black market poses a significant obstacle to the Libyan economy. Specifically, the problem lies in traditional models' inability to account for the sudden fluctuations that characterize the Libyan market. Studies have shown that non-economic variables play a crucial role in directing exchange rates in conflict environments

[2]. This necessitates the immediate development of innovative analytical tools capable of accurately forecasting exchange rates, thereby strengthening efforts to counter these phenomena. Relying on traditional methodologies in the face of contemporary complexities may be insufficient for capturing the intricate patterns and interconnected interactions that govern the parallel exchange market. The significance of this research lies in providing an advanced analytical solution based on the Long Short-Term Memory (LSTM) algorithm, a sophisticated machine learning technique aimed at forecasting the US Dollar (USD) exchange rate against the Libyan Dinar (LYD). This algorithm is characterized by its superior ability to process data with "long-range dependencies," making it outperform classical statistical models in financial forecasting [3]. By leveraging a historical dataset of exchange rates from the Central Bank of Libya and integrating key economic and political variables, this research aims to provide a robust tool to assist policymakers at the Central Bank and other financial institutions. This tool will enable them to gain greater insight into market dynamics, predict future fluctuations, and formulate more effective policies to address economic and financial challenges. The applied methodology of this paper relies on processing historical time-series data of the price variable representing the closing rate. The data is transformed into the [0, 1] range using Min-Max Normalization to ensure training efficiency. The technical architecture of the model is based on defining a sequence length (Timesteps) of 30 days based on hyper-parameter tuning results, with data reshaped into a three-dimensional array (S×T×F) to enable the LSTM network to capture sequential patterns, ultimately extracting the predicted value using a Dense layer and the Adam optimizer with a learning rate of 0.01. This study seeks to achieve several primary objectives, including analyzing the factors contributing to the spread of the foreign currency parallel market and exchange rate volatility in Libya. Additionally, it aims to evaluate the effectiveness of the LSTM algorithm in forecasting USD/LYD exchange rates and to propose practical recommendations based on forecast results to support policy initiatives aimed at combating currency speculation.

II. LITERATURE REVIEW

The process of forecasting foreign exchange rates constitutes a fundamental challenge in financial and economic research, given the complex and non-linear nature of foreign exchange time series. Previous studies in this domain aim to develop computational models that extract hidden patterns and temporal dependencies from historical data, thereby supporting investment decisions and monetary policy. The research literature has witnessed a qualitative shift from relying on traditional standard models to adopting machine learning techniques, which have demonstrated superior ability to handle the volatility of financial markets [4].

1. Foreign Currency Speculation

Foreign currency speculation is a financial activity that demands high forecasting accuracy, as it relies heavily on traders' and financial institutions' ability to anticipate future price movements. In this context, machine learning algorithms have proven their efficiency as advanced tools to support speculation decisions. The Long Short-Term Memory (LSTM) network model is the most prominent choice in this field, due to its architecture's ability to retain information over long periods. The study by [5] confirmed the effectiveness of LSTM networks in forecasting the exchange rate of the Egyptian Pound against the US Dollar. It showed clear superiority over the traditional (ARIMA) model in prediction accuracy and error reduction, underscoring the efficiency of these networks in forecasting exchange rates in emerging economies undergoing rapid structural change. To enhance predictive performance. For instance, the study by [6] reviewed a hybrid model called (ALFA), which integrates LSTM networks with an Attention Mechanism. This integration aims to assign different importance weights to input features, and the model demonstrated superiority over traditional benchmark models. Similarly, [7] developed a hybrid model combining the Gated Recurrent Unit (GRU) with LSTM networks, aiming to leverage GRU's learning speed and LSTM's ability to capture long-term temporal dependencies. The results confirmed

that this hybrid model achieved very high accuracy in forecasting the future closing prices of major currency pairs.

Furthermore, some studies have focused on integrating LSTM with standard statistical models to enhance their ability to capture the specific characteristics of financial data. The study by [8] reviewed a hybrid model combining the standard (GARCH) model with an LSTM network to estimate Value at Risk (VaR) in the Rwandan foreign exchange market. The study aimed to utilize GARCH's ability to capture Volatility Clustering, and the results revealed that the hybrid model achieved up to a 10% improvement in prediction accuracy compared to standalone models. In an advanced context, the integration of non-financial data represents a significant trend. The study by [9] developed an innovative model based on "Deep Multimodal Fusion" to forecast the exchange rate of the US Dollar against the Chinese Yuan. The (MF-LSTM) model integrates financial time series data with "investor sentiment" extracted from social media texts using the BERT model. The results demonstrated that combining textual sentiment with historical data achieved significantly higher predictive accuracy than models relying on a single data type.

Despite this notable progress, research still points to persistent fundamental challenges, most notably the need for Real-time data processing and the difficulty of interpreting complex model predictions within the context of dynamic market dynamics [4].

III. THE OBJECTIVES

The objectives of this paper are to develop a comprehensive data-driven framework for the Central Bank of Libya that utilizes data science analytics techniques to address key challenges faced by the institution, such as the following:

- Develop a data-driven forecasting framework for the Central Bank of Libya that utilizes deep learning techniques to enhance monetary decision-making and mitigate foreign currency speculation.
- Analyze exchange rate fluctuations and temporal market trends in the parallel market to provide an automated early-warning mechanism for monetary authorities.
- Evaluate the predictive performance of the Long Short-Term Memory (LSTM) algorithm against non-linear temporal dynamics using daily historical exchange rate data.
- Formulate optimized time-series forecasting configurations (evaluating sequence lengths and hyperparameters) to generate reliable short-term USD/LYD exchange rate predictions for strategic planning.

IV. PROBLEM FORMULATION

The core problem addressed in this paper is that the violent fluctuations in the Libyan dinar's exchange rate on the black market have become too complex for traditional statistical models to comprehend and predict. We may realize the dimensions of this issue clearly in the following points:

- The Price Gap and Speculation: The exchange rate gap fueled speculation, distorting the economy and increasing living costs.
- The Shortcomings of Classic Models: Classic financial models fail in the Libyan market; they assume order where there is only high volatility, 'noise', and unpredictable price jumps.

- The Impact of Sudden Structural Shocks Standard analytical tools struggle to capture sudden, non-linear market shocks and severe exogenous events that cause abrupt regime shifts in parallel exchange rate dynamics within short timeframes.
- The "Long Memory" Challenge: Current tools fail to capture 'Long Memory'—the complex impact of past shocks on today's exchange rates—which requires specialized temporal analysis.

V. CONTRIBUTIONS

This paper builds qualitative scientific contributions to the use of advanced data analytics to predict exchange rate fluctuations, with a focus on the role of the Central Bank of Libya in reducing speculation and achieving financial stability:

- Algorithmic Innovations: Foreign Currency Market Trend Prediction: We apply Long Short-Term Memory (LSTM) networks to predict USD/LYD exchange rates, capturing complex temporal patterns in historical currency data.
- Supporting decision-making to combat speculation: The goal is to provide a practical solution that offers decision-makers at the central bank an early warning tool.
- Empirical Architecture Optimization: We evaluate sequential time-series configurations (establishing an optimal sequence length of 30 daily timesteps paired with hyperparameter tuning), proving the superiority of deep learning over classical statistical baselines in highly volatile environments.

VI. DATASET

1. Historical Dataset for USD/LYD Exchange Rates (2010–2020)

The dataset provided by the Central Bank of Libya contains 3484 records of daily historical exchange rates of the Libyan Dinar (LYD) against the US Dollar (USD) in the legal market (not the black market) from January 1, 2010, to December 31, 2020. The dataset includes the following columns:

- Date: The date of the exchange rate.
- Price: The closing exchange rate of the LYD to USD on the given date.
- Open: The opening exchange rate of the LYD to USD on the given date.
- High: The highest exchange rate of the LYD to USD on the given date.
- Low: The lowest exchange rate of the LYD to USD on the given date.
- Vol.: The volume of the LYD to USD exchange on the given date.
- Change %: The percentage change in the exchange rate from the previous day.

This dataset was used to train an LSTM (Long Short-Term Memory) model to predict future trends in the foreign currency market. The LSTM model can learn patterns and relationships between historical exchange rates and use this information to predict future exchange rates. By analyzing predicted trends, investors can make informed decisions about when to buy or sell the Libyan Dinar against the US Dollar in the foreign currency market (black market).

1	Date	Price	Open	High	Low	Vol.	Change %

Figure 1. Illustrates a sample of the historical daily exchange rates of Libyan Dinar (LYD) against the US Dollar (USD).

VII. METHODS AND ALGORITHMS

This section outlines the specific method and algorithm to be employed in the paper, including detailed descriptions, mathematical formulations, and illustrative examples using historical data derived from the Libyan financial sector.

- Combating Foreign Currency Speculation: Foreign Currency Market Trend Prediction using LSTM (Long Short-Term Memory)

LSTM is a type of recurrent neural network (RNN) designed to learn long-term dependencies in sequential data, making it suitable for predicting currency exchange rates[10].

- Data Preprocessing: To ensure efficient performance of the neural network, a set of steps was applied to the time variable price, which represents the closing price.
- Normalization: Before the data was entered into the model, it was converted to a range of [0, 1] using a Min-Max Normalization formula to avoid large values dominating the training process and to accelerate the convergence of the optimization algorithm.

$$X_{scaled} = (X - X_{min})/(X_{max} - X_{min}) \quad (1)$$

Where X is the original value of the price, and X_{min} and X_{max} are the minimum and maximum prices in the entire dataset.

- Time Series Sequencing: LSTM models rely on sequential input to learn time patterns. Based on the results of setting the characteristics, which showed that 30 days achieved the best accuracy, the length of the time-step memory (T) was set to 30 days.

The dataset was reshaped so that the model inputs are a three-dimensional (S×T×F) matrix where:

- S: Number of training samples.
- T: Length of time sequence (memory), T = 30 days.
- F: Number of features, F = 1 (where price was the sole consideration in the final model).

The relationship between inputs and outputs is defined as follows:

$$\{X_t\} = \{P_{t-29}, P_{t-28}, \dots, P_{t-1}, P_t\} \rightarrow Y_{t+1} = P_{t+1} \qquad (2)$$

Where X_t is the input vector, and Y_{t+1} is the expected closing price for the next day.

- LSTM (LSTM Network Architecture): A sequential model with a unilateral structure for the LSTM network was used for price prediction, and the optimal structure was determined based on experience:

Table 1 .LSTM Network Architecture

Layer	Type	Units	Function
1	LSTM	50 Units	The primary processing layer accepts input sequences of size (30×1).
2	Dropout	Rate: 0.2	Prevents **Overfitting** by randomly dropping 20% of the neurons' connections during training.

3	Dense	1 Unit	The output layer that generates the final prediction value (P_{t+1}).

- LSTM (The Core Mechanism): The LSTM (Long Short-Term Memory) cell features a gate mechanism that allows it to control the flow of information, enabling it to store data over long periods:
- Forget Gate (ft): Specifies the information to be discarded from the previous cell state (Ct−1).

$$f_t = \sigma(W_f \cdot [h_{t-1}, x_t] + b_f) \quad (3)$$

- Input Gate (it): Specifies which new values will be updated in the cell state.

$$i_t = \sigma(W_i \cdot [h_{t-1}, x_t] + b_i), \quad (4)$$

- Cell State Update (Cell State, Ct): The new cell state is updated based on forgetting and new input.

$$C_t = f_t \circ C_{t-1} + i_t \circ \tilde{c_t}, \quad (5)$$

- Output Gate (ot): Specifies the cell state portion to be output as a hidden state (ht).

$$o_t = \sigma(W_o \cdot [h_{t-1}, x_t] + b_o) \quad (6)$$

Where σ is a sigmoid function, and W and b are the weight and bias matrices.

- Training and Optimization: The model was trained using settings that proved effective in achieving the lowest RMSE:
- Loss Function: The Mean Squared Error (MSE) function was used to measure the difference between actual and expected values. The training objective is to minimize this loss.

$$\text{MSE} = (1/N)\sum_{i=0}^{n}(y_i - \hat{y_i})^2, \quad (7)$$

Where N is the number of samples, y_i is the actual value, and yi is the expected value.

- Optimizer: The Adam algorithm was chosen because it is effective in deep learning applications and works well in handling non-stationary data.

  Learning Rate: 0.01

  Number of Courses (Epochs): 50

- Evaluation Metric: The model's performance on the test set was evaluated using the Root Mean Squared Error (RMSE) metric, which provides the error value in the original unit (Libyan Dinar LYD).

$$\text{RMSE} = \sqrt{\left((1/N)\sum_{i=0}^{N}(\text{y}_\text{i} - \hat{y}_i)^2\right)}, \qquad (8)$$

VIII. IMPLEMENTATION

In this stage, a phase of building and improving a forecasting model for the exchange rate of the US dollar against the Libyan dinar (USD/LYD) using long-term short-term memory networks (LSTM) in the "RStudio" environment, based on the "Keras" and "TensorFlow" libraries:

1. Determine the path and upload the data

This stage involves setting up the software work environment by linking the R platform to the Python engine via the reticulate package to ensure compatibility with TensorFlow libraries, followed by the process of importing historical data from an external file using the read_delim function, which allows specifying the structural parameters of the file (such as the type of divider) to ensure that the data is properly organized in preparation for processing it.

2. Data Pre-processing

A historical dataset of the US dollar-Libyan dinar exchange rate was imported and converted to numeric values to ensure the stability of the neural network and accelerate its convergence. Min-max scaling was applied to compress values within the range [0],[1]. The data was also converted from a one-dimensional time series to a supervised learning format using a 30-day sliding window as input (X) to predict the price for the following day (Y).

```
reticulate::use_python(
  "C:/Users/ALNOOR/Documents/.virtualenvs/r-tensorflow/Scripts/python.exe",
  required = TRUE)

# Load the dataset
data <- read_delim(
  file.choose(),
  delim = ";",
  col_names = TRUE
)
```

Figure 2. RStudio script for environment setup and dataset ingestion

3. Time-Series Windowing

Convert the data into a supervised learning format, a 30-day sliding window (X) was selected via hyperparameter tuning to predict the 31st-day price (Y).

```
# Reshaping data into sliding windows (30 days look-back)
create_sequences <- function(data, timesteps) {
  X <- list(); Y <- list()
  for (i in 1:(length(data) - timesteps)) {
    X[[i]] <- data[i:(i + timesteps - 1)] # Input features
    Y[[i]] <- data[i + timesteps]         # Target label
  }
  X_array <- array(unlist(X), dim = c(length(X), timesteps, 1))
  return(list(X = X_array, Y = Y_array))
```

Figure 3. Configuring the R-to-Python interface using reticulate and importing the USD/LYD

4. Model Architecture

The study employed a Sequential model featuring a 50-unit Long Short-Term Memory (LSTM) layer, followed by a 20% Dropout layer to mitigate overfitting. A single-unit Dense layer was used to produce the price output. The model was compiled with the Adam optimizer and Mean Squared Error (MSE) loss, and trained for 100 epochs with a batch size of 32.

```
# Compiling and training the model
model_final %>% compile(
  loss = "mean_squared_error",
  optimizer = optimizer_adam(learning_rate = 0.01)
)

model_final %>% fit(x = X_train, y = Y_train, epochs = 50, batch_size = 32)
```

Figure 4. Model compilation using Adam optimizer and Mean Squared Error (MSE)

5. Training and improvement

The model was compiled with the Adam optimizer and a learning rate of 0.01, and trained with Mean Squared Error (MSE) as the loss function. Training was executed over 50 epochs with a batch size of 32, ensuring efficient convergence and optimal temporal pattern extraction.

```
# Defining LSTM model architecture
model_final <- keras_model_sequential() %>%
  layer_lstm(units = 50, input_shape = c(timesteps, 1)) %>%
  layer_dropout(rate = 0.2) %>%
  layer_dense(units = 1)
```

Figure 5. Defining the LSTM model architecture with a Dropout layer to prevent overfitting and a Dense output layer

6. Final price prediction

The optimized model (30-day memory, RMSE = 0.0428 LYD) was used to predict the expected price after the last day in the dataset:

Table 2. Prediction Results (LYD)

Metric	Value (LYD)
Last Actual Closing Price	1.2340
Predicted Price for the Next Day	1.3010

IX. EXPERIMENT AND RESULT

The final evaluation phase revealed the proposed model's ability to predict price trends with high statistical accuracy; the model achieved an RMSE of 0.0428 Libyan dinars. Based on a temporal analysis of historical data, the out-of-sample forecast indicates a potential upward trend in the US dollar's exchange rate against the Libyan dinar. Table 2 compares the last actual closing price with the expected value, clearly showing a positive difference that points to bullish expectations.

Table 3. LSTM Model Architecture

Metric	Value (LYD)	Notes / Observations
Last Actual Closing Price	1.2340 LYD	The last known price provided to the model.
Predicted Next-Day Price	1.3010 LYD	The final output/forecast generated by the model.
Difference (Forecast - Actual)	+0.067 LYD	The model predicts a relatively significant price increase.

This projected increase of 0.067 LYD reflects the LSTM algorithm's response to dynamic patterns detected within the time-memory window, accounting for the observed mean margin of error. These results demonstrate the model's effectiveness in providing proactive indicators of exchange rate movements, thus offering a valuable analytical tool for decision-makers during periods of monetary volatility.

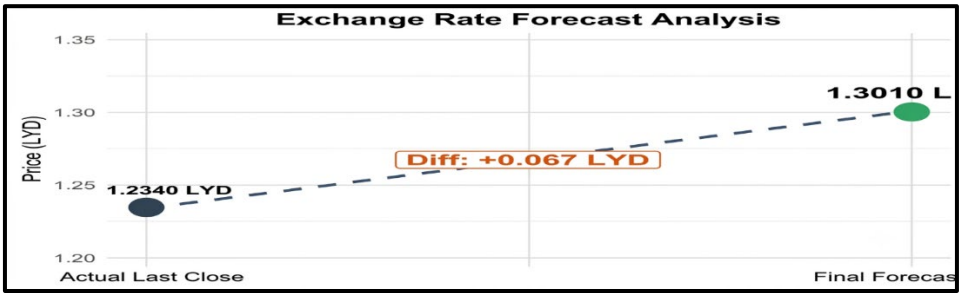

Figure 6. Comparison between the last actual closing price and the predicted price

Figure 6 shows the model's predictive output, comparing the last recorded actual closing price (1.2340 LYD) with the predicted price for the following day (1.3010 LYD). The upward trajectory illustrated between the two points highlights the LSTM model's capability to extrapolate temporal patterns and forecast future price movements. This visualization is analytically significant because it identifies the expected direction of the trend, helping decision-makers anticipate potential exchange rate fluctuations.

X. PERFORMANCE COMPARISON AND ANALYSIS

To determine the optimal architecture, four distinct LSTM model scenarios were evaluated using Root Mean Squared Error (RMSE) as the primary criterion. Table 4 presents the empirical performance comparison across different input configurations and hyperparameters.

Table 4. Model Performance Comparison

Model Type	Features (Inputs)	Memory (Timesteps)	Units	RMSE (LYD)	Evaluation
Original (Univariate)	Price only	10 Days	50	0.0494	Baseline Performance
Multivariate	Features (P, O, H, L, C)	10 Days	50	0.0904	Weak Performance (Overfitting)
Tuned	Price only	10 Days	100	0.1116	Weak Performance (Low Learning Rate)
Final & Optimized	Price only	30 Days	50	0.0428	Best Performance

While the baseline setup (Model 1) yielded acceptable results, performance degraded in Models 2 and 3 due to overfitting and suboptimal learning-rate adjustments. Notably, Model 4 achieved the highest precision with an RMSE of 0.0428 LYD, confirming that extending the temporal memory depth to 30 days was decisive in minimizing prediction errors.

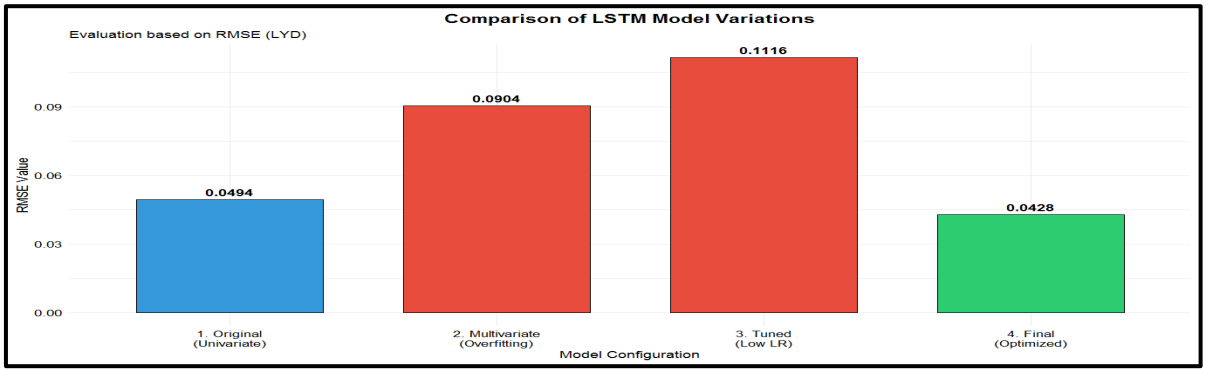

Figure 7. Performance comparison of LSTM model variants based on RMSE values

As illustrated in Figure 7, the comparative analysis highlights the model's sensitivity to learning rate and memory length, with the distinct drop in the fourth column demonstrating Model 4's superior efficiency in reducing predictive deviations.

XI. CONCLUSION

This paper presented a short-term predictive framework based on a Long Short-Term Memory (LSTM) neural network architecture to analyze and forecast USD/LYD exchange rate trends using an empirical dataset from the Central Bank of Libya. The experimental evaluations demonstrated the model's strong capability to capture complex non-linear financial time-series dynamics, achieving high predictive accuracy with a Root Mean Squared Error (RMSE) of 0.0428 LYD. By analyzing historical daily sequences with a 30-day temporal window, the model provided out-of-sample projections indicating an upward trend to 1.3010 LYD, marking a positive variation of +0.067 LYD over the last recorded closing price. Furthermore, the expected speculative trend indicator of 5.43% was identified by subtracting the previous closing price of 1.2340 LYD from the predicted price of 1.3010 LYD, then dividing the result by the previous closing price and multiplying by 100, representing the speculator's expected yield and serving as an early warning signal for the Central Bank. These empirical findings confirm that deep learning techniques, particularly optimized LSTM networks, serve as reliable predictive tools for financial time series, empowering central bank decision-makers and financial analysts with proactive analytical insights to mitigate market uncertainty and curb parallel market currency speculation.

Abstract
Postnatal depression (PND) remains a significant global public health concern, with many cases going undetected and adversely affecting the well-being of both mothers and their infants. This study presents an enhanced multimodal explainable artificial intelligence (OMEAI) framework for early postnatal depression screening by integrating facial features, vocal characteristics, textual sentiment, and Edinburgh Postnatal Depression Scale (EPDS) scores. The framework incorporates multimodal fusion, explainable artificial intelligence techniques, reliability & validation, and SOAP-based clinical reporting within a unified healthcare-oriented architecture. The feasibility of the framework was evaluated using the Extended DAIC-WOZ dataset for speech and language analysis, a dataset of 100 postnatal facial images, and a multimodal postnatal case integrating facial, vocal, textual, and psychometric information. Comparative analysis against single-modality baseline models demonstrated improved interpretability and classification performance, with the receiver operating characteristic area under the curve (ROC-AUC) increasing from 0.84 to 0.92. The integration of explainability and reliability components enhanced transparency and facilitated clinically meaningful interpretation of model outputs. The findings demonstrate the feasibility and potential of the OMEAI framework to support early postnatal depression screening and decision-making. The framework may contribute to the development of intelligent digital health technologies and maternal healthcare screening support systems. Future work will focus on validation across larger, more diverse postnatal populations and real-world clinical settings to support translation into clinical practice.

Keywords: Multimodal Biomarkers, Postnatal Depression, Postnatal, Clinical Decision Support, Reliability, Explainability, Clinical Interpretability, SOAP Reporting, McNemar, DAIC WOZ, Mental Health, Psychosocial

I. INTRODUCTION

Women's health during the postnatal period is an important public health concern, particularly because postnatal depression (PND) can affect both maternal well-being and child development. Over the past decade, PND prevalence has increased globally, with reported rates ranging from 10–20% in high-income countries such as the UK and up to 30% in Southeast Asia, raising further concerns during and after the COVID-19 period [1], [2]. Reports from the Royal College of Psychiatrists UK highlighted that thousands of mothers in England may experience postnatal depression annually [3]. Despite the widespread use of screening tools such as the Edinburgh Postnatal Depression Scale (EPDS), challenges remain because current methods rely heavily on self-reported responses and may not fully capture behavioral or emotional changes [4]. These limitations highlight the need for more accessible and reliable approaches for early postnatal clinical screening. Recent advances in artificial intelligence (AI) have enabled the use of behavioral signals, such as facial expressions,

speech patterns, and language use, for depression-related assessment [5-10]. Speech datasets such as DAIC-WOZ, along with computer vision and natural language processing techniques, have supported the identification of emotional and cognitive indicators associated with depressive symptoms. Explainable AI approaches, including SHAP and Grad-Cam, have also been introduced to improve transparency and help clinicians understand how AI systems generate predictions [11-13]. Structured documentation approaches, such as the SOAP (Subjective, Objective, Assessment, and Plan) format, have been shown to improve the completeness and organization of clinical records. Their use can support clearer communication and more interpretable reporting, making them suitable for integrating AI-assisted findings into routine clinical practice.[14]

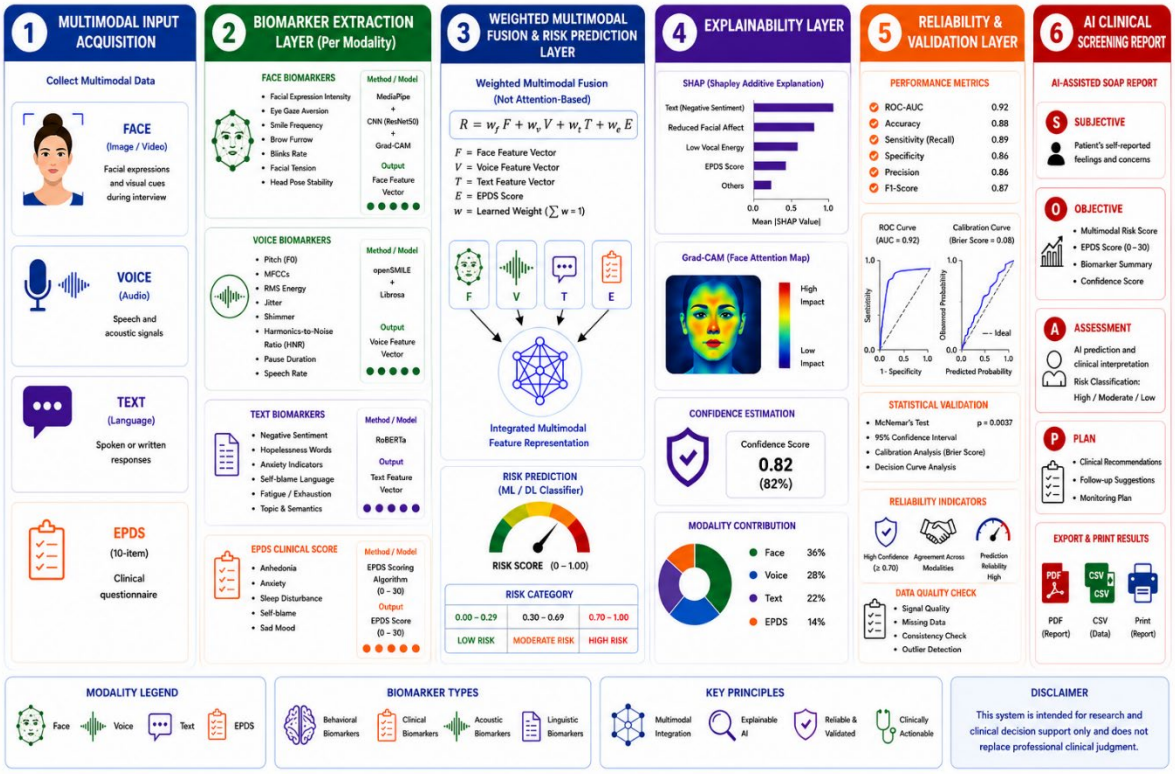

Figure 1. Proposed reliability and explainability-oriented multimodal AI framework integrating facial, vocal, textual, and psychometric biomarkers with explainable AI, statistical reliability validation, and SOAP-based clinical decision support for early detection of postnatal depression. However, many existing studies focus on single modalities or loosely integrate multimodal systems and often operate as black-box models with limited clinical interpretability [15-21]. In addition, psychometric tools such as the EPDS are commonly used independently based on text rather than integrated into AI-based predictive frameworks. These limitations highlight the need for more transparent and reliable multimodal approaches for postnatal depression screening.
In this study, a framework integrating multiple information modalities is proposed. As illustrated in Figure 1, the system embeds multi-modal information, including facial expressions (images), voices (audio), and questionnaires (text).

II. METHODOLOGY

This study developed a reliability- and explainability-oriented multimodal artificial intelligence (OMEAI) prototype framework (Figure 1) to support early screening and AI-assisted clinical screening for postnatal depression, using integrated facial, vocal, and textual data to develop psychometric biomarkers. The proposed methodology included multimodal data acquisition, biomarker extraction, multimodal fusion, explainability analysis, reliability & validation, and SOAP-based clinical report generation (Figure 1). The system architecture follows a sequential multimodal process that begins with a user input acquisition and concludes with AI-assisted clinical reporting. Facial image analysis, speech-based acoustic analysis, text sentiment interpretation, and psychometric screening indicators are integrated within a unified multimodal fusion pipeline. The data processing architecture described the flow of information from multimodal input collection through biomarker extraction, multimodal fusion integration, explainability analysis, reliability & validation, and SOAP (Subjective, Objective, Assessment, and Plan) report generation to support transparent, interpretable, and reliable postnatal depression risk assessment (Figure 2). To evaluate the proposed OMEAI framework, this study used publicly available pretrained AI models, feature extraction tools, and explainability methods, including MediaPipe, a pretrained ResNet50 convolutional neural network (CNN), openSMILE, Librosa, the Robustly Optimized BERT Pretraining Approach (RoBERTa), SHapley Additive exPlanations (SHAP), and Gradient-weighted Class Activation Mapping (Grad-CAM). These methods were evaluated using 100 simulated multimodal samples generated by integrating face images, voice recordings, and textual data obtained from publicly accessible digital sources and limited proprietary sources, together with one real 5-month postpartum case. The Extended DAIC-WOZ dataset, which contains over 189 audio recordings annotated for depressive symptoms, served as the primary publicly available dataset for framework development and prototype evaluation. The 100 simulated multimodal samples were created by combining facial, vocal, and textual features. At the same time, the corresponding Edinburgh Postnatal Depression Scale (EPDS) scores were estimated using the proposed weighted multimodal fusion approach. The integrated multimodal features were then used to estimate the risk of postnatal depression. The simulated samples were designed to represent realistic multimodal screening scenarios during the early stages of framework development. Their use supported ethical research practices by reducing reliance on sensitive clinical data, particularly given the limited availability of large, multimodal postpartum datasets. In addition, the use of real patient data requires ethical approval and careful protection of participant privacy. Participant recruitment for postpartum mental health research may also be influenced by concerns about stigma, fear of judgment, and the sensitive nature of mental health conditions [22]. Therefore, informed consent was obtained for the real postpartum case, and appropriate measures were implemented to safeguard participant privacy throughout the study. The inclusion of one real postpartum case provided an initial demonstration of the framework's potential clinical applicability while supporting responsible prototype development. Prospective clinical validation using a larger cohort of real-world postpartum participants is planned in a future phase**.**

Table 1. Summary of Data Sources and Modalities

Dataset	Description	Sample Size	Purpose	Modality
Extended DAIC-WOZ Dataset	189 Depression interview speech dataset	100 sessions	Speech and NLP validation	Voice + Text
Postnatal Facial Image Collection	Postnatal facial image dataset	100 postnatal images	Facial biomarker extraction	Face
5-Month Postnatal Case	5-month lactating women or postnatal mothers	1 complete case	Integrated multimodal evaluation	All modalities

The proposed framework takes input of facial images or video, voice recordings, text responses, and psychometric screening information through a Streamlit-based interface designed to simulate a real-time clinical screening environment. Before training, all inputs undergo preprocessing procedures, including normalization,

cleaning, formatting, and quality checking, to improve consistency across modalities. A human validation layer is incorporated before facial biomarker extraction to verify human facial inputs and to remove non-biological images such as cartoons, synthetic faces, printed photographs, and visual artifacts (Figure 2).

For facial depression imaging analysis, preprocessing steps include face detection, image resizing, facial alignment, landmark localization, and normalization. Then, fine-tuning using postnatal and depression-related facial datasets [12]. This process aims to improve image quality, reduce noise, and enhance the extraction of clinically relevant behavioral features. The facial imaging component is included to support human validation and extraction of behavioral biomarkers before multimodal analysis.

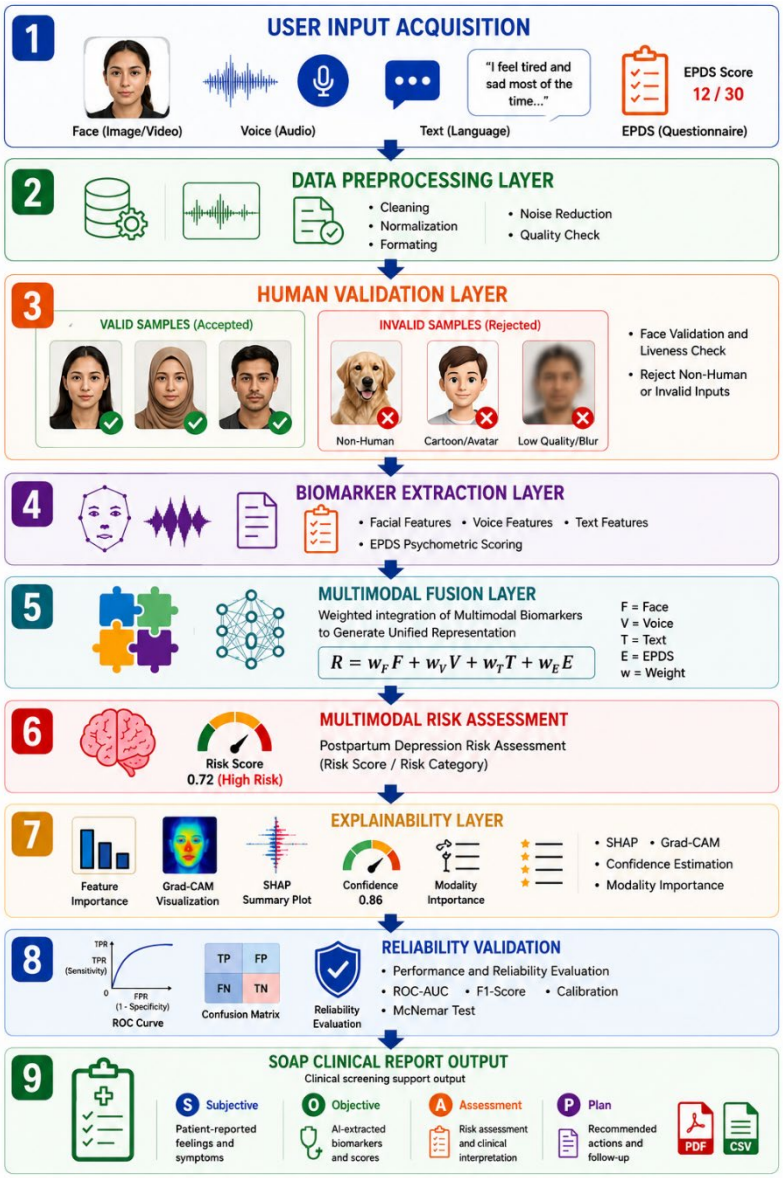

Figure 2. Proposed multimodal postnatal depression data processing pipeline illustrating the flow of information from user input acquisition, preprocessing, and biomarker extraction through multimodal fusion, explainability analysis, reliability validation, and SOAP-based clinical report generation.

The facial analysis pipeline uses MediaPipe [20], developed by Google for facial expression recognition and the Facial Action Coding System (FACS)-based Action Units (AUs) [21] for associating facial detection, facial muscle movements with displayed emotions in real-time to extract indicators including facial expression, gaze patterns, emotional responsiveness, smile behaviour and resizing into 224 x 224 pixels to ensure consistent image representation followed by a pretrained ResNet50 CNN for facial feature extraction, with Grad-Cam used to visualise the learned facial features. Voice recordings undergo preprocessing using Librosa, followed by acoustic biomarker extraction with OpenSMILE to derive features such as pitch, vocal energy, Mel-frequency cepstral coefficients (MFCCs), and pause duration. Voice and text processing incorporates multilingual analysis to support English, Filipino, and mixed-language responses through acoustic biomarker extraction and transformer-based natural language processing. Text responses are analyzed using the RoBERTa transformer model to identify depressive linguistic patterns. The Edinburgh Postnatal Depression Scale (EPDS) is also integrated as a psychometric screening component to provide clinically relevant postnatal mental health indicators. The extracted features from all four modalities are subsequently integrated through a multimodal fusion strategy to generate a unified representation of the participant's behavioral and psychometric profile. The integrated multimodal features are processed by a Multilayer Perceptron (MLP) to estimate the risk of postnatal depression and produce the corresponding confidence score. To improve transparency and clinician interpretability, the framework incorporates SHAP for feature attribution and Grad-CAM for visual explanation of facial biomarkers.

The multimodal AI fusion layer combines all four modalities (facial, voice, text, and EPDS features) using a weighted fusion strategy to generate an overall postnatal depression risk score, as shown in Eq. (1). The integrated features are then processed by a Multilayer Perceptron (MLP) to estimate the risk level and generate a confidence score.

$$R = w_f F + w_v V + w_t T + w_e E \tag{1}$$

where F represents facial features, V voice features, T textual features, E EPDS scores, and w_i modality weighting coefficients. An explainability layer, including SHAP for feature attribution, Grad-CAM for visual explanation of facial biomarkers, confidence estimation, and modality contribution analysis, is incorporated to improve transparency and clinician interpretation.

Reliability & validation layer evaluates models' performance using ROC-AUC, F1-score, sensitivity, specificity, confusion matrix analysis, calibration analysis, and McNemar testing before the results are summarised in a structured SOAP-based clinical report to support healthcare decision-making, as illustrated in Figures 4 and 5. Performance evaluation assesses the framework's ability to distinguish between higher- and lower-risk postnatal cases across different thresholds (Eq. (2).

$$AUC = \int_0^1 TPR(FPR^{-1}\left(x\right))dx \tag{2}$$

where **TP** represents the True Positive Rate, and **FP** represents the False Positive Rate. F1-score was also included to measure the balance between precision and recall, particularly for datasets with class imbalance:

$$F1 = 2 \times \frac{Precision \times Recall}{Precision + Recall} \tag{3}$$

This metric provided a balanced assessment of predictive performance beyond accuracy alone (Table 5). The performance of the proposed multimodal framework was then compared with baseline unimodal models reported in previous studies using the Extended DAIC-WOZ dataset.

The McNemar statistical test was applied to determine whether the multimodal framework performed significantly differently from the unimodal baseline models as formulated in Eq. (4).

$$\chi^2 = \frac{(b-c)^2}{b+c} \tag{4}$$

Where **b** represents cases misclassified by the multimodal model but correctly classified by the baseline model, and **c** represents cases correctly classified by the multimodal model but misclassified by the baseline model. A significant result indicates meaningful performance differences between the models being compared. In addition, a clinical decision support layer that converts multimodal AI findings generates structured clinical summaries to improve readability and ease system support for clinical interpretation through Subjective, Objective, Assessment, and Plan (SOAP) [22]- based reports (Figure 6).

III. RESULTS

Preliminary results demonstrate the potential performance of the proposed multimodal postnatal depression framework using facial, voice, text, and EPDS biomarkers, evaluated through classification, reliability, explainability, confidence, statistical testing, and SOAP-based clinical reporting.

Table 2. Facial, Voice & NLP Biomarker Findings

Facial Biomarker	**Observation**	**Clinical Screening Interpretation**
Reduced smile intensity	High occurrence	Emotional flattening
Eye gaze aversion	Moderate occurrence	Anxiety/withdrawal
Reduced facial affect	High contribution	Depressive presentation
Voice Biomarker		
Low vocal energy	Elevated	Emotional fatigue
Monotonic pitch	Moderate	Emotional blunting
Increased pause duration	High	Cognitive/emotional hesitation
Text Biomarker		
Negative sentiment	Strong	Emotional distress
Hopelessness language	Present	Depressive cognition
Self-blame expressions	Moderate	Psychological burden

The biomarker findings in Table 2 showed that postnatal depressive patterns are observed across multiple behavioral signals rather than a single source. Facial analysis has identified reduced affect and changes in gaze. In contrast, voice and text analysis revealed low vocal energy, negative sentiment, language related to hopelessness, and self-blame, all of which are associated with emotional distress, in line with other published work. Figure 3 further demonstrates that multimodal information outperforms any single dataset type.

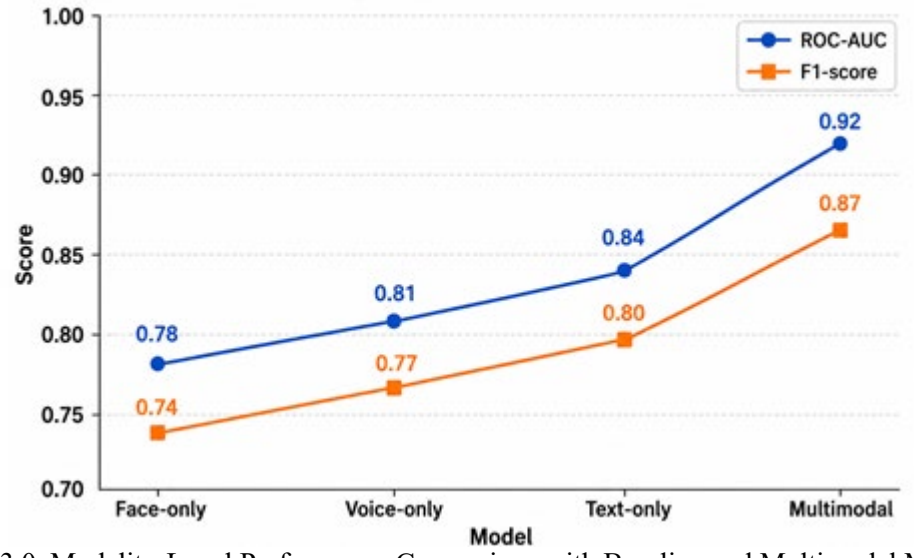

Figure 3.0. Modality-Level Performance Comparison with Baseline and Multimodal Model

The integration of multimodal biomarkers improved classification performance and stability, reflected by an ROC-AUC of 0.92 and an F1-score of 0.87. The increase from baseline unimodal ROC-AUC values of 0.78–0.84 to 0.92 suggests that combining facial, vocal, textual, and psychometric information improved the interpretation of postnatal emotional patterns. These findings [Figure 3] support previous studies showing that depressive behaviors are multidimensional and are better understood through multiple behavioral signals rather than a single modality.

Table 3. Explainability Results

Explainability Output	**Observation**
SHAP	Text modality has the highest contribution.
Grad-CAM	Reduced facial affect regions highlighted
Confidence Score	0.87

The explainability layer is a key strength of the proposed framework, as it improves transparency beyond traditional black-box AI approaches through SHAP, Grad-CAM, modality contribution ranking, and confidence scoring. The explainability results show that the text modality makes the greatest contribution to the final prediction, according to SHAP analysis. Grad-CAM highlights facial regions associated with reduced affect, while the confidence score of 0.87 indicates a relatively high level of prediction certainty. [Table 3] These methods help identify the biomarkers that contribute most to postnatal risk assessment, such as negative text sentiment, reduced facial affect, and low vocal energy in higher-risk cases. In addition, multimodal integration supports clearer clinician interpretation by showing how different behavioral signals contributed to the results, helping make screening outcomes more understandable and clinically meaningful.

The reliability-oriented validation layer provides a more comprehensive evaluation by incorporating ROC-AUC, calibration analysis, confusion matrices, confidence estimation, and McNemar testing. As shown in Table 4, the multimodal framework improves ROC-AUC from 0.78 to 0.84 in unimodal models to 0.92, indicating better classification consistency while reducing reliance on individual behavioral biomarkers. [Figures 4 & 5]

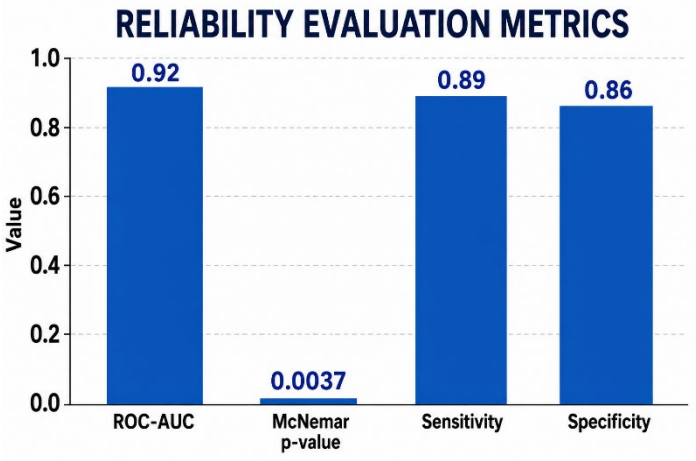

Figure 4. Reliability Results

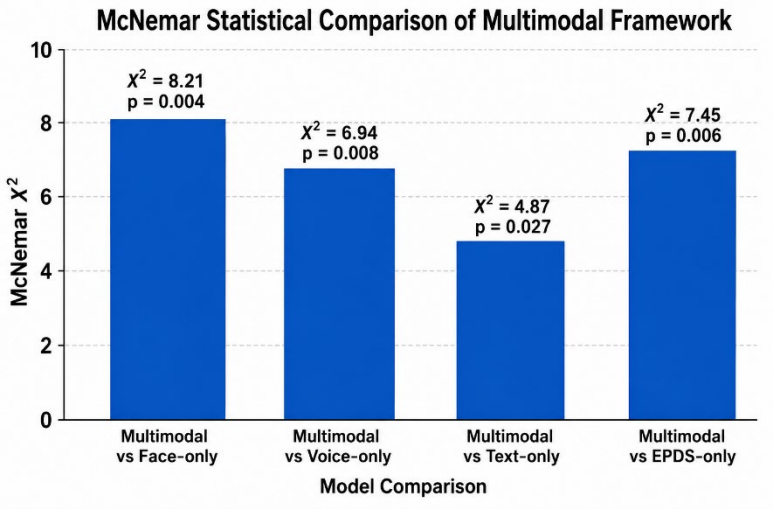

Figure 5. Multimodal vs Unimodal Reliability Results

McNemar test results show significant differences between the multimodal framework and the face-only ($p = 0.004$), voice-only ($p = 0.008$), text-only ($p = 0.027$), and EPDS-only ($p = 0.006$) models. These findings suggest that combining multiple modalities improves contextual understanding and reduces reliance on any single source during postnatal depression risk assessment. [Figure 5]

The SOAP-based clinical reporting layer enhances clinical usability by converting multimodal AI outputs into structured, clinician-readable summaries that can align well with routine healthcare documentation practices. Rather than presenting only numerical risk scores, the framework generates organized subjective findings, objective biomarker observations, assessment summaries, and follow-up recommendations, with reports available in PDF or CSV format to support transparency, interpretability, and potential integration into maternal clinical screening workflows. [Figure 6]

Table 4. Comparison with Monomodal Baseline and Multimodal Models

Baseline Model	Input Modality	Primary Biomarkers	Purpose
Face-only Model	Facial video/images	Facial affect, gaze, smile variability, blink patterns	Evaluate visual behavioral indicators
Voice-only Model	Speech recordings	Pitch, MFCC, vocal energy, pause duration	Evaluate depressive acoustic biomarkers
Text-only Model	NLP responses	Sentiment polarity, hopelessness language, and emotion al expressions	Evaluate linguistic depressive indicators
EPDS-only Model	EPDS questionnaire	Psychometric postnatal scoring	Evaluate structured clinical screening
Proposed Multimodal Framework	Face + Voice + Text + EPDS	Integrated multimodal biomarkers	Evaluate the combined contextual postnatal interpretation

To evaluate the proposed reliability and explainability-oriented multimodal AI framework, models for each modality are first developed using individual modalities, including face-only, voice-only, text-only, and EPDS-only configurations. These baseline models are applied to examine the contribution of each modality and to determine whether combining behavioral and psychometric biomarkers within a unified multimodal framework could improve contextual understanding and yield more stable screening performance than unimodal approaches. [Table 4] Figure 7 illustrates a screenshot of the proposed online OMEAI multi-modal framework.

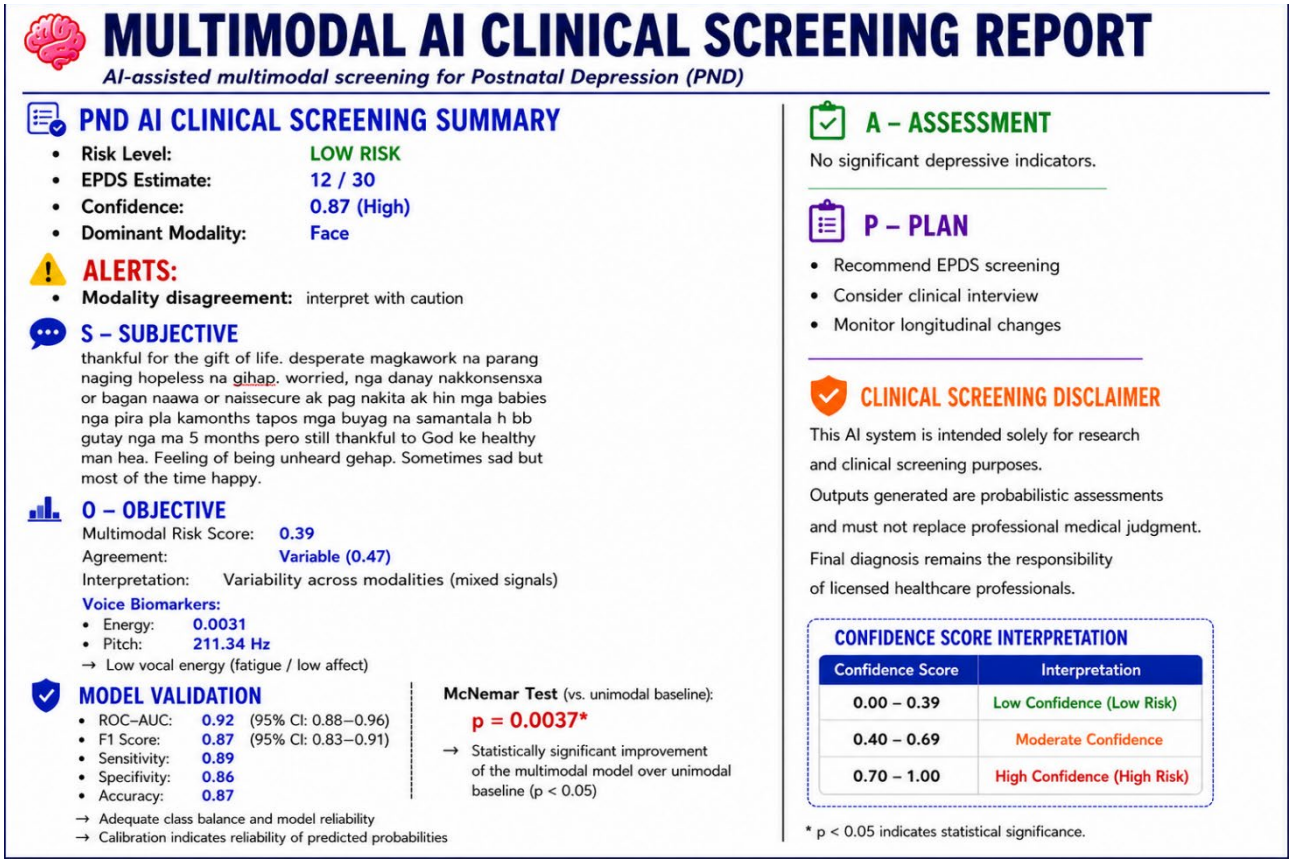

Figure 6. SOAP-Based Multimodal Clinical Screening Report generated by the proposed OMEAI framework for postnatal depression screening support.

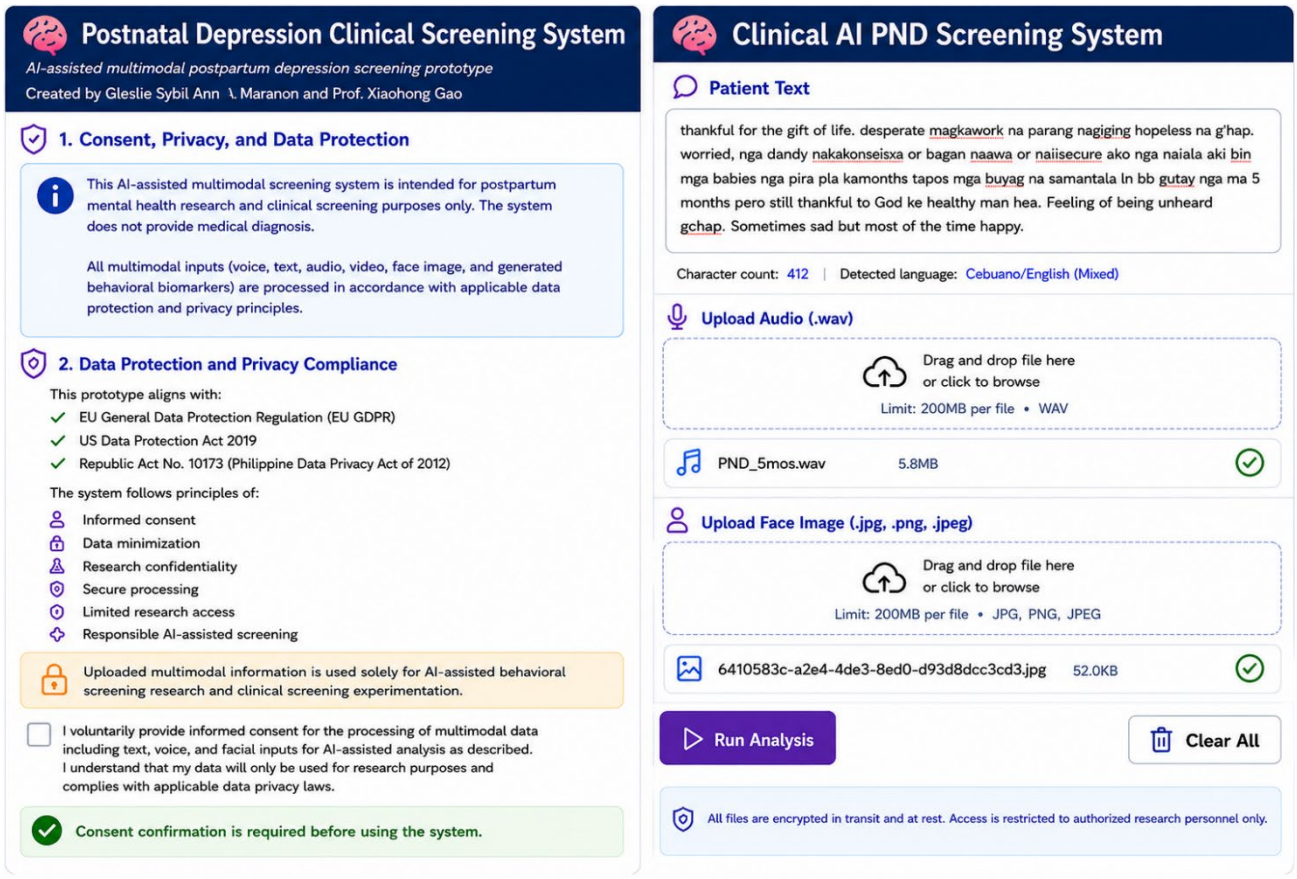

Figure 7. OMEAI prototype interface illustrating the informed consent workflow, privacy and data protection compliance, and multimodal data acquisition module for patient text, voice, and facial image inputs before AI-assisted postnatal depression clinical screening

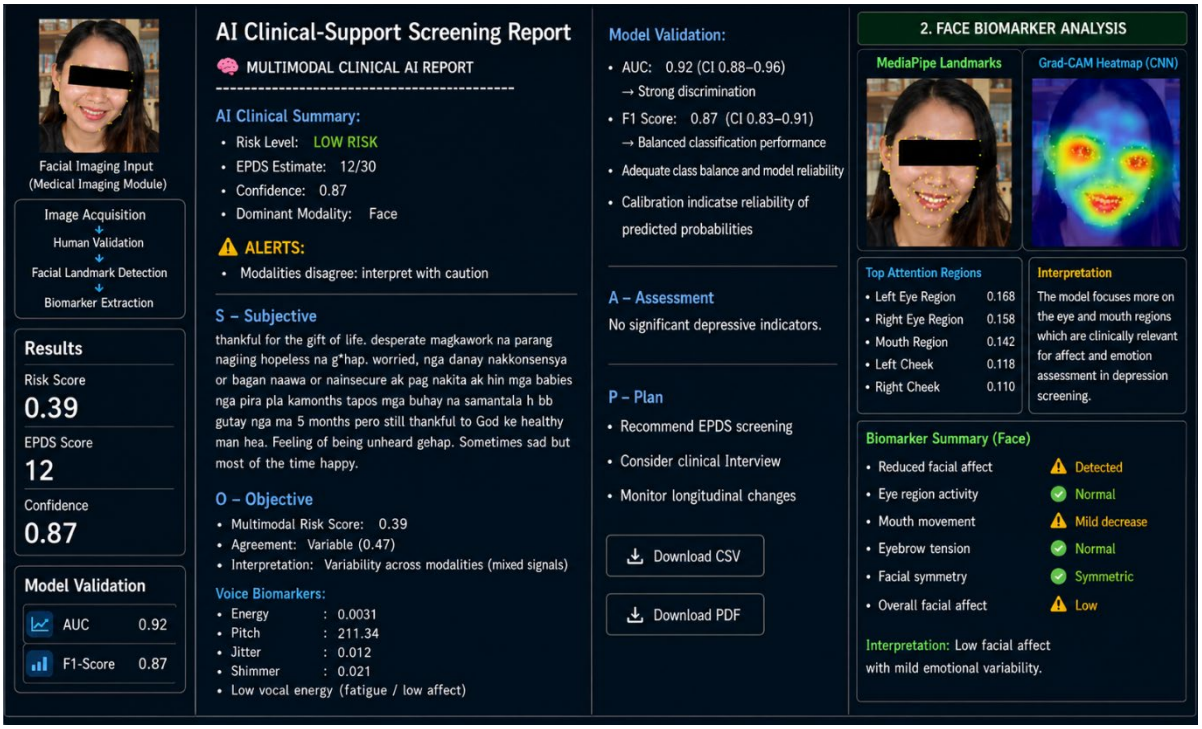

Figure 8. OMEAI prototype interface showing the facial imaging biomarker analysis (MediaPipe landmarks and Grad-CAM visualization), multimodal screening results, explainability outputs, model validation metrics, and AI-generated SOAP clinical screening report with PDF and CSV export capabilities.

IV. DISCUSSION

The results presented in Table 5 indicate that the proposed multimodal framework outperforms baseline unimodal models across major evaluation metrics. While face-only and voice-only models captured important behavioral indicators associated with depressive presentation, their contextual understanding remains limited when used independently. Similarly, the text-only model demonstrates stronger emotional contextualization through sentiment analysis, although linguistic features alone appear insufficient to capture nonverbal postnatal behavioral patterns.

Table 5. Comparison of Baseline and Multimodal AI Performance, Sen=Sensitivity, Spe=Specificity

Model	ROC-AUC	F1 Score	Sen	Spec	Interpretation
Face-only Model	0.78	0.74	0.76	0.73	Facial affect alone captured only partial emotional indicators and lacked contextual behavioral interpretation.
Voice-only Model	0.81	0.77	0.79	0.75	Acoustic biomarkers demonstrated depressive speech sensitivity but remained limited in the context of postnatal assessment.
Text-only Model	0.84	0.80	0.82	0.78	NLP interpretation improved emotional contextualization by detecting sentiment- and hopelessness-related language.
EPDS-only Model	0.79	0.75	0.83	0.70	EPDS psychometric screening remained clinically useful but depended heavily on self-reported responses.
Proposed Multimodal Framework	0.92	0.87	0.89	0.86	Multimodal integration improved contextual understanding, reliability, explainability, and classification stability.

In summary, the findings indicate that reliability- and explainability-oriented multimodal AI systems have the potential to contribute to more transparent, clinically interpretable, and contextually informed postnatal clinical screening frameworks. The integration of multimodal behavioral biomarkers, explainability mechanisms, reliability & validation, and SOAP-oriented clinical reporting represents a meaningful advancement towards translational maternal healthcare artificial intelligence systems. While the proposed OMEAI framework demonstrates the potential of multimodal AI for early postnatal depression screening, this study was limited to a prototype evaluation using simulated multimodal samples. This approach enabled the framework to be tested ethically while protecting sensitive clinical data during the early stages of development. However, simulated data cannot fully capture the complexity of real postpartum populations. Future studies should validate the framework using larger, ethically approved clinical datasets to assess its potential for clinical screening further.

V. CONTRIBUTION

The main contribution of this study lies in integrating reliability-oriented validation, explainable AI, multimodal behavioral biomarkers, EPDS scoring, and SOAP-based clinical reporting within a unified postnatal mental health framework. The proposed framework also emphasizes clinician interpretability and transparent AI-assisted clinical screening support.

VI. CONCLUSION

The study demonstrates the feasibility of using an explainable, reliability-oriented multimodal AI framework to support the early screening of postnatal depression. By integrating facial analysis, voice biomarkers, natural language processing, and EPDS psychometric assessment within a unified framework, the system provides a more comprehensive assessment of postnatal emotional states. The framework also showed encouraging performance compared with the range of results reported in published unimodal studies using the DAIC WOZ or Extended DAIC-WOZ datasets, suggesting that combining multiple behavioral modalities may improve

screening performance. The inclusion of explainability features and a reliability & validation layer enhances the transparency and interpretability of the screening results, which are essential for healthcare environments where understanding the reasoning behind AI-generated outputs is critical. Overall, the findings demonstrate the feasibility of integrating multimodal behavioral signals with explainable, reliability-focused AI for postnatal screening support.
Future work includes larger datasets and real-world, real-time evaluations.

Abstract

In recent years, there has been a noticeable emergence of edge computing-driven Wireless Body Area Networks (WBANs) as a prominent trend in the healthcare sector. With the help of optimization techniques, this application can achieve the desired performance and increase the quality of service. Because of the nature of the application, the most significant factors are speed, reliability, and latency. Therefore, the algorithm's time complexity is a critical factor and must be thoroughly evaluated before implementing optimization techniques in healthcare applications. Most of the current literature focuses on resource optimization techniques, with limited attention to their applicability to edge computing-based WBANs. Additionally, these works lack comprehensive analyses of the algorithms' time complexities or comparative assessments thereof. This paper presents a new optimization technique with a low time complexity for edge-based WBANs. The new optimization technique combines Particle Swarm Optimization (PSO) and Tabu search. The research problem is designed to optimize workload allocation in edge-based WBANs. This paper compares the time complexity of a new hybrid optimization technique with that of four other existing optimization techniques used in edge-computing-based WBANs. The findings of this paper help bridge the gap by comparatively analyzing the time complexity of optimization techniques and introducing a new method that enables informed algorithm selection for specific applications.

Keywords: Time complexity, Edge computing, Optimization techniques, Wireless body area networks

I. INTRODUCTION

A wireless body area network (WBAN) is an emerging technological trend that has developed from advances in wireless and electronic technologies [1]. The WBAN has developed into a practical approach for collecting physical and symptom-related data remotely and has become a highly promising technology. It enables continuous, all-day health monitoring and economical diagnostics. The importance of WBAN extends beyond medical applications, encompassing areas such as military, entertainment, sports, aerospace, and other human-related industries, thereby holding considerable economic and social value [1]. Edge computing distributes data processing to the point of data generation, typically on edge devices or gateways. Edge computing moves data storage, processing power, and enterprise applications closer to the points where information is consumed. The goal of edge computing systems is to reduce latency by shifting medical data analysis to local edge servers and to enhance security by recommending secure connection techniques [2]. As optimization techniques continue to proliferate and diversify in their implementations, researchers have conducted comparative studies to assess their performance. The effective studies serve as valuable resources for end users looking for the best optimization technique to address their specific challenges. These evaluations are often known as optimization benchmarking.

The effectiveness of an algorithm's execution is determined by several factors, particularly the significance of time and space complexity. Space complexity measures the amount of memory or storage space required by an algorithm. In contrast, time complexity quantifies the computational time it takes to execute an algorithm as a function of the input size. The most suitable algorithm provides a significant advantage to the application, including increased cost efficiency and facilitating the integration of innovative technologies [3]. Existing reviews often emphasize the time complexity of various optimization algorithms, yet they tend to conduct comparative analyses for specific applications. This paper presents a comparative study of the time complexity of different optimization techniques for specific WBAN applications. It introduces a new low-time-complexity algorithm to optimize workload allocation in edge-based WBANs.

1. Time complexity in optimization techniques

Time complexity in an optimization technique is primarily considered a factor in time-critical applications. In computer science, time complexity is an important aspect of computational complexity, encompassing the evaluation of the time required to complete a specific task. This analysis focuses on quantifying the amount of computer time required to complete a given task. The time complexity of an algorithm is the time it takes to run as a function of its input size. As the time complexity of an algorithm can vary with different inputs of the same size, the longest runtime over all inputs of size n is usually taken. This is referred to as the worst-case complexity analysis [4]. The big Omicron (big-O) notation expresses this worst-case runtime as a function of its input size. Time complexity can be categorized by the function's behavior in big O notation. The responses for the different time complexities are shown in Figure 1. As an illustration, when considering an algorithm with a time complexity denoted as O(n), wherein 'n' represents the dimension of the input data, this implies that the algorithm's execution will require a maximum of 'n' operations to reach completion.

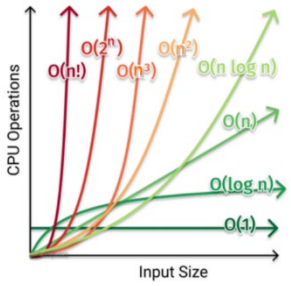

Figure 1. Algorithm time complexity [5]

This classification system enables the organization and characterization of algorithms and computational processes, allowing for a better understanding of their efficiency and scalability. The process of determining time complexity entails examining an algorithm's sequence of actions and its effectiveness. For instance, if an algorithm contains a loop that traverses 'n' elements and performs a constant-time operation on each element, the algorithm's time complexity is O(n). However, if the algorithm includes nested loops or performs resource-intensive operations, its time complexity could be higher. Mainly, there are 8 classification types, where n denotes the size of the input data set [6]. Those are; Constant ($O(1)$), Logarithmic ($O(log\ n)$), Linear ($O(n)$, Linearithmic ($O(\text{n } log\ n)$), Quadratic ($O(n2)$), Polynomial ($O(nk)$), Exponential ($O(2n)$), Factorial ($O(n!)$).

2. Optimization techniques application in edge-based WBANs

Previous studies have investigated several optimization techniques to improve the performance of edge computing-based WBAN applications, particularly in computation offloading, resource allocation, and workload allocation. Common approaches include metaheuristic optimization, Lyapunov optimization [7], [8], Convex optimization [9], [10], Game theory [11], and machine learning-based optimization methods [12], which have emerged as widely adopted approaches for optimizing edge-based WBANs [13]. This study was conducted to evaluate the system effectiveness with the Particle Swarm Optimization (PSO), Genetic Algorithm Optimization (GAO), Firefly Optimization (FFO), and Grey Wolf Optimization (GWO) methods in edge-based WBANs. Many research initiatives have focused on evaluating the effectiveness of these optimization techniques in the WBAN context. Each optimization method consists of unique advantages and disadvantages. Selecting an appropriate optimization technique for the application can be streamlined by reviewing comparative studies and reports [14]. Some techniques offer significant value and advantages for addressing problems that traditional optimization methods often find challenging. These challenges include problems featuring discontinuous, non-differentiable, stochastic, or highly non-linear objective functions. Some researchers conducted comparative analyses of the time complexities of optimization techniques, but not specifically for the edge-based WBAN application. In 2024, Shitharth [15] published a comprehensive study on bio-inspired optimization techniques for engineering problems. In that study, researchers compared the computational complexity of ten methods. The analysis was conducted theoretically and did not specifically focus on a single application. Another comprehensive time complexity analysis of the extant optimization techniques employed in optical communication systems is presented in the research [16].

3. Comparing time complexity in each algorithm

The literature reports different complexity characteristics depending on the algorithm formulation and application. GA and PSO are both population-based search algorithms, although their computational complexity depends on their specific implementation. For example, the GA-based method presented in [17] was designed with fewer computational steps and reported to have linear complexity büyük harf O sol parantez g n m sağ parantez,, demonstrating lower computational requirements than the other schemes evaluated in that study. Similarly, You and Tang [18] applied PSO to a multi-objective task-offloading problem that considered delay, energy consumption, and execution cost, and reported linear computational complexity, consistent with [19]. Wang [20] proposed a distributed PPPSO-based fuzzy clustering protocol for balancing and reducing energy consumption in wireless sensor networks, with an overall complexity of büyük harf O sol parantez büyük harf N sağ parantez, where N represents the number of nodes. These studies demonstrate that GA- and PSO-based approaches can achieve relatively low computational complexity for specific resource-allocation and task-offloading formulations; however, their complexity characteristics depend on the particular algorithm design and application scenario.

The Firefly Optimization Algorithm (FFO) has also been applied to wireless sensor network optimization. In [21], FO was employed for power management, with a reported quadratic computational complexity of O(m^2). In [23], GWO is introduced, inspired by the social behavior of grey wolves. When applied wisely, both techniques can contribute to achieving improved system performance, albeit with varying computational demands. The choice between them depends on the specific problem at hand and the trade-off between optimization quality and computational resources. Reference [24] conducted an extensive review of optimization techniques employed in edge computing, specifically for computation offloading. However, some studies [20] employ multiple optimization techniques to achieve their objectives. In those cases, the total time complexity depends on the implementation and the underlying hardware. The purpose of using multiple optimization

techniques is to achieve lower time complexity and higher accuracy than with a single technique. But if not implemented carefully, the resultant time complexity could be higher. Hybrid optimization techniques combine complementary characteristics of multiple algorithms to improve application-specific performance. In particular, global search techniques such as PSO and GA can be integrated with other search mechanisms to improve exploration and refinement. Several hybrid approaches have been reported for WSN and WBAN applications. In [25], a hybrid PSO-GWO model was proposed for node localization in wireless sensor networks, where a modified PSO was used to identify the optimal node, and GWO was employed to determine the optimal path. Similar research presented in [26] optimizes cluster nodes in the WBAN using a hybrid GA-ant colony optimization (ACO) method. In this research, optimal cluster formation is achieved using GA, and ACO is used to find energy-efficient and reliable routing paths. Another combination is the artificial bee colony (ABC) technique and the chicken swarm optimization (CSO) algorithm. This combination is used to optimize an energy-efficient routing protocol for WBAN [27]. The ABC algorithm is used to improve cluster head selection in WBAN and reduce energy consumption. Similarly, the CSO algorithm was integrated with ABC to increase population divergence and the likelihood of escaping local solutions. PSO-simulated annealing (SA) [28], GA–PSO [29], and black widow optimization (BWO)–ABC [30] are other hybrid methods used in edge-based WBAN to enhance application performance. Although these studies demonstrate the potential of hybrid optimization, limited research has specifically examined the computational performance of hybrid methods for workload allocation in edge-based WBANs. Moreover, combining multiple algorithms does not necessarily reduce computational cost, as the resulting complexity and execution time depend on the individual algorithms, their integration strategy, parameter settings, and computational budget.

II. INTRODUCE NEW OPTIMIZATION TECHNIQUE

After conducting an extensive literature review and evaluating the characteristics of existing optimization techniques, a hybrid approach was developed by integrating PSO with Tabu Search (TSO). The proposed workload allocation algorithm leverages the complementary strengths of these two metaheuristic techniques. PSO provides effective global search capabilities and is used to generate a high-quality initial solution, while Tabu Search performs local refinement through a neighborhood-based search. Since Tabu Search requires an initial solution to begin its search, the solution obtained from PSO serves as its starting point. Tabu Search subsequently explores neighboring solutions while maintaining a short-term memory to discourage repeated exploration of previously visited solutions and to reduce the likelihood of becoming trapped in local optima. This sequential integration enables PSO to perform the initial global exploration and Tabu Search to refine the resulting solution through local exploitation. The resulting hybrid algorithm, referred to as PSO-TSO, was implemented in Python. The fitness function was specifically designed to address the research problem [31]. The fitness function determines the effectiveness of workload allocation by prioritizing each sensor according to this context. The priority values are represented by a. l t i., which denote the weights assigned to each sensor based on their significance in the system. Since these weights are adjustable, they can be adjusted according to the application and specific user requirements. The formula for the fitness function is as follows:

$$= \sum_{i=1}^{n} [T_p(s_i) \times N(s_i)] \times w_i$$

$n =$ total numbr of sensors in the WBA em$T_p(s_i)$ = i^{th} sensor's processing time + i^{th} sensor's data transferring time
$N(s_i)$ = i^{th} sensor scanning count for collecting data
w_i = weight of i^{th} sensor

The specified fitness function offers adaptability for WBAN applications and can be used effectively across various scenarios. By modifying the weight in the fitness function, greater priority can be assigned to life-critical biomedical sensors in healthcare applications or to activity-related sensors in fitness-monitoring applications. Given the formula's structure, it can be applied in various scenarios with minimal modification. In this study, however, the fitness function is specifically evaluated for workload allocation based on sensor processing time, data transmission time, scanning count, and assigned priority weights; objectives such as energy consumption and reliability are not explicitly evaluated.

The experimental WBAN environment was simulated using OMNeT++, while the optimization algorithms were implemented in Python. A WBAN designed with five different biomedical sensors, named oxygen saturation (SpO2), electrocardiogram (ECG), body temperature, blood pressure, and electroencephalogram (EEG), to measure the data transmission time of each sensor node to the edge processor. The simulation was used to obtain the data transmission time from each sensor node to the edge processor. In contrast, the corresponding sensor data processing time was measured using a Raspberry Pi 4 as the edge-processing platform [27].

III. COMPARATIVE STUDY WITH EXISTING METHODS.

To evaluate the proposed PSO-TSO method for the workload-allocation problem considered in this study, its computational performance was compared with four existing metaheuristic optimization techniques: PSO, GAO, GWO, and FFO. The evaluation primarily focuses on the measured central processing unit (CPU) execution time as the input size increases. For the standalone PSO, GAO, GWO, and FFO implementations, 1,000 iterations and a population size of 1,000 were used. The proposed PSO-TSO method employs a different computational configuration. In the first stage, PSO is executed for 500 iterations with 1,000 particles to generate an initial solution. This solution is subsequently provided to the Tabu Search stage for local refinement. Tabu Search explores neighboring solutions for 100 iterations, with a tabu tenure of 200.

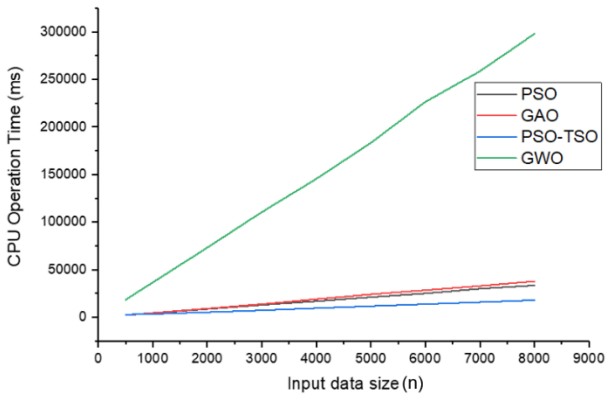

Figure 3. Measured CPU execution time for this research problem

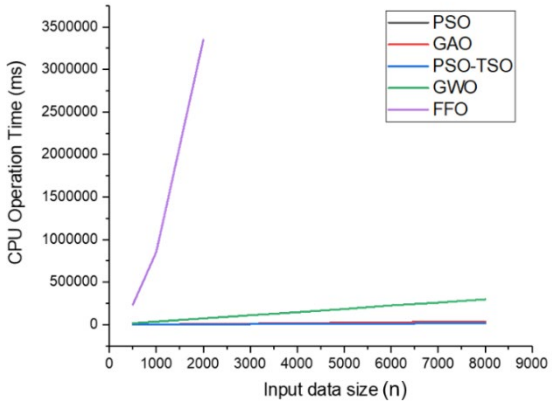

Figure 4. Measured CPU execution time of four (PSO_TSO, PSO, GAO, GWO) algorithms for this

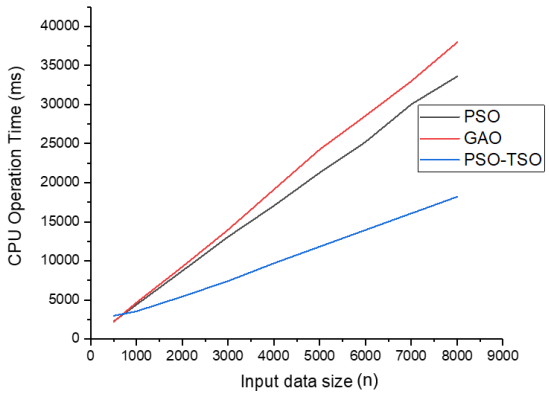

Figure 5. Measured CPU execution time of the three best (PSO_TSO, PSO, GAO) algorithms for this research problem

Data were collected during the study by measuring the CPU execution time of each algorithm for different input sizes. Figures 3, 4, and 5 demonstrate the time complexity variation of all algorithms for this research problem. Figure 3 compares all five algorithms. FFO exhibits the most rapid increase in CPU execution time as the input size increases and consequently becomes substantially slower than the other evaluated methods at larger input sizes. In contrast, all the other optimization techniques, including the newly introduced PSO-TSO algorithm, demonstrate linear growth. The CPU execution times for the PSO-TSO, PSO, GAO, and GWO are shown in Figure 4. Among these four methods, GWO exhibits a higher measured CPU execution time than PSO-TSO, PSO, and GAO across the evaluated input sizes. Figure 5 shows the CPU operation time for those three best optimization techniques, which have linear time complexity. As the input size increases, the CPU operation times of the PSO-TSO, PSO, and GAO algorithms generally increase. This is expected because a larger input dataset requires more computational resources to process. The new algorithm PSO-TSO consistently outperforms the other algorithms, achieving the lowest CPU runtime across all input data sizes. Among the evaluated configurations, FFO and GWO required substantially greater CPU execution time, particularly as the input size increased. Therefore, they may not be suitable for applications that require real-time processing or handling large amounts of data. PSO and GAO perform nearly identically, with CPU times increasing at a moderate rate. These algorithms are suitable for many applications where efficiency is important. However, the newly presented hybrid algorithm, PSO-TSO, required less CPU time than PSO and GAO. To statistically validate the observed performance difference, we conducted more than 60 independent runs of each algorithm across input sizes ranging from 1000 to 8000. The average CPU operation time at each input size is presented in Table 1. Statistical analysis was conducted using an independent-samples t-test, and the results showed that the average CPU execution time of PSO-TSO was significantly lower than that of PSO and GAO across all input sizes. Statistical analysis results for $p<0.001$ and the 95% confidence interval are presented in Table 1. According to the results in the table, the new hybrid algorithm PSO-TSO has approximately 45% lower time complexity than the PSO algorithm and more than 50% lower than the GAO algorithm. These statistically significant results, with narrow confidence intervals, demonstrate that the new algorithm, PSO-TSO, is the most efficient among the compared methods for time-critical applications such as WBAN. It can process larger datasets faster than other algorithms.

Table 1. Average CPU operation time and statistical comparison

Algorithm	Iterations	Mean CPU Time (ms)	Standard Deviation (ms)	Mean Difference vs. PSO-TSO (ms)	95% Confidence Interval of Difference (ms)	p-value vs. PSO-TSO	Time complexity reduction of PSO-TSO (%)

IV. CONCLUSIONS

WBANs are significant in numerous fields, with medical applications being a prominent domain. In the field of healthcare, there is a growing trend towards employing edge computing-based architectures. This approach enables near real-time outcomes by processing data as close to the source as possible. The research aims to introduce a suitable algorithm to reduce time complexity and achieve the desired performance. This paper discusses various strategies for optimizing edge-based WBAN systems and compares the time complexities of these techniques with those of a new technique. The proposed method achieved more than 45% less time complexity than the second-best algorithm. There exist additional factors to consider before selecting an algorithm. These factors include efficient memory utilization, minimized power consumption, and the return of an accurate final value. The researchers can study these factors in future work to find a suitable algorithm for WBAN applications. Therefore, as an extension of this research, performance analysis can be conducted for these optimization techniques. Moreover, this new PSO-TSO method can be enhanced by further studying each algorithm's strengths and limitations, dynamically adjusting each algorithm's contribution based on problem characteristics, and implementing an effective information-sharing method between algorithms. In many instances, implementing fast algorithms can reduce costs for developers and facilitate the adoption of innovative technologies. Hence, the findings of this study can be of great value to researchers and developers in choosing the most suitable optimization method for their problems. Furthermore, these results provide a foundation for researchers to explore and implement various techniques, algorithms, and applications in edge-computing-based WBAN research.

Abstract

In the electronics industry, optimizing the manufacturing process of Printed Circuit Boards (PCBs) is critical for cost and time efficiency. The mechanical drilling process performed on CNC machines is modeled as an industrial variation of the NP-Hard Traveling Salesperson Problem (TSP). This study evaluates the performance of the Genetic Algorithm (GA), Grey Wolf Optimizer (GWO), Ant Colony Optimization (ACO), and a Lamarckian Memetic Algorithm (GA + 2-Opt) that incorporates heavy tool-change penalties. To ensure statistical precision and evaluate scalability, the algorithms were tested across 30 independent runs in a standard scenario and 10 in a large-scale, complex scenario. Experimental results demonstrate that pure swarm and classical evolutionary approaches struggle with premature convergence and combinatorial explosion in discrete spaces. On the contrary, the Lamarckian Memetic Algorithm exhibits superior statistical stability. Although incorporating the 2-Opt local search operator increases computational time, the resulting robust minimization of production costs validates the applicability of the hybrid approach in industrial CNC environments.

Keywords: Combinatorial Optimization, Memetic Algorithm, Traveling Salesperson Problem (TSP), PCB Routing, Tool-Change Penalty, Scalability.

I.INTRODUCTION AND PROBLEM DEFINITION

The acceleration in the evolving electronics industry and its technologies has led to Printed Circuit Boards (PCBs) becoming both more complex and more compact. High-speed signal lines, multi-layer structures, and dense component placement make cost and time optimization mandatory in PCB manufacturing processes. One of the biggest bottlenecks in the PCB production line is the mechanical drilling process performed on CNC (Computer Numerical Control) machines. A standard industrial PCB may contain hundreds, sometimes thousands, of vias, integrated circuit (IC) pin slots, and mounting screw holes. The CNC machine's path while drilling these holes, as well as the frequency of tool changes, directly determines the total production time. Unnecessary back-and-forth movements on the route and unplanned tool changes cause massive time and energy losses in mass production. In the computer science literature, this problem is modeled as an industrial variation of the Traveling Salesperson Problem (TSP), which belongs to the famous NP-Hard class, with added cost and penalty parameters.

Mathematical and Physical Boundaries of the Problem

The PCB drilling problem addressed in this study is not merely about finding the shortest distance in a two-dimensional (X-Y) plane. The problem includes the following industrial constraints:

1) Distance Constraint: The linear time spent by the CNC head moving from one hole to another.
2) Tool Change Penalty: The mechanical delay time spent by the CNC machine to change the drill bit (M06 command) during transitions between holes of different diameters (T1: Screw, T2: IC, T3: Via). Traditional exact algorithms suffer from combinatorial explosion as the number of holes increases, rendering them incapable of solving this problem in a reasonable time. This situation necessitates the use of meta-heuristic algorithms.

II.LITERATURE REVIEW AND THEORETICAL BACKGROUND

Nature-inspired metaheuristic algorithms have been extensively used in combinatorial optimization. The Classical Genetic Algorithm (GA) is highly successful in global space exploration using crossover and mutation operators; however, it often suffers from premature convergence in discrete routing tasks [1]. Swarm-based algorithms, such as the Grey Wolf Optimizer (GWO), excel at continuous optimization but encounter mathematical constraints in discrete environments [2]. Ant Colony Optimization (ACO), specifically designed for TSP, shows significant stability through pheromone trails, though it risks stagnation in local minima [3]. To bridge the gap between global exploration and local exploitation, Memetic Algorithms (MA) introduce a Lamarckian evolution paradigm [4]. Recent studies (2019-2024) in industrial routing strongly emphasize hybrid metaheuristics. Research indicates that combining evolutionary global search with local optimizers, such as the 2-Opt algorithm, drastically improves routing efficiency [5]. This study contributes to the literature by statistically evaluating these foundational and hybrid algorithms under a realistic scenario featuring heavy tool-change penalties, analyzing the trade-off between CPU time and statistical robustness.

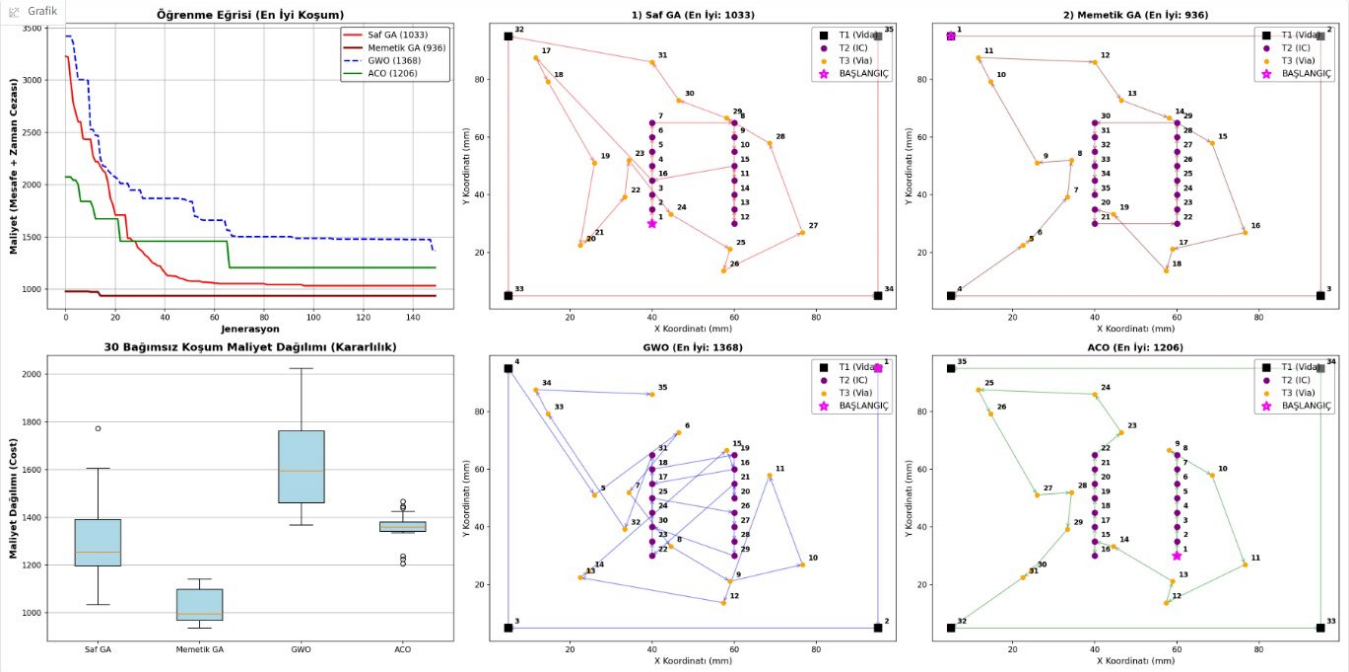
III.METHODOLOGY

To test the optimization algorithms, simulated PCB layouts were generated comprising three different tool types: T1 (Screws), T2 (IC pins), and T3 (Vias). The cost function evaluates the Euclidean distance between consecutive points and incorporates a constant penalty (150 units) simulating the mechanical delay incurred when the CNC machine performs a tool change (M06 command).

$$Büyük Büyük Cost = \sum_{i=1}^{n-1} \left(d_{i,i+1} + \begin{cases} 150, & \text{If } Tool_i \neq Tool_{i+1} \\ 0, & \text{If } Tool_i = Tool_{i+1} \end{cases} \right)$$

Four meta-heuristic architectures were coded in Python:

1) Pure GA: Utilizes Order Crossover (OX1) and mutation with an elitism principle [1].
2) GWO: Adapted to combinatorial space using discrete “Swap Sequences” [2].
3) ACO: Employs Roulette Wheel selection based on pheromone and visibility matrices [3],[6].
4) Lamarckian Memetic Algorithm (GA + 2-Opt): In this selective Lamarckian architecture, the champion route of each generation is subjected to the 2-Opt local search to untangle crossed paths [4], [7]. The refined chromosome is reintegrated into the population, merging global exploration with local exploitation.



Experimental Setup: To ensure statistical significance, a Standard Scenario (100x100mm board, 35 holes) was evaluated over 30 independent runs. To assess scalability, a Complex Scenario (200x200mm board with 73 holes) was used. Due to the exponential time complexity ($O(N^2)$) of local search and swarm evaluations on larger graphs, the complex scenario was subjected to 10 independent runs as a stress test.

IV.EXPERIMENTAL RESULTS AND DISCUSSION

1. Standard Scenario Analysis (35 Holes)

In the standard scenario, the algorithms were executed across 30 independent runs to rigorously assess their learning curves, route-generation quality, and statistical robustness.

Figure 1. Standard Scenario Results

1) Learning Curves and Convergence: As observed in the learning curve graphs, the Lamarckian Memetic Algorithm demonstrates an extraordinary "fast convergence" phenomenon. By using the 2-Opt local search operator at generation 0, it instantly resolves chaotic initial routes, dramatically reducing the cost in the first iteration. In contrast, Pure GA and GWO require more than 60 generations to plateau, demonstrating the significant impact of local search mechanisms during the early evolutionary phases.

2) Visual Routing and Drilling Order: Visual inspection of the best drilling routes reveals the practical impact of these algorithms on the CNC tool path. The Pure GA route exhibits the "spaghetti effect," characterized by highly entangled paths and unnecessary tool-change (M06) jumps among T2 (IC) components. Conversely, the Memetic GA yields a smooth, non-intersecting trajectory. The drill bit systematically finishes clusters of the same hole type before transitioning to the next, thereby minimizing mechanical delays.

3) Statistical Stability: The box-plot analysis illustrates the distribution of the final best costs across 30 runs. Memetic GA displays a highly compressed box at the lowest cost tier, indicating that it consistently converges to near-optimal results regardless of random initializations. Pure GA and GWO exhibit high variance (wide boxes), highlighting the instability of pure evolutionary algorithms in discrete spaces.

Table 1. Statistical Comparison Table (Standard Scenario)

Algoritma	En İyi (Min)	En Kötü (Max)	Ortalama (Mean)	Std. Sapma	Ort. CPU Süresi (sn)
GA	**1033.28**	1773.47	1297.79	±176.87	4.42 s
Memetic	**936.42**	1141.96	1022.54	±65.79	8.14 s
GWO	**1367.52**	2024.82	1626.54	±176.72	1.50 s
ACO	**1206.13**	1466.61	1357.24	±56.19	30.71 s

The numerical data in Table 1 support these visual findings. The Memetic Algorithm achieved the lowest mean cost (1022.54) with a minimal standard deviation of ±65.79. Pure GA achieved a competitive minimum cost in some runs, but its high standard deviation (±176.87) indicates unreliability. Furthermore, a critical engineering trade-off regarding computational time is observed. ACO required a mean CPU time of 30.71 seconds due to heavy pheromone matrix calculations, whereas Memetic GA required only 8.14 seconds. While Pure GA was the fastest (4.42s), the ~4-second computational delay incurred by the Memetic approach is a negligible cost for offline CNC programming, given the substantial improvement in routing quality.

2. Complex Scenario Analysis (73 Holes)

To evaluate algorithmic scalability, the workspace was expanded to 73 holes, effectively increasing the search space exponentially. The algorithms were stress-tested over 10 independent runs.

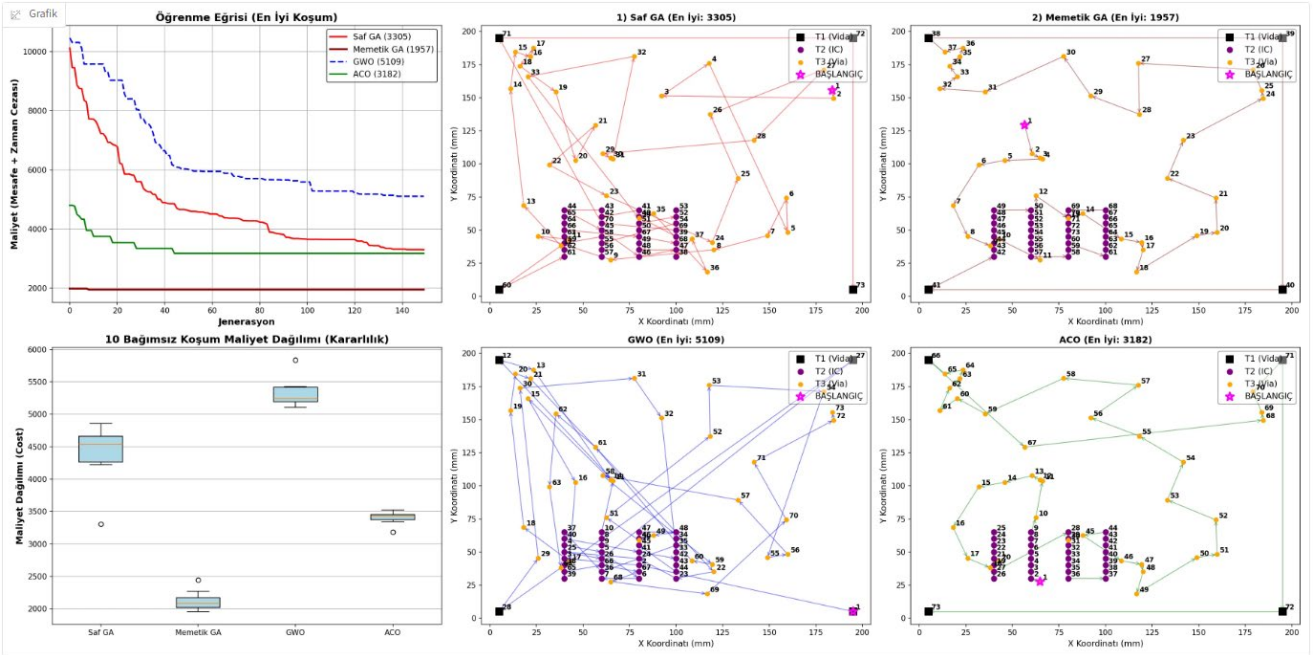


Figure 2. Complex Scenario Results

1) Combinatorial Explosion in Routing: When the problem size increases, the learning curves and visual routes explicitly highlight the vulnerability of pure evolutionary methods. Pure GA suffers from combinatorial explosion, resulting in highly entangled "spaghetti" routes that fail to converge efficiently. GWO completely failed to adapt to the enlarged discrete space. ACO's heuristic nature (relying on node visibility) prevented total divergence, allowing it to maintain a structured path. However, Memetic GA retained its systematic, non-overlapping routing order even in this highly complex layout.

2) Scalability and $O(N^2)$ Complexity Penalty: The scalability table provides crucial insights into algorithmic behavior under stress. Pure GA's mean cost degraded severely to 4402.14 (±418.86). ACO demonstrated the resilience of swarm intelligence in larger graphs, securing the second-best mean cost of 3404.85. However, the Memetic Algorithm significantly outperformed all baselines, maintaining a mean cost of 2123.07 (±139.43). The impact of the $O(N^2)$ time complexity inherent in local search operators is clearly visible in CPU times. As the node count doubled, ACO's runtime increased to 50.34s, and Memetic GA's runtime increased to 35.97s. These results explicitly demonstrate that while the 2-Opt local search incurs a higher CPU penalty on larger datasets, its ability to untangle complex routes systematically is indispensable for industrial-scale optimization.

Table 2. Statistical Comparison Table (Complex Scenario)

Algoritma	En İyi (Min)	En Kötü (Max)	Ortalama (Mean)	Std. Sapma	Ort. CPU Süresi (sn)
GA	**3305.11**	4858.49	4402.14	±418.86	5.09 s
Memetic	**1957.28**	2442.55	2123.07	±139.43	35.97 s
GWO	**5108.76**	5837.51	5324.54	±200.92	2.22 s
ACO	**3182.43**	3523.79	3404.85	±88.06	50.34 s

V. CONCLUSION

This study comprehensively addressed the critical challenge of time and cost optimization in CNC drilling processes for industrial Printed Circuit Board (PCB) manufacturing. By modeling the routing process as a discrete, NP-Hard Traveling Salesperson Problem (TSP) heavily penalized by mechanical tool-change delays, four distinct meta-heuristic architectures were comparatively evaluated. Through rigorous statistical testing, comprising 30 independent runs for a standard PCB layout and 10 for a large-scale stress test, the fundamental behavioral differences among pure evolutionary, swarm-based, and hybrid algorithms were explicitly revealed. The experimental findings conclusively demonstrate that meta-heuristic algorithms lacking local search capabilities are inadequate for complex, discrete industrial routing. The Grey Wolf Optimizer (GWO), while traditionally dominant in continuous spaces, completely failed to adapt to the discrete combinatorial constraints, resulting in severe stagnation. The Pure Genetic Algorithm (GA) exhibited fast execution times but suffered from premature convergence and a severe combinatorial explosion as the problem scaled. Its inability to fine-tune local routes led to the highly inefficient "spaghetti effect," proving that global exploration alone is insufficient. Ant Colony Optimization (ACO) demonstrated the inherent resilience of swarm intelligence; its

heuristic dependence on node visibility prevented total divergence in large-scale problems, yet it struggled with extended computational times and sub-optimal final routes due to the absence of genetic elitism. The absolute superiority in both standard and scaled scenarios belonged to the Lamarckian Memetic Algorithm. By seamlessly integrating the global exploration power of a Genetic Algorithm with the precise local exploitation of the 2-Opt operator, the Memetic approach consistently untangled crossing paths and minimized costly tool changes. It systematically grouped operations by drill bit types, achieving the lowest mean costs and the highest statistical stability (lowest standard deviation) across all independent runs. While the hybridization of the 2-Opt local search incurs higher CPU time overhead due to its $O(N^2)$ time complexity, this study demonstrates that this computational expense is a highly favorable engineering trade-off. In industrial mass production, CNC G-Code programming is an offline, one-time preparatory process. Sacrificing a few additional seconds of CPU time during the algorithmic optimization phase translates into real-world reductions in machine wear, shorter tool-change durations, and substantial cumulative time savings on the active manufacturing assembly line.

Abstract
Oil spills pose a critical threat to marine and coastal ecosystems. Synthetic Aperture Radar (SAR) has become one of the most valuable remote sensing tools for detecting and monitoring ocean oil spills due to its all-weather, day-and-night imaging capability at various spatial resolutions. However, automated segmentation of oil spills in SAR imagery remains challenging due to speckle noise, look-alike phenomena, and the morphological variability of oil slicks. In this work, we adapt and evaluate a Swin Transformer backbone (Swin-B) coupled with UPerNet for the semantic segmentation of oil spills in single-channel SAR images. The model leverages hierarchical shifted-window self-attention to capture both local texture and long-range spatial structure, providing coherent segmentation of spills with diverse shapes and sizes. We employ a compound loss configuration (JointLoss = BCE + Dice + SSIM) designed to address class imbalance and boundary diffuseness common in SAR oil spill imagery. To rigorously validate the model, we evaluate it across four datasets spanning two frequency bands (C and L), two polarizations (VV, HH), and spatial resolutions from 5 m to 150 m: MKLab (Sentinel-1), CIMAT (ENVISAT-ASAR), and the SOS dataset with ALOS-PALSAR and Sentinel-1 subsets. Results show that JointLoss consistently improves segmentation quality over standard BCE, with average gains of +1.8% IoU, +1.2% F1, and +3.5% Recall. The model achieves competitive or superior performance compared to published baselines where available. Additional cross-domain experiments highlight likely contributors to the observed performance differences across sensors, providing insights for future domain-adaptation studies.

Keywords: SAR, oil spill detection, semantic segmentation, Swin Transformer, UPerNet, multi-sensor evaluation, compound loss.

I. INTRODUCTION

Oil spills and leaks in the ocean are among the main threats to marine and coastal ecosystems, causing ecological and socioeconomic damage that may take years to reverse [1]. Although the frequency of large-scale disasters has decreased since the 1970s—largely due to improved regulations and double-hull tanker designs—smaller incidents associated with exploration, transportation, and offshore operations continue to occur regularly. The International Tanker Owners Pollution Federation (ITOPF) estimates that routine operational discharges and minor spills account for a substantial portion of annual petroleum input into the oceans, maintaining the need for effective surveillance and early-response strategies. The detection and monitoring of oil spills at sea requires sensors capable of covering vast ocean areas with sufficient temporal and spatial resolution. Optical satellite sensors, while useful under clear-sky conditions, are severely limited by cloud cover, nighttime operation, and sun-glint effects. In contrast, Synthetic Aperture Radar (SAR) sensors have proven particularly suitable for maritime monitoring due to their ability to operate day and night, regardless of weather conditions [2], [3]. Their physical principle, based on detecting changes in sea surface roughness via microwave backscatter, enables identification of the damping effect that hydrocarbon films exert on short gravity-capillary waves at the water surface. The interaction between microwaves and the ocean surface is governed by Bragg scattering theory [2]: when an oil film is present, it suppresses short gravity-capillary waves by increasing surface viscosity, producing a localized reduction in radar backscatter visible as a dark region in the SAR image. However, SAR-based oil

spill detection faces several technical challenges: (i) multiplicative speckle noise inherent to coherent imaging systems, (ii) look-alike phenomena (biogenic films, low-wind zones, rain cells, internal waves) that produce similar dark features, and (iii) variability across sensors in terms of frequency band, polarization, incidence angle, and spatial resolution [2]. Classical detection methods based on thresholding and machine learning with handcrafted features achieved limited robustness, with false positive rates reaching 50–70% [2]. Deep learning approaches—particularly CNN-based architectures such as U-Net and DeepLabV3+—have substantially improved performance [4], and, more recently, Vision Transformers have demonstrated greater structural coherence through self-attention mechanisms [5]. Despite the progress in deep learning for SAR oil spill detection, most existing methods are evaluated on a single dataset from a specific sensor, limiting our understanding of their generalization capabilities. Real-world operational scenarios involve multiple satellite platforms with different frequency bands (C-band at 5.4 GHz, L-band at 1.3 GHz), polarization modes (VV, HH, VH, HV), and spatial resolutions ranging from 1 m to 150 m. A model that performs well on Sentinel-1 C-band imagery may fail when applied to ALOS-PALSAR L-band data, due to differences in the physical interaction with the oil film and the underlying sea state. In this work, we adapt and evaluate a Swin Transformer backbone coupled with UPerNet for oil spill segmentation in single-channel SAR imagery. The Swin Transformer's hierarchical shifted-window attention provides an effective mechanism for capturing both local speckle patterns and the large-scale spatial structure of oil slicks. At the same time, UPerNet enables multi-scale feature fusion for precise boundary delineation. Our contributions are:

Adaptation of Swin-B + UPerNet pretrained on ADE20K to single-channel SAR input via filter averaging, demonstrating that a general-purpose vision architecture achieves competitive or superior performance for oil spill segmentation with minimal domain-specific modifications.

A compound loss function (BCE + Dice + SSIM) that consistently improves mask completeness and boundary coherence across all evaluated datasets, with particular effectiveness for weathered or diffuse spills.

Rigorous validation across four datasets spanning C-band and L-band SAR, with resolutions from 5 m to 150 m, demonstrating stable performance across diverse sensor configurations. Complementary cross-domain experiments identify the main sources of the domain gap for future work.

II. RELATED WORK

1. Classical Methods

Traditional oil spill detection in SAR imagery follows a three-stage pipeline: (1) dark spot detection via adaptive thresholding,

(2) feature extraction using geometric, textural, and contextual attributes, and (3) classification using machine learning [2]. While effective under controlled conditions, these methods require manual tuning for each sensor configuration, with false alarm rates reaching 50–70% due to look-alike phenomena that can account for up to 90% of detected dark spots [2]. Recent reviews [3] confirm that the field is moving toward deep learning, while cross-sensor generalization remains an open question.

2. CNN-Based Methods

Krestenitis et al. [4] published the first large public dataset with over 2,000 annotated SAR images from Sentinel-1. They benchmarked several CNN architectures for multi-class segmentation (oil spill, look-alike, ship, land,

sea). U-Net achieved an mIoU of 64.97%, and DeepLabV3+ reached 65.06%, significantly outperforming classical methods. The dataset introduced a standardized evaluation protocol that enabled fair comparison across methods. Subsequent improvements include multi-channel inputs integrating wind speed maps and auxiliary layers [6] (IoU 97.17%). Although these multi-channel approaches report high performance, they rely on auxiliary information and are therefore not directly comparable to single-channel SAR-only models. Li et al. [7] proposed multi-scale feature fusion modules (mIoU 80%) that address the varying sizes of oil spills, from small localized leaks to massive slicks extending hundreds of kilometers. Zhu et al. [8] introduced boundary-supervised networks with attention blocks (mIoU 83%, F1 87%), addressing the challenge of delineating diffuse spill boundaries. Huang et al. [9] proposed a two-stage Faster R-CNN + U-Net++ framework for Sentinel-1, emphasizing detection followed by delineation. Despite these advances, CNN architectures exhibit inherent limitations in modeling long-range spatial dependencies due to their local receptive fields. Oil spills can extend over very large, irregularly shaped areas with variable internal intensities, requiring the model to integrate information across distant spatial locations. This limitation motivates the exploration of attention-based models capable of capturing global context.

3. Transformer-Based Approaches

The Vision Transformer (ViT) [5] introduced self-attention to image recognition, dividing images into fixed-size patches and processing them as sequences. While powerful, standard ViT has quadratic complexity in sequence length and lacks a built-in multi-scale hierarchy, making it computationally expensive for dense prediction tasks such as segmentation. Dehghani-Dehcheshmeh et al. [10] proposed hybrid CNN–Transformer architectures (DL-ViT variants) that combine convolutional feature extraction with Transformer-based global attention. Their best model achieved mIoU of 64.59% and F1 of 78.48% on the MKLab dataset, demonstrating that attention mechanisms improve spatial consistency in segmentation outputs. Basit et al. [11] explored CNN–ViT combinations with gradient profile loss, achieving an mIoU of 78.45%, where the gradient profile loss was specifically designed to improve edge delineation. Li et al. [7] compared their multi-scale CNN against TransUNet and Swin-UNet, reporting competitive results that highlight the need for hierarchical multi-scale attention in SAR applications. More recently, Sai et al. [12] introduced Ocean Shield, a Transformer-based approach for marine oil spill detection from SAR imagery, reflecting the growing interest in attention-based models for this application. Sun et al. [13] proposed MAF-UFormer, a U-shaped Transformer incorporating multi-scale alignment and fusion mechanisms for SAR oil spill segmentation, and evaluated it on both the Sentinel-1 and PALSAR subsets of the SOS dataset. These developments reinforce the relevance of hierarchical and multi-scale attention for representing oil spills with heterogeneous sizes, textures, and boundary characteristics. The Swin Transformer [14] addresses the computational limitations of standard ViT through shifted-window self-attention, achieving linear complexity with respect to image size while maintaining the ability to capture long-range dependencies through cross-window connections. Its hierarchical structure naturally produces multi-scale feature maps well-suited for dense prediction, making it an attractive backbone for segmentation tasks. Our work combines Swin-B with UPerNet and validates it across multiple SAR sensors, addressing the single-dataset limitation common in prior evaluations. More broadly, foundation models such as SAM [15] have attracted attention for zero-shot segmentation, though their application to single-channel SAR with severe speckle and look-alike phenomena remains unexplored. Domain adaptation techniques represent complementary strategies to improve cross-sensor transfer and constitute a relevant direction for future work.

III. METHODOLOGY

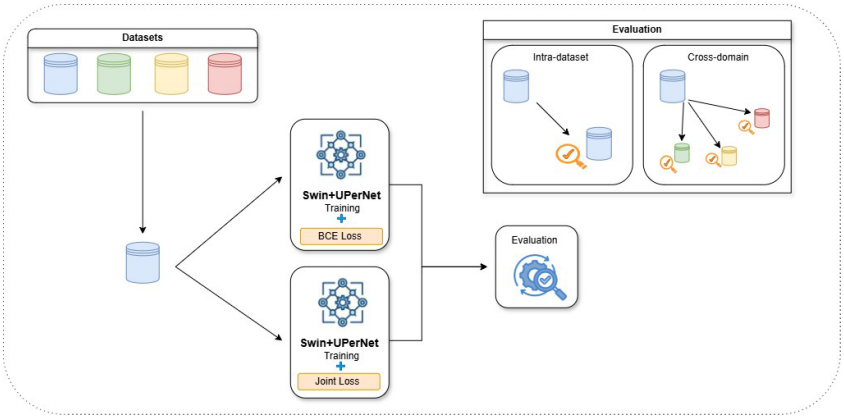

Figure 1 presents an overview of the proposed methodology, which consists of four main stages: data preparation and normalization, SAR-adapted model architecture, compound loss training, and multi-sensor evaluation.

Figure 1. Overview of the proposed multi-sensor oil spill segmentation methodology. The pipeline includes data preparation from multiple SAR sensors, model adaptation for single-channel input, training with compound loss, and cross-domain evaluation.

1. Model Architecture

We employ Swin-B [14] as the backbone encoder coupled with UPerNet [16] as the segmentation head. The Swin Transformer introduces two key innovations over the standard Vision Transformer: (1) hierarchical feature maps with progressive down-sampling, producing representations at multiple scales analogous to CNN feature pyramids, and (2) shifted-window self-attention that restricts computation to local windows while enabling cross-window interaction through alternating shift patterns.

a) Swin-B Encoder. Swin-B constructs hierarchical feature maps through four stages with channel dimensions {128, 256, 512, 1024} and block counts {2, 2, 18, 2}. Each stage consists of multiple Swin Transformer blocks, where each block applies Layer Normalization, Window-based Multi-Head Self-Attention (W-MSA or SW-MSA), another Layer Normalization, and a 2-layer MLP with GELU activation.

The window-based self-attention computes attention within non-overlapping local windows of size $M \times M$ (default $M = 7$):

$$Attention(Q, K, V) = SoftMax\left(\frac{QK^T}{\sqrt{d}} + B\right)V,$$

M kare×dє $\mathbb{R}^{M^2 \times d}$ are the query, key, and value matrices, d is the head dimension, and B is a learnable relative position bias. The shifted-window mechanism in alternating layers displaces the window partition by $(\lfloor M/2 \rfloor, \lfloor M/2 \rfloor)$ pixels, enabling cross-window connections without increasing computational cost.

Between stages, patch-merging layers concatenate features from 2x2 neighboring patches and apply a linear projection to halve the spatial resolution while doubling the number of channels. These yield feature maps at

resolutions $\left\{\frac{H}{4}\times\frac{W}{4},\frac{H}{8}\times\frac{W}{8},\frac{H}{16}\times\frac{W}{16},\frac{H}{32}\times\frac{W}{32}\right\}$ with corresponding channel dimensions, providing the multi-scale representations required for dense prediction.

b) Adaptation to Single-Channel SAR. The original patch embedding layer is designed for 3-channel RGB input, using a convolutional layer with a 4×4 kernel and a stride of 4. For single-channel SAR images, we adapt the pretrained filters by averaging across the channel dimension:

$$W_{SAR} = \frac{1}{3}\sum_{c=1}^{3} W_{RGB}[:, c, :, :],$$

producing a single-channel input projection $W_{SAR} \in \mathbb{R}^{124\times1\times4\times4}$ while preserving the 128-dimensional output. This strategy avoids architectural modifications and enables effective transfer learning from ImageNet-22K and ADE20K weights [17]. An alternative approach is to duplicate the SAR channel three times to match the original RGB input; however, filter averaging preserves an explicitly single-channel projection and avoids unnecessary memory overhead.

c) UPerNet Decoder. UPerNet [16] fuses the multi-scale encoder outputs through a Pyramid Pooling Module (PPM) applied to the deepest feature map and a Feature Pyramid Network (FPN) that merges all four stages via top-down lateral connections, producing aligned feature maps at ¼ resolution. The final prediction head applies a 3x3 convolution and bilinear up-sampling to the original input at the original input resolution. Figure 2 illustrates the complete architecture.

2. Loss Functions

The choice of loss function significantly impacts segmentation quality in SAR imagery, where class imbalance (ocean pixels vastly outnumber spill pixels) and boundary ambiguity are prevalent. We compare two training configurations:

BCE (baseline): Standard binary cross-entropy providing pixel-wise supervision:

$L_{BCE} = -\frac{1}{N}\sum_{i=1}^{N}[\bar{y}_i log(y_i) + (1-\bar{y}_i)log(1-y_i)]$,Wh
$i. is\ the\ predicted\ probability\ for\ pixel\ i, y$ çubuk alt $i.$, $\bar{y}_i$ is the ground truth label, and N is the total number of pixels. BCE treats each pixel independently, which can lead to fragmented predictions when the network is uncertain about contiguous regions.

JointLoss (compound): A weighted combination addressing complementary aspects of SAR segmentation:

$\mathcal{L}$ = LBCE + β LSSIM + γ LDice,

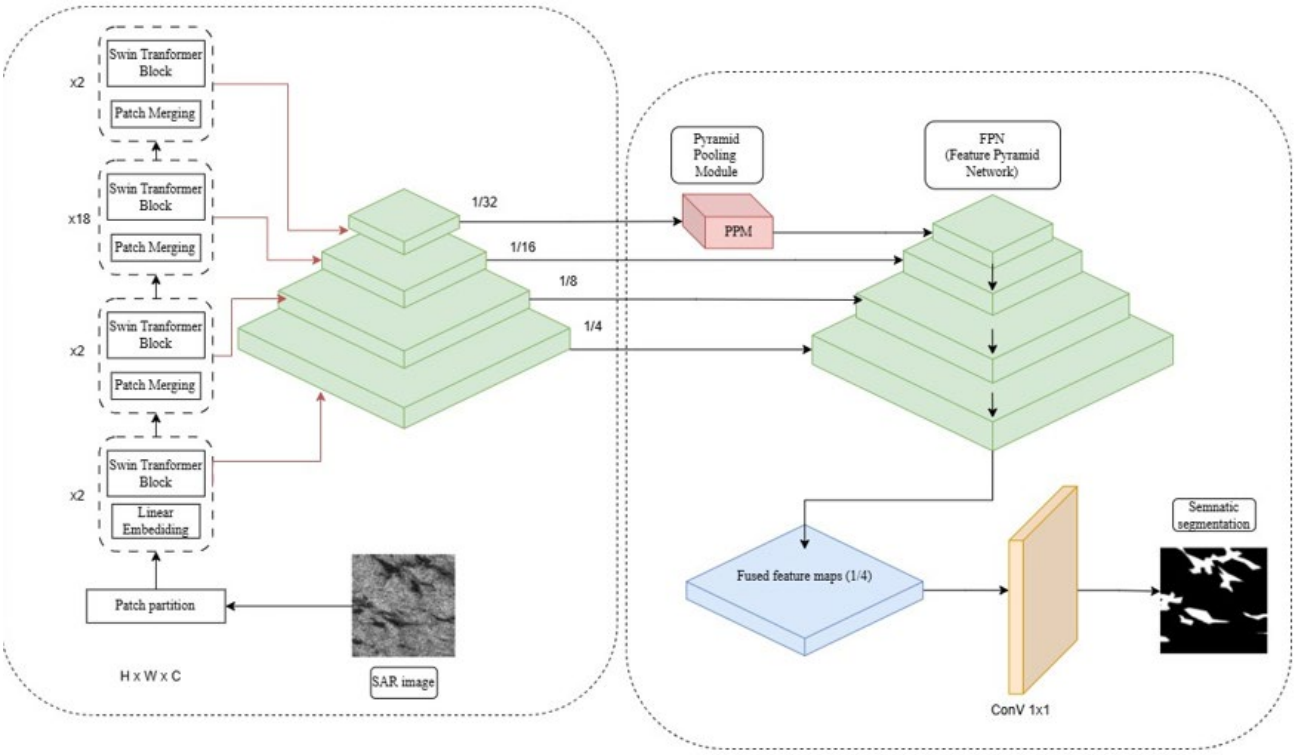

Figure 2. Detailed architecture of the Swin-B + UPerNet model for SAR oil spill segmentation, showing the hierarchical encoder stages, shifted-window attention mechanism, and the UPerNet decoder with PPM and FPN modules.

The Structural Similarity Loss is defined as:

$$L_{SSIM} = 1 - SSIM(y, \bar{y}) = 1 - \frac{(2\mu_y\mu_{\bar{y}} + c_1)(2\sigma_{y\bar{y}} + c_2)}{(\mu_y^2 + \mu_{\bar{y}}^2 + c_1)(\sigma_y^2 + \sigma_{\bar{y}}^2 + c_2)}$$

where μ and σ denote the local mean and variance computed over a sliding window, $\sigma_{y\bar{y}}$ is the local covariance, and $c1$, $c2$ are stability constants. SSIM enforces structural coherence between the prediction and the ground truth at the local patch level, which is particularly beneficial for oil spills with diffuse boundaries resulting from weathering and emulsification. Unlike pixel-wise losses, SSIM captures the structural pattern of the segmentation mask, penalizing fragmented predictions that are structurally inconsistent with the ground truth.

The Dice Loss directly optimizes the overlap metric:

$$L_{Dice} = 1 - \frac{2\sum_{i=1}^{N} y_i \bar{y}_i}{\sum_{i=1}^{N} y_i^2 + \sum_{i=1}^{N} \bar{y}_i^2}$$

which mitigates class imbalance by focusing on the foreground overlap rather than treating all pixels equally. This is critical in oil spill segmentation, where spill pixels often constitute less than 10% of the image area.

. The weights $\alpha = 0.5$, $\beta = 0.5$, $\gamma = 0.6$ were determined via preliminary grid search on internal validation splits, explring configuration in the r ange $\alpha, \beta \in \{0.3, 0.5, 1.0\}$ and $\gamma \in \{0.3, 0.6, 0.8\}$. The selected combination provided the best trade-off between Recall and Precision on the validation set of the SOS-PALSAR dataset. These weights were kept fixed across all subsequent experiments to ensure fair comparison and avoid per-dataset overfitting. The rationale for these weights reflects the complementary roles: BCE provides a gradient signal for all pixels (including easy negatives), SSIM ensures structural consistency at the patch level, and Dice focuses the optimization on the minority class. A slightly higher weight for Dice ($\gamma = 0.6$) compensates for the severe class imbalance typical of SAR oil spill imagery, where spill pixels often account for less than 10% of the patch area.

3. Datasets

Four datasets spanning different sensors, bands, spatial resolutions, and geographic regions are used (Table 1). The SAR frequency bands employed in this study correspond to two distinct portions of the microwave pectru: C-band at a frequeny of approxmately 405 GHz (waelength $\lambda = 5.6\ cm), whiband\ operates\ at\ approximately\ 1.270\ Gwavelength\ wavelength\ Hz$ ($\lambda = 3.6$ cm). These bands interact differently with the ocean surface and oil films: C-band is generally more sensitive to short gravity-capillary waves, whereas L-band responds to longer surface structures and may be less sensitive to small-scale roughness variations. These differences can affect the apparent contrast, texture, and boundary definition of oil slicks. Regarding polarization, VV (Vertical-Vertical) denotes vertically polarized transmission and reception, the standard co-polarization mode for ocean monitoring due to its enhanced sensitivity to Bragg scattering from the sea surface. HH (Horizontal-Horizontal) denotes horizontally polarized transmission and reception, which provides complementary information about surface roughness and has shown effectiveness in detecting oil films at lower incidence angles. Spatial resolution varies substantially across datasets, ranging from 5 m (Sentinel-1A azimuth) to 150 m (ENVISAT-ASAR WSM mode). This diversity is central to our evaluation, as resolution determines the level of detail captured within oil slicks and directly affects the model's ability to delineate spill boundaries. The CIMAT dataset is particularly interesting in this regard, as it combines patches from two acquisition modes (IMP at 15 m and WSM at 150 m), introducing intra-dataset resolution variability.

Table 1. Summary of datasets used in this study. Band frequencies: C-band ≅ 5.405 GHz ($\lambda \cong 5.6$ cm), L-band ≅ 1.270 GHz ($\lambda \cong 23.6$ cm). Polarization: VV = vertical transmit/vertical receive; HH = horizontal transmit/horizontal receive.

Dataset	Sensor	Res. (m)	Band (freq.)	Pol.	Patch	Train	Test
MKLab [4]	Sentinel-1	10	C (5.405 GHz)	VV	160×160	3900	420
CIMAT [6]	ENVISAT-ASAR	15 / 150	C (5.331 GHz)	VV	224×224	2508	628
SOS-PALSAR [8]	ALOS-PALSAR	12.5	L (1.270 GHz)	HH	256×256	3101	776
SOS-S1 [8]	Sentinel-1A	5×20	C (5.405 GHz)	VV	256×256	3354	839

Each dataset preserves its original preprocessing pipeline and train/test split to ensure comparability with published baselines. All patches contain at least one positive pixel (oil spill). The datasets cover different geographic regions (Gulf of Mexico, Persian Gulf, Black Sea, global coastal areas), acquisition conditions, and spatial resolutions spanning over one order of magnitude (5–150 m), providing a comprehensive testbed for evaluating model robustness across the operational variability encountered in real SAR monitoring systems.

4. Training Protocol

All experiments use the AdamW optimizer with an initial learning rate of 1x10-4 and weight decay of 1x10-2, learning rate reduction on plateau (factor 0.5, patience 3), early stopping (patience 5), batch size 16, and a maximum of 30 epochs. Training was performed on an NVIDIA RTX 3090 (24 GB VRAM). Hyperparameters were held constant across all datasets and cross-domain experiments to ensure a fair comparison. Data augmentation: To improve generalization and reduce overfitting, we apply random geometric transformations during training: horizontal and vertical flips (probability 0.5 each), random rotations (±15◦), and random scaling (factor 0.8-1.2). No photometric augmentations (contrast, brightness) are applied because SAR intensity values carry physical meaning related to surface backscatter coefficients, and arbitrary photometric transformations could disrupt the radiometric relationships the model needs to learn. Preprocessing: Each dataset maintains its original preprocessing pipeline to ensure comparability with published results. MKLab and SOS datasets provide patches already extracted and normalized; CIMAT applies patch-level min-max normalization to [0, 1]. All images are resized to the network input size (224 × 224) using bilinear interpolation for images and nearest-neighbor for masks. Model initialization: The Swin-B backbone is initialized from weights pretrained on ImageNet-22K and fine-tuned on ADE20K for semantic segmentation. The UPerNet decoder is also initialized from ADE20K pretraining. Only the patch embedding layer is modified for single-channel input as described in Section III. All layers are fine-tuned end-to-end with the same learning rate. Model complexity and inference cost: The complete Swin-B + UPerNet architecture contains 123.5M parameters and requires 55.9 GFLOPs per forward pass for a 224 × 224 single-channel input. On an NVIDIA TITAN RTX GPU, the average inference time is 42.2ms per patch (batch size 1), corresponding to an approximate throughput of 24 patches/second, with a peak GPU memory footprint of 2.0 GB during inference.

IV. RESULTS AND DISCUSSION

1. Intra-Dataset Performance

Table 2 presents the test-set performance across all datasets, comparing our model against the best published baselines.

Table 2. Test results across datasets. Best results per dataset in bold. Baseline results are taken from their respective original publications and were not reproduced under identical splits, hardware, or evaluation protocol; comparisons should therefore be interpreted as contextual references rather than a strictly controlled benchmark. All our metrics correspond to the oil-spill foreground class computed pixel-wise on the test set.

Dataset	Method	Acc.	Prec.	Rec.	F1	IoU
SOS-PALSAR	Multi-Map [7]	0.930	0.729	–	0.784	–
	Ours (BCE)	0.931	**0.777**	0.824	0.800	0.666
	Ours (JointLoss)	**0.932**	0.765	**0.863**	**0.811**	**0.682**
SOS-S1	Multi-Map [7]	0.879	0.769	–	0.815	–
	Ours (BCE)	**0.898**	**0.865**	0.837	0.850	0.740
	Ours (JointLoss)	0.895	0.806	**0.919**	**0.859**	**0.753**
MKLab	DL-ViT-2 [10]	0.965	**0.861**	0.721	**0.785**	**0.646**
	Ours (BCE)	0.961	0.748	0.787	0.767	0.623
	Ours (JointLoss)	**0.967**	0.768	**0.795**	0.781	0.641

CIMAT	Ours (BCE)	0.875	0.832	0.897	0.863	0.759
	Ours (JointLoss)	**0.890**	**0.851**	**0.909**	**0.879**	**0.785**

On SOS-PALSAR, JointLoss improves Recall by +3.9 percentage points and IoU by +1.6 points over BCE, producing more complete masks for weathered spills. These differences may reflect the distinct imaging characteristics of L-band SAR, whose longer wavelength can produce smoother spatial responses and different sensitivity to surface roughness variations, favoring more continuous predictions in this dataset. On SOS-Sentinel-1, the model surpasses Multi-Map [7] with an F1 of 0.859 vs. 0.815. JointLoss achieves a substantial Recall improvement (+8.3 pp over BCE), indicating more complete spill coverage at the cost of slightly lower Precision, consistent with the loss design prioritizing structural completeness. C-band provides higher surface contrast but is more sensitive to local wind conditions and look-alike interference. On MKLab, performance is comparable to the best hybrid CNN-Transformer (DL-ViT-2: F1 0.785 vs. ours 0.781), with notably higher Recall (0.795 vs. 0.721), indicating better spill coverage. The slightly lower Precision is attributable to imprecise boundary annotations in the reference masks, where correctly detected spill regions beyond the annotated contour are penalized as false positives.

CIMAT shows the strongest absolute performance (F1 0.879, IoU 0.785), possibly due to differences in preprocessing, acquisition mode, annotation consistency, and coarser WSM resolution, which may reduce high-frequency speckle variability.

Across all four datasets, JointLoss improves Recall, F1, and IoU over BCE, with average gains of +1.8% IoU, +1.2% F1, and +3.5% Recall, although the increased mask completeness reduces Precision in some cases.

2. Cross-Domain Evaluation

Complementary cross-domain experiments were conducted to assess how the adapted Swin-B + UPerNet model behaves when transferred across datasets and sensors. These experiments are not intended to establish a fully optimized domain adaptation strategy, but rather to identify the main factors affecting transferability in SAR oil spill segmentation.

Table 3 summarizes the transfer results for both loss configurations, reporting F1 and IoU when training on one dataset and testing on others.

Table 3. Cross-domain evaluation: F1 / IoU. Rows = training set; columns = test set. (a) BCE loss; (b) JointLoss.

(a) BCE

Train \ Test	CIMAT	MKLab	PALSAR	S1
CIMAT	–	0.3040 / 0.1792	0.3262 / 0.1949	0.7267 / 0.5707
MKLab	0.1174 / 0.0624	–	0.6811 / 0.5164	0.3589 / 0.2187
PALSAR	0.3148 / 0.1868	0.5209 / 0.3521	–	0.8199 / 0.6947
S1	0.1888 / 0.1042	0.5142 / 0.3461	0.7699 / 0.6259	–

(b) JointLoss

Train \ Test	CIMAT	MKLab	PALSAR	S1
CIMAT	–	0.3139 / 0.1862	0.5260 / 0.3569	0.7066 / 0.5463
MKLab	0.0550 / 0.0283	–	0.6598 / 0.4923	0.3024 / 0.1781
PALSAR	0.5218 / 0.3530	0.5218 / 0.3530	–	0.8082 / 0.6781
S1	0.2243 / 0.1263	0.5331 / 0.3634	0.7777 / 0.6362	–

Key findings:

Transfers involving the two SOS subsets show the highest out-of-domain robustness. PALSAR→S1 achieves F1=0.808, while S1→PALSAR yields F1=0.778, suggesting that annotation consistency and related acquisition contexts facilitate cross-band transfer.

Band alignment does not guarantee optimal transfer: PALSAR→S1 (L→C, F1=0.808) outperforms CIMAT→S1 (C→C, F1=0.707), indicating that annotation consistency, preprocessing protocol, and spill morphology may contribute more than frequency match alone.

CIMAT, as a target, exhibits limited transfer. The best result comes from PALSAR→CIMAT (F1=0.522), while MKLab→CIMAT degenerates almost completely (F1=0.055). This failure likely stems from a combination of factors: (i) CIMAT applies patch-level min-max normalization that produces a distinct intensity distribution compared to the global normalization used in MKLab; (ii) CIMAT combines two acquisition modes (IMP at 15 m and WSM at 150 m), creating intra-dataset resolution variability absent from MKLab's uniform 10 m Sentinel-1 patches; (iii) annotation conventions differ—CIMAT includes diffuse spill boundaries typical of WSM's coarser pixel spacing, while MKLab annotations follow sharper contours. These compounding mismatches render the MKLab-trained features largely uninformative for CIMAT's target domain. Compared to BCE, JointLoss improves transfer in 8 of 12 out-of-domain pairs, with average gains of +2.6 pp in F1 and +12.9 pp in Recall. The improvement is most pronounced for transfers involving CIMAT and SOS-PALSAR as source or target. However, when MKLab is used as the source, JointLoss reduces F1 across all three target datasets, suggesting that the increased Recall-driven component of the compound loss amplifies prediction noise when the source-domain features are already poorly matched to the target distribution.

3. Qualitative Analysis

Figure 3 shows representative segmentation examples from SOS-PALSAR, comparing BCE and JointLoss predictions against ground truth. JointLoss produces more continuous masks, filling thin or interrupted regions without requiring overly sharp boundaries—a behavior consistent with the quantitative Recall improvement and physically plausible given the gradual transitions observed in weathered spills. Although visual differences between BCE and JointLoss predictions may appear subtle at display scale, they are operationally significant. At PALSAR's 12.5 m pixel spacing, even a few recovered pixels along spill boundaries correspond to tens of meters of additional detected coverage. The quantitative improvements reported in Table 2 (+3.9 pp Recall, +1.6 pp IoU) confirm that these subtle spatial differences translate into measurable segmentation gains. Similar qualitative patterns were observed on the CIMAT dataset, where JointLoss improved boundary delineation in coarser WSM imagery.

In both datasets, JointLoss is most beneficial for elongated, thin spills where BCE alone produces fragmented predictions with isolated positive pixels that are spatially inconsistent.

V. DISCUSSION

The results demonstrate the effectiveness of Swin-B + UPerNet for SAR oil spill segmentation across diverse sensor configurations:

Architecture suitability: The Swin Transformer's hierarchical shifted-window attention captures both local texture patterns and global spatial structure of oil slicks. Unlike standard CNNs, cross-window connections enable coherent segmentation of large, irregularly shaped spills without requiring explicit multi-scale input pipelines. Loss function design: JointLoss consistently improves Recall, F1, and IoU across all datasets, sometimes at the cost of lower Precision. The +3.5% average Recall gain is critical for operational monitoring, where underestimating the extent of a spill can have severe environmental consequences. Multi-sensor stability: The model achieves competitive results across all four datasets without any architecture modifications between sensors, confirming that large-scale pretraining with filter-averaging adaptation supports stable performance across C-band and L-band SAR with different resolutions and polarizations. Cross-domain insights: The transfer patterns suggest that preprocessing consistency, annotation quality, and spatial-resolution alignment are important contributors to the observed domain gap, whereas frequency-band matching alone is insufficient to explain cross-domain performance. Domain adaptation remains a promising direction for future work.

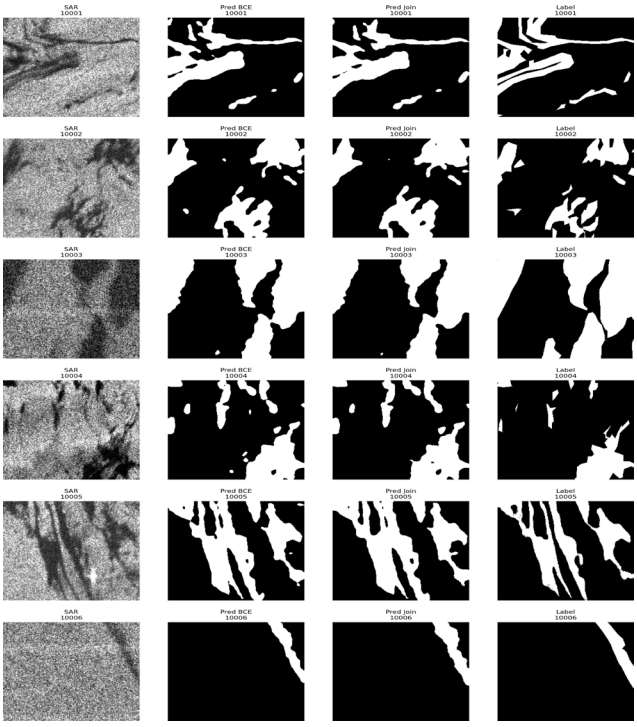

Figure 3. Segmentation examples on SOS-PALSAR (L-band, HH). Each row shows: SAR image, BCE prediction, JointLoss prediction, and ground truth (GT). JointLoss produces more complete masks with fewer fragmented regions.

VI. CONCLUSION

This work demonstrated that the Swin Transformer (Swin-B), coupled with UPerNet and adapted to single-channel SAR input, is an effective and versatile architecture for oil-spill semantic segmentation. The hierarchical shifted-window attention mechanism captures both local texture patterns and long-range spatial dependencies inherent to oil slick morphology, achieving competitive performance compared with published CNN and hybrid CNN–Transformer baselines where available.

The compound JointLoss (BCE + Dice + SSIM) consistently improves segmentation quality, with average gains of +1.8% IoU,

+1.2% F1, and +3.5% Recall over standard BCE training. The Recall improvement is particularly relevant for operational monitoring, where detecting the full extent of a spill takes priority over minimizing false positives. The combination of overlap-based and structural loss components is particularly beneficial for elongated, weathered, or fragmented spills, for which BCE alone tends to produce discontinuous masks. The model was rigorously validated across four datasets spanning C-band (Sentinel-1, ENVISAT-ASAR) and L-band (ALOS-PALSAR), with resolutions ranging from 5 m to 150 m and two polarization modes (VV, HH). This multi-sensor evaluation confirms the stability of the proposed approach under diverse acquisition conditions. Complementary cross-domain experiments suggest that differences in radiometric normalization, inconsistencies in annotation protocols, and resolution mismatches are important contributors to the observed domain gap. Several limitations should be acknowledged. First, because all evaluated patches contain at least one oil-spill pixel, the study does not quantify scene-level false alarm rates on entirely oil-free images or on scenes composed exclusively of look-alike phenomena (biogenic slicks, low-wind zones, rain cells). Operational deployment requires measuring specifically these conditions to ensure the model does not trigger excessive false positives in routine surveillance. Second, the reported baseline comparisons rely on results from the original publications rather than reproduction under identical experimental conditions, so performance differences should be interpreted with appropriate caution. Third, the loss weights were selected via a limited grid search without a full sensitivity analysis. Future work includes: (1) domain adaptation and fine-tuning strategies to improve cross-sensor transfer with minimal target labels, including recent foundation-model approaches such as the Segment Anything Model (SAM) adapted for remote sensing [15] and domain-adaptation frameworks for SAR imagery; (2) standardized radiometric normalization based on calibrated sigma-nought values; (3) evaluation of lightweight variants (Swin-T, SegFormer-B0) for resource-constrained deployment; (4) a comprehensive multi-model benchmark under the same multi-sensor protocol to establish standardized evaluation practices; and (5) systematic evaluation on oil-free and look-alike-only scenes to quantify operational false alarm rates.

Abstract
Text classification is a fundamental task in natural language processing, with applications including sentiment analysis, spam detection, and information retrieval. Deploying these systems in real-world application scenarios requires not only accuracy but also efficiency and the preservation of privacy. Centralized training of large language model-based approaches poses significant challenges related to data privacy, communication overhead, and inference latency. This paper investigates the use of fine-tuned small language models for text classification in federated learning environments. We propose FedSLM, a novel federated framework that combines small language models with parameter-efficient fine-tuning via LoRA (Low-Rank Adaptation). Our experiments on three benchmark datasets show that the proposed framework achieves an average accuracy of 91.85% while reducing the amount of data transmitted per communication round by more than 75 times. These results demonstrate that the proposed framework is an effective solution that balances accuracy, privacy protection, and resource efficiency, making it well-suited for federated learning systems in resource-constrained environments. The source code is publicly available at https://github.com/NguyenNhatThienQNU/FedSLM.

Keywords: Federated Learning, Small Language Models, LoRA, Parameter-Efficient Fine-Tuning, Text Classification.

I. INTRODUCTION

Text classification is a fundamental task in natural language processing (NLP), powering applications from sentiment analysis to news categorization and content moderation [1]. In these applications, the text is generated on users' own devices and carries sensitive information, so it cannot be freely collected on a central server for training. This has motivated the development of federated learning (FL) [2], a distributed paradigm that enables model training across clients without transferring raw data to a central server, thereby preserving privacy while supporting large-scale learning. According to the modern approach, FL has achieved impressive performance through large-scale language models [3]. However, the deployment process introduces challenges in computational cost and inference latency. Consequently, recent research has turned to small language models (SLMs) [4], [5], which retain much of the accuracy of larger models while being far lighter and deployable on constrained hardware. In this paper, we investigate whether such SLMs can support accurate text classification within FL while keeping communication and computation low. To adapt an SLM without the cost of full fine-tuning, we employ parameter-efficient fine-tuning (PEFT). In particular, LoRA [6] freezes the backbone and trains only a small set of low-rank matrices, so that each client exchanges just these matrices and the classification head rather than the entire model. To the best of our knowledge, this is among the first works to jointly exploit SLMs and LoRA for text classification in a federated, resource-constrained setting. The main contributions of this work are summarized as follows:

1. We propose FedSLM, a novel federated framework that combines SLMs with LoRA for text classification, where each client fine-tunes and transmits only the LoRA parameters and the classification head instead of the full backbone.
2. We investigate the effectiveness of the PEFT methods to reduce the computational cost while maintaining a competitive model performance.
3. We evaluate the proposed method on three benchmarks under a non-IID federated setting, comparing it with classical machine learning, centralized training, and a larger language model fully fine-tuned under federated learning, and analyze the trade-offs among classification accuracy, communication cost, and resource efficiency.
4. We demonstrate the potential of SLMs for federated text classification in resource-constrained environments.

The rest of the paper is organized as follows. Section II reviews some related work. Section III formalizes the problem and details the proposed method. Section IV presents the experimental setup and results. Finally, Section V concludes and outlines future work.

II. RELATED WORK

Text classification has evolved from early machine learning methods to deep neural architectures. Convolutional models for sentence-level and character-level classification [1] provided strong early baselines, and the Transformer architecture [7] later reshaped the field. Pre-trained models such as BERT [8] and RoBERTa [9] became the de facto backbone for text classification by learning contextualized representations. These models, however, are typically trained in a centralized manner, storing all data on a single server, which raises data privacy concerns and hinders deployment across distributed devices. To address the aforementioned concerns, FL [2] shifted the paradigm from centralized training toward collaborative on-device learning, in which raw data never leaves the client. Building on FedAvg, optimization methods such as FedProx [10] improved convergence under non-IID data, while general frameworks such as Flower [11] and benchmarks such as FedNLP [12] extended FL to a range of NLP tasks [13]. Applying FL to large language models (LLMs), however, reintroduces heavy computation and per-round communication [3], thereby limiting their use in resource-constrained environments. In recent years, SLMs have emerged as a potential alternative to large models due to their low inference latency and cost-effectiveness [14], [15]. Distilled models such as DistilBERT [5] and TinyBERT [16] retain competitive accuracy within a compact parameter space [4], and remain effective even in industrial text classification settings [17]. Nevertheless, fully fine-tuning an SLM on every client still incurs substantial computation and communication in each federated round, and aggressively compressed models may sacrifice representational capacity. At the same time, PEFT offers a complementary approach to reducing this cost by updating only a small subset of parameters. Adapter-based tuning [18], notably LoRA [6], has become a standard PEFT technique [19]. Several studies have introduced LoRA into the federated setting, such as FedEx-LoRA [20] and FLoRA [21], to reduce communication overhead. A trend documented in recent surveys [22] and extended to multilingual modeling by FedLFC [23]. These efforts, however, largely target LLMs or text-generation tasks, leaving the joint use of SLMs and LoRA for federated text classification underexplored. This paper builds upon these advancements by integrating SLMs with LoRA to bridge the gap between resource efficiency and classification accuracy in resource-constrained federated environments.

III. PROPOSED METHOD

This section presents the proposed FedSLM framework. We first formalize the problem and describe the overall architecture. Then we introduce the framework's main components: the SLM backbone, the resource-efficient LoRA-based fine-tuning strategy, and the FedAvg-based federated optimization mechanism.

1. Problem Definition

Federated text classification is defined as the process of training a global classification model from data distributed across multiple clients without sharing their local data. Assume a system of K clients, where the k-th client holds a llocal dataset D_k = { (x_i, y_i) }, in which x_i is the input text and y_i e corresponding label. The objective is to find the model parameters θ that are optimal over the entire distributed dataset:

$$\min_{\theta} F(\theta) = \sum_{k=1}^{K} \frac{n_k}{N} F_k(\theta), \tag{1}$$

Here, $F_k(\theta)$I have the local loss function of the $k$the client, n_k is the number of samples on that client, and $N = \sum_{k=1}^{K} n_k$ is the total number of samples across the whole system [2].

The problem addressed here is to design an FL method that maintains text classification effectiveness while reducing computational and communication costs under heterogeneous data.

2. System Architecture

Figure 1 illustrates the overall architecture of FedSLM for text classification in the FL setting. The system comprises three main components. At the top is the central server, which hosts the global model comprising the SLM backbone, the LoRA parameters, and the classification head. In the middle are K clients, each holding its own text dataset and performing local LoRA fine-tuning. At the bottom is the FedAvg module, which receives parameters from clients to update the global model.

The dataset of the client k is denoted by the uppercase D subscript k, where n_k n_k is the number of samples on the client. The data D_k is stored entirely on the local device and is never transmitted to the server. The workflow consists of five steps:

1. The server initializes the global model, comprising the SLM backbone, LoRA, and the classification head.
2. The server sends the global LoRA parameters and classification head to the K clients.
3. Each client keeps the backbone frozen and fine-tunes LoRA and the classification head on its own data.
4. Each client sends the updated LoRA parameters, the updated classification head, and its sample count n_k to the server.
5. The server aggregates the received parameters with FedAvg to form a new global model.

Step 1 is performed only once before training begins. Thereafter, steps 2–5 are repeated over the communication rounds until the model converges or the maximum number of rounds is reached.

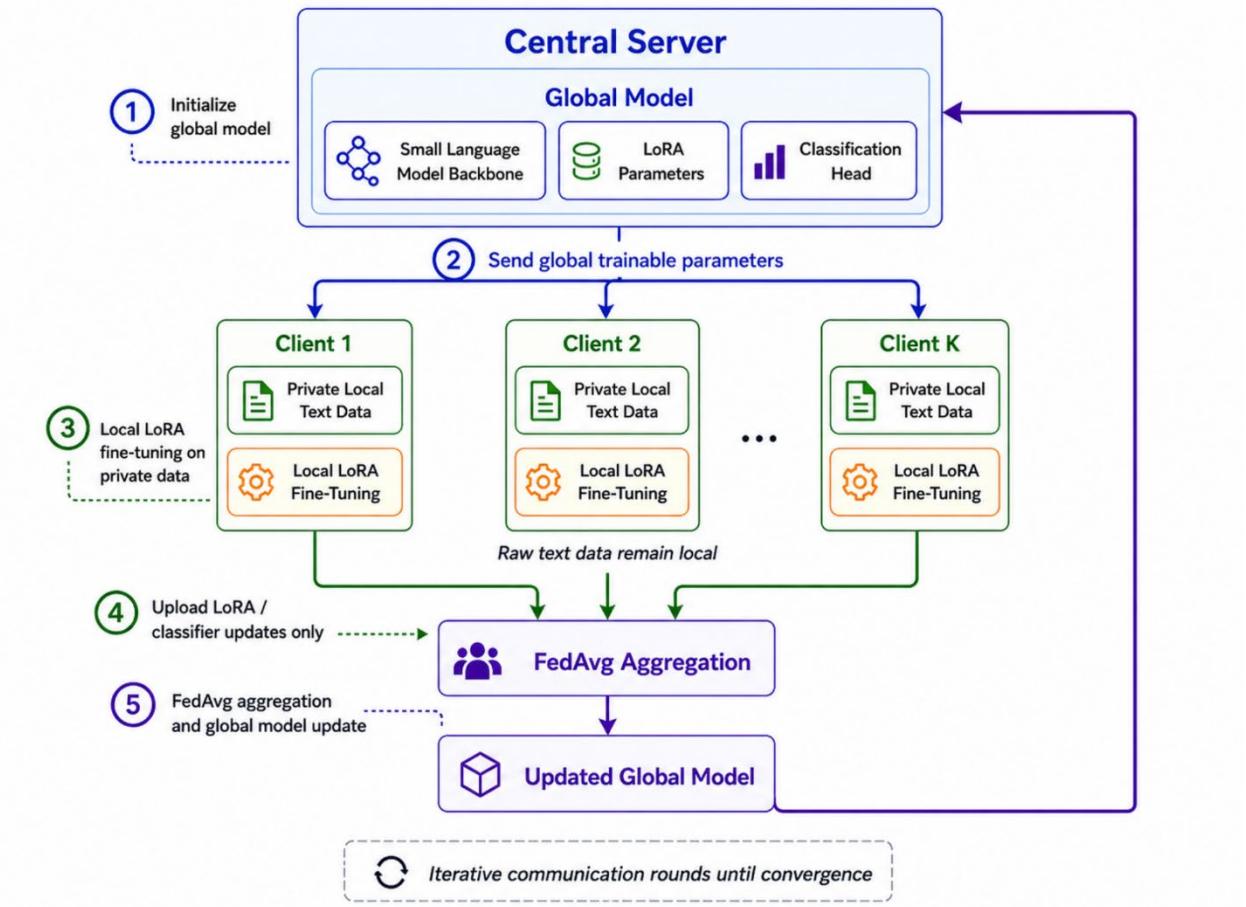

Figure 1. Overall workflow of the FedSLM framework.

3. Small Language Model Backbone

The SLM backbone is the central component of FedSLM, responsible for encoding the input text and producing the semantic representation used for classification. LoRA does not replace the backbone; instead, it adds low-rank updates to the targeted attention projections. The classification head then uses the representation of the [CLS] token to predict the label. In this study, DistilBERT [5] is chosen as the backbone. This model is smaller than BERT-base and is well-suited to clients in resource-constrained environments.

At step 1, the serout ×s the pre-trained weight set W_alt.W_b of the backbone. These weights are frozen throughout training. The server simultaneously attaches LoRA to the targeted attention projections and initializes a linear classification head. For the $j$the attention projection, with weights $W_{b,j} \in \mathbb{R}^{d_{\text{out}} \times d_{\text{in}}}$, LoRA introduces two low-rank matrices:

$$A_j^{(0)} \in \mathbb{R}^{r \times d_{\text{in}}},\ B_j^{(0)} \in \mathbb{R}^{d_{\text{out}} \times r},\ r \ll \min(d_{\text{in}}, d_{\text{out}}). \tag{2}$$

classificaon head is denoted by (W_c, b_c), where $W_c \in \mathbb{R}^{C \times d}$ and $b_c \in \mathbb{R}^C$. Here, d is the representation size of the backbone and $C = |Y|$ is the number of classes. The global model at round t is represented as $M^{(t)} = \{W_b, \theta_L^{(t)}, \theta_c^{(t)}\}$, where $\theta_L^{(t)} = \{A_j^{(t)}, B_j^{(t)}\}_{j \in J}$ is the full set of LoRA parameters at the targeted attention

modules, and $\theta_c^{(t)} = \{W_c^{(t)}, b_c^{(t)}\}$ is the classification-head parameter set. The trainable global parameter set is denoted by $\theta^{(t)} = \{\theta_L^{(t)}, \theta_c^{(t)}\}$.

The backbone $is\ installed\ on\ or\ distributed\ to$the clients once before training begins. At step 2 of round t, the server sends only $\theta^{(t)} = \{A^{(t)}, B^{(t)}, W_c^{(t)}, b_c^{(t)}\}$ to each client $k = 1, \dots, K$. Since all clients use the same frozen backbone, W_b need not be retransmitted in each communication round.

4. Resource-Efficient Fine-Tuning

After receiving $\theta^{(t)}$, client k initializes its local parameter set $\theta_k^{(t,0)} = \theta^{(t)}$. The client combines these parameters with its local copy of the backbone to carry out step 3. LoRA is inserted directly into the backbone's attention projections and participates in producing the semantic representation. For the j The projection at client k, LoRA produces the update

$$\Delta W_{j,k} = \frac{\alpha_{\text{LoRA}}}{r} B_{j,k} A_{j,k}, \qquad W_{j,k} = W_{b,j} + \Delta W_{j,k}, \tag{3}$$

where r is the simge are $W_{b,j}$ remain unchanged; only the two matrices $A_{j,k}$ and $B_{j,k}$ are updated.

For each sample $x_i^{(k)}$, the client produces the semantic representation

$$h_i^{(k)} = \text{Encoder}_{\text{SLM}}\left(x_i^{(k)}; W_b, \theta_{L,k}\right).$$

The representation of the [CLS] token is fed into the local classification head. The logit vector and the predicted probability distribution are computed as

$$z_i^{(k)} = W_{c,k}\, h_{i,[\text{CLS}]}^{(k)} + b_{c,k}, \qquad \hat{p}_i^{(k)} = \text{Softmax}\left(z_i^{(k)}\right). \tag{4}$$

Client k minimizes the cross-entropy loss

$$F_k(\theta_k) = -\frac{1}{n_k} \sum_{i=1}^{n_k} \sum_{c=1}^{C} \mathbf{1}\left[y_i^{(k)} = c\right] \log \hat{p}_{i,c}^{(k)}, \tag{5}$$

where $\hat{p}_{i,c}^{(k)}$ is the probability that sample i belongs to class c, and $\mathbf{1}[\cdot]$ is the indicator function.

AdamW is used to update the LoRA matrices $A_{j,k}, B_{j,k}$ and the classification-head parameters $W_{c,k}, b_{c,k}$. Gradients are not propagated to W_b, so the backbone remains unchanged throughout local training. After E local epochs, client k obtains

$$\theta_k^{(t,E)} = \{A_k^{(t,E)}, B_k^{(t,E)}, W_{c,k}^{(t,E)}, b_{c,k}^{(t,E)}\}.$$

At step 4, each client sends $\theta_k^{(t,E)}$ together with its sample count n_k to the central server. In Figure 1, the term “updates” refers to the LoRA and classification-head parameters that have been updated after local training. The text data D_k and the backbone W_b are not transmitted in this step.

5. Federated Optimization Strategy

Following step 4, the central server receives, from the K clients, the LoRA matrices, the classification-head parameters, and the sample counts $\{\left(\theta_1^{(t,E)}, n_1\right), \ldots, \left(\theta_K^{(t,E)}, n_K\right)\}$. After collecting all parameters, the server performs step 5 by applying FedAvg [2]:

$$\theta^{(t+1)} = \sum_{k=1}^{K} \frac{n_k}{N} \theta_k^{(t,E)}, \qquad N = \sum_{k=1}^{K} n_k. \tag{6}$$

FedAvg is applied element-wise to the tensors $A_k, B_k, W_{c,k}$, and $b_{c,k}$. Clients with more data samples receive a larger contribution weight. The backbone W_b is neither uploaded nor aggregated, since it is frozen and identical across all clients.

After aggregation, the server obtains $\theta^{(t+1)} = \{A^{(t+1)}, B^{(t+1)}, W_c^{(t+1)}, b_c^{(t+1)}\}$. This parameter set is combined with the frozen backbone to form the updated global model $M^{(t+1)} = \{W_b, \theta^{(t+1)}\}$. In the next round, the server distributes $\theta^{(t+1)}$ to the clients at step 2. The distribution, local training, parameter upload, and aggregation are repeated until the validation loss no longer improves; communication rounds are reached.

IV. EXPERIMENTS

1. Experimental Setup

Datasets. To evaluate the generalization ability of the proposed method, we use three benchmark datasets: AG News [1], IMDB [24], and SST-2 [25]. These datasets cover both binary and multi-class classification, and include both sentence-level and document-level text, enabling us to assess the effectiveness of FedSLM across a range of text classification scenarios. Table 1 summarizes their statistics.

Table 1. Statistics of the benchmark datasets.

Dataset	Task	Classes	Train	Test
AG News	News topic classification	4	120,000	7,600
IMDB	Movie review sentiment classification	2	25,000	25,000
SST-2	Sentence sentiment classification	2	67,349	1,821

To simulate a realistic FL environment, the training set of each dataset is partitioned across 5 clients using a Dirichlet distribution with concentration parameter alpha = 0.5.. This setting produces a moderately non-IID scenario that reflects a common characteristic of FL systems, in which the data distribution across clients is heterogeneous but not overly imbalanced. In each communication round, the server distributes the global model to all clients. Each client performs one local training epoch on its own data following the procedure described in Section III. After training, only the LoRA parameters and the classification layers are sent back to the server for aggregation via FedAvg. At the same time, all text data is always stored locally on each client.

Baselines. To evaluate the effectiveness of FedSLM, we compare the proposed method against baselines that represent common approaches to text classification and FL. The baselines are divided into three groups:

- *Centralized SLM training.* DistilBERT [5] trained on centralized data with LoRA. This group is used to assess the impact of FL on classification effectiveness.
- *A larger language model under federated learning.* BERT-base [8] with full fine-tuning, an FL baseline with a larger backbone, used to compare classification effectiveness and communication cost against FedSLM.
- *Classical machine learning.* SVM with TF-IDF, which serves as a traditional machine learning baseline for text classification.

Evaluation Metrics. To assess both the prediction quality and the operating cost of the FL system, the metrics are divided into two groups: classification performance and resource efficiency. On all three datasets, the model is evaluated using accuracy (Acc) and macro-F1, which are regular evaluation metrics for text classification and information retrieval problems. The communication cost is determined by the size of the updated parameter set $|\Delta\theta|$, the number of clients K, and the number of communication rounds T:

$$C_{\text{total}} = 2 \times T \times K \times |\Delta\theta|. \quad (7)$$

In addition, we report the number of trainable parameters per client and the total training time, measured as the wall-clock time of a communication round.

Implementation Details. Each dataset is partitioned across 5 clients using a Dirichlet distribution (alpha =. 5). The system uses FedAvg for up to 20 communication rounds; each client performs one local epoch per round. DistilBERT is used as the SLM bbackbone LoRA is applied to the attention projections with $r = 8$, $\alpha_{\text{LoRA}} = 16$, and a dropout of 0.1. The model uses AdamW with early stopping at a patience of 3. The framework is implemented in Python with PyTorch, Hugging Face Transformers, and PEFT on Google Colab with a single NVIDIA T4 16 GB GPU. The same training program is used for both the centralized and the federated models to ensure a fair comparison.

V. RESULTS

Overall Performance. Table 2 compares our FedSLM against three groups of baselines:

- *Comparison with classical machine learning methods.* FedSLM outperforms the best classical machine learning method on all three datasets. The accuracy improvements are 8.83 points on SST-2, 0.85 points on IMDB, and 1.90 points on AG News. On average, the proposed method achieves 3.86 points higher accuracy and 3.89 points higher macro-F1. This result indicates that the Transformer encoder exploits contextual information more effectively than TF-IDF lexical features, especially for the short sentences in SST-2.
- *Comparison with centrally trained SLM.* FedSLM achieves 1.49 points higher on SST-2 and 0.26 points higher on IMDB, while being only 0.39 points lower on AG News. On average, FedSLM achieves 0.45 points higher accuracy and 0.47 points higher macro-F1 than the centralized model. This shows that moving to FL does not reduce the average performance, while the raw text data remains stored on the clients.
- *Comparison with a larger language model under federated learning.* The federated BERT-base with full fine-tuning achieves the highest average results, with 92.95% accuracy and 92.96% macro-F1. FedSLM achieves 91.85% and 91.86%, respectively, which is 1.10 points lower on both metrics. The gap on AG News is only 0.06 points on both metrics. Although BERT-base retains a performance advantage, the proposed method comes fairly close to the larger model at a substantially lower resource cost.

Table 2. Classification performance across three datasets.

Models	Setting	Tuning	Dataset	Acc (%)	Macro-F1 (%)
SVM	Classical	–	SST-2	81.65	81.60
			IMDB	90.09	90.09
			AG News	92.24	92.23
DistilBERT	Centralized	LoRA	SST-2	88.99	88.97
			IMDB	90.68	90.68
			AG News	94.53	94.50
DistilBERT	Federated	Full	SST-2	90.37	90.37
			IMDB	90.55	90.55
			AG News	94.09	94.10
BERT-base	Federated	Full	SST-2	93.00	93.00
			IMDB	91.66	91.66
			AG News	94.20	94.21
Ours (FedSLM)	Federated	LoRA	SST-2	90.48	90.48
			IMDB	90.94	90.94
			AG News	94.14	94.15

Resource Efficiency. Table 3 compares the number of trainable parameters and the update size of the three main FL configurations.

FedSLM updates only about 0.89 million parameters, corresponding to about 1.32% of the model's total parameters. Compared with the federated DistilBERT with full fine-tuning, the proposed method reduces the number of trainable parameters by about 98.67% and the update size by about 75×. Compared with the federated BERT-base with full fine-tuning, the number of updated parameters is reduced by about 99.19%, while the update size is reduced by about 123×. Although the average accuracy and macro-F1 are only 1.10 points lower than those of BERT-base, the proposed method requires exchanging only about 3.38 MB of parameters per round.

Training time requires more careful reading, as early stopping allows each configuration to run for a different number of rounds. Measured *per round*, FedSLM is the cheapest of the three federated configurations on every dataset: 82.4 s against 125.9 s for full fine-tuning of the same DistilBERT and 374.2 s for BERT-base on SST-2, 205.1 s against 232.0 s and 480.9 s on IMDB, and 294.7 s against 344.9 s and 898.5 s on AG News. Its higher *total* on IMDb (3691.9 s against 1856.2 s) therefore reflects convergence speed rather than per-round cost. By optimizing far fewer parameters, LoRA needed 18 rounds to reach its best checkpoint, compared to 8 for full fine-tuning. Compared with the federated BERT-base, FedSLM is faster overall on all three datasets. The advantage of LoRA thus lies in the number of updated parameters, the communication cost, and the per-

round compute, rather than in the total time to convergence. Overall, FedSLM achieves a suitable balance between classification performance and resource efficiency, indicating its potential for deployment in environments with limited memory and bandwidth.

Table 3. Comparison of resource efficiency.

Models	Setting	Tuning	Trainable params	Trained ratio	Update size	Training time (s)		
						SST-2	IMDB	AG News
DistilBERT	Federated	Full	66.96 M	100%	≈255.41 MB	503.4	1,856.2	3,449.5
BERT-base	Federated	Full	109.48 M	100%	≈417.65 MB	2,245.0	4,809.2	8,086.9
Ours (FedSLM)	Federated	LoRA	≈0.89 M	≈1.32%	≈3.38 MB	576.7	3,691.9	3,536.4

2. Discussion

The results show that FedSLM does not merely aim for the highest accuracy but also balances performance, privacy, and resource cost.

- *Trade-off among performance, privacy, and efficiency.* The proposed method achieves accuracy of 90.48%, 90.94%, and 94.14% on SST-2, IMDB, and AG News, respectively. Compared with the federated BERT-base with full fine-tuning, the largest drop is only 2.52 percentage points, while the number of parameters to be trained is reduced from 109.48 million to 0.89 million. The communication size per client in one round is also reduced from 417.65 MB to 3.38 MB. Notably, LoRA achieves results equal to or slightly better than those of the federated DistilBERT with full fine-tuning across all three datasets, showing that updating the entire model is unnecessary in the FL context. At the same time, the raw text data always remains stored locally, and only the LoRA parameters and the classifier are exchanged. However, this mechanism only provides privacy protection at the structural level; techniques such as differential privacy and secure aggregation still need to be added to defend against inference attacks based on the model updates.
- *Implications for real-world deployment.* With its small update size and low number of trainable parameters, FedSLM is well-suited to resource-constrained environments such as edge devices, mobile phones, and internal systems that handle sensitive data. The method can be applied to customer-feedback analysis, news classification, and the education, healthcare, and finance domains, where data cannot be centralized on a single server. Nevertheless, the current experiments are simulated using only five clients on an NVIDIA T4 GPU. Therefore, further evaluation on real devices, with a larger number of clients, and under unstable network conditions is needed before large-scale deployment.

VI. CONCLUSION

In this study, we proposed FedSLM, a novel framework that combines SLMs, LoRA, and FedAvg for federated text classification in resource-constrained environments. The framework freezes the backbone, updates only the LoRA parameters and the classification head, and then aggregates the updates on the server. The method was evaluated on three benchmark datasets with non-IID data distributed across five clients. It was compared against traditional machine learning methods, centralized training, and full fine-tuning in the FL setting. The experimental results confirm that combining SLMs with LoRA can maintain competitive classification performance without updating the entire model. This indicates that choosing the right parameters to fine-tune matters more than increasing model size, and shows that FedSLM achieves an effective balance among classification quality, data privacy, and resource cost. In doing so, the method opens up the possibility of deploying federated NLP systems on edge devices and in domains involving sensitive data.

In the future, we will extend the experiments to a larger number of clients, higher degrees of data heterogeneity, and realistic conditions such as heterogeneous devices, disconnections, or partial participation. Secure aggregation and differential privacy mechanisms will be integrated to strengthen security and robustness. In addition, we plan to multitask and use multilingual backbones, specialized adapters, and a suitable adapter-selection mechanism in multilingual settings.

ACKNOWLEDGEMENT

This research is conducted within the framework of science and technology projects at the institutional level of Quy Nhon University, Vietnam, under the project code T2026.923.07.

Abstract

Ride-hailing drivers frequently need to finish a working session at a specific location — an airport, a garage, their home district — and offers that pull them away from it waste driving time. This paper presents Smart Route, a microservice developed at Bitaksi, a Turkish ride-hailing platform, that ranks candidate trips for drivers who have declared a target destination. It builds a spatial corridor with Yen's k-shortest-path algorithm over an OpenStreetMap-derived road graph of Istanbul, discretizes the paths into a buffered set of hexagonal H3 cells held in an in-memory store for constant-time membership tests, and assesses drop-offs with three interpretable conditions: corridor membership, forward progress, and a bounded relative detour from a hybrid of Haversine and road-graph distances. A Datalog rule engine mirrors the policy in shadow mode. We evaluate the service offline on 200 driver–destination scenarios and 4,000 candidate trips against a ground truth that computes every leg on the road network. The ranking comes close to it: the trip puts first costs the driver 6.7 extra minutes on average, against 5.9 for the exact computation, 15.6 with no destination awareness, and 95 percent of those trips are genuinely acceptable. The measurements also corrected the shipped configuration: Yen's alternative paths add no corridor cells, and the deployed cell resolution rejected 49 percent of acceptable trips, so the rollout uses one path and a coarser, wider corridor that retains 96 percent of them. Evaluation takes 2.8 milliseconds with a warm distance cache and 159 milliseconds without.

Keywords: ride-hailing, smart mobility, spatial indexing, graph databases, k-shortest paths, microservices, declarative rule engines

I. INTRODUCTION

Ride-hailing platforms match millions of passenger requests per day to nearby drivers. Most dispatching research optimizes platform-level efficiency, but a driver who repeatedly receives offers that conflict with personal constraints may go offline. One common constraint is the desire to end a session near a chosen place, and commercial platforms expose this through destination modes, in which the driver specifies a target and the platform is expected to prefer trips that progress towards it. Deciding whether a trip moves a driver towards a destination is difficult when geography constrains movement. In Istanbul, the Bosphorus divides the city between two continents, and a few bridges and one tunnel join it, so a drop-off close to the destination, in straight-line distance, can be half an hour's drive away. Over our sampled origin–destination pairs, the road distance exceeds the straight line by a median of 24 percent, and the cost of ignoring this is measurable: a straight-line destination-distance test accepts 37 percent of the trips a road-network computation rejects, and 33 percent on cross-continental pairs, where the error is a whole bridge crossing. This paper is a practical experience report on Smart Route, a microservice built at Bitaksi, a ride-hailing platform in Turkey, that answers two questions for a destination-bound driver: whether an offered trip is compatible with the declared destination and which of

several candidates best serves the driver. The constituent techniques are established, and we claim no new algorithm; the contribution is a composition that runs under production constraints, whose accuracy–cost trade-off is measured rather than asserted, and whose harness and scenario set are released with the service. The contributions are the following.

- A corridor-based destination-awareness model combining Yen's k-shortest-path algorithm with hexagonal spatial indexing, so that corridor membership is a constant-time test and a full evaluation adds at most one shortest-path query, with the accuracy this costs measured against an exact computation.
- A hybrid distance strategy that reserves graph queries for the long legs of the detour, with the direction and size of the resulting bias measured per leg.
- An interpretable composite scoring function that filters trips and totally orders sets of them, with a formal condition (Proposition 1) under which no rejected trip outranks an accepted one.
- A declarative rule engine mirroring the imperative logic in Datalog in shadow mode, and a path from the hand-set threshold to a learned one, with the stages at which it can be validated safely.
- An offline evaluation against four baselines and an all-road-network ground truth, covering decision quality, driver benefit, latency under load, and parameter sensitivity, which changed the corridor parameters and the ranking penalties.

Section II reviews related work, Section III formalizes the problem and states Proposition 1, Section IV describes the methodology, Section V describes the experimental setup, Section VI describes the results, Section VII describes the limitations, and Section VIII concludes.

II. RELATED WORK

Order dispatching has been studied extensively as an optimization and learning problem: Zhang et al. proposed a combinatorial model across many driver–order pairs [1], Xu et al. described a production learning-and-planning approach [2], and surveys catalog the field [3]. These methods optimize platform-level objectives and treat the driver as direction-indifferent. A growing line of work instead treats driver preferences as first-class objectives, balancing passenger fairness against driver preferences in a learned policy [4], and stated-preference studies show that a trip's direction and detour are among the attributes drivers weigh when accepting a trip [5]. Matching trips that lie on a traveler's way is also the core of ridesharing, where surveys cover the case of a driver with an origin–destination pair of their own [6], and Pan and Li prune candidates geometrically before any shortest-path computation [7]. Smart Route differs in where the preference comes from — the driver states it explicitly, once per session — and in discretizing the corridor into a hexagonal grid, a looser bound in exchange for a constant-time test any stateless replica can serve. To our knowledge, no peer-reviewed study has evaluated destination-mode dispatch itself, which is documented only in platform engineering materials [8]. Discrete global grid systems are standard in mobility analytics. We build on H3, a hexagonal hierarchical index developed at Uber [9]; at resolution 8, a cell covers roughly 0.74 square kilometers, and because such grids distort cell area, the buffer is only approximate in meters. Road networks come from OpenStreetMap [10] via OSMnx [11]; path computation uses Dijkstra [12] and Yen's k-shortest-path algorithm [13], both in the Neo4j Graph Data Science library [14]. Unmodified k-shortest-path sets are known to overlap heavily [15], which Section VI.C confirms on this network. Finally, the rule engine draws on neurosymbolic programming: DeepProbLog integrates neural predicates into probabilistic logic programs [16], and Scallop provides a Datalog language whose provenance semirings make inference differentiable [17]. We use Scallop declaratively and exercise only its symbolic subset; because the threshold is a fact rather than a constant, it can later be learned as a parameter without changing the rule. Exact inference does not scale to production rule sizes, hence approximate methods [18], and validating a

learned rule needs off-policy evaluation [19] and an interference-aware experiment design [20]; Section IV.E returns to this.

III. PROBLEM FORMULATION

Consider a driver at x who has declared a destination D. The upstream trip-matching service periodically presents candidate trips; each trip t = (p, o) consists of a pickup point p and a drop-off point o. Let dH denote the Haversine distance between two points and dR the length of the shortest path between them in the road network. During activation, the system computes a corridor C, a set of H3 cells covering plausible driving routes from x to D. The relative detour of a trip is

$$d(t) = [d_H(x, p) + d_H(p, o) + d_R(o, D)] / d_R(x, D) - 1 \qquad (1)$$

A value of 0 means the trip lies perfectly on the way, while 1 means it doubles the distance. A trip is valid when all three of the following hold:

$$\text{valid}(t) \iff \text{h}(o) \in C \ \wedge \ d_R(o, D) < d_R(x, D) \ \wedge \ d(t) \leq \tau \quad (2)$$

where h(o) is the H3 cell containing the drop-off, and τ is an acceptance threshold, currently set to 0.5. The first condition restricts drop-offs to the corridor, the second requires forward progress along the road network, and the third bounds the extra distance the driver accepts. When several candidate trips are available, they are ranked by the composite score

$$c(t) = d(t) + \lambda_C \, I_C(t) + \lambda_F \, I_F(t) \qquad (3)$$

where IC and IF are indicator variables equal to 1 when the corridor condition and the forward-progress condition fail, respectively, and λC and λF are penalty weights; Proposition 1 fixes the condition they must satisfy. Lower scores are better. The full ranking is always returned, so the upstream service can still surface the least harmful option when no candidate satisfies all three conditions.

It is therefore worth stating when that ordering respects validity. All leg distances are non-negative, so d(t) ≥ −1, and a valid trip satisfies d(t) ≤ τ.

Proposition 1 (validity dominance). Under (3), every valid trip ranks strictly above every invalid trip, for all admissible inputs, if λC > 1 + τ and λF > 1 + τ: a failed condition then adds more than the largest gap between two detour scores in [−1, τ]. The bound is tight, since otherwise a valid trip with a detour near τ is outranked by one that fails only the corridor test, with a detour near −1. The submitted values λC = 0.5 and λF = 1.0, with τ = 0.5, do not satisfy it, and Section VI.C reports that the inversion occurs in 1.0 percent of scenarios containing both; we therefore adopt λC = λF = 1.6.

IV. METHODOLOGY

1. Service architecture

Smart Route is a standalone microservice that the trip-matching service consults before offering a trip to a destination-bound driver. The upstream service pre-filters candidates to those within a few kilometers, and Smart Route returns decisions and rankings with human-readable explanations. It is stateless per request: driver state

lives in Redis, which stores the corridor as a set of H3 cell identifiers, so a drop-off check is a single constant-time membership test, plus the destination and the road distance to it, both of which expire after 24 hours.

The road network resides in Neo4j 5 with the Graph Data Science library [14]; the service runs on Python 3.10 and FastAPI; state and caching use Redis 7; the network is built with OSMnx; the rule engine is Scallop; and a Streamlit visualizer supports validation. The Istanbul projection holds 320,805 intersections and 827,830 segments with travel-time and length weights, so pathfinding never touches disk. Dependency failures are handled at two levels: a brief interruption degrades corridor construction to a straight-line cell sequence and long legs to Haversine estimates, as quantified in Section VI.C. At the same time, a sustained outage causes the readiness signal to divert traffic away from the instance. The graph itself is built once, offline: an OpenStreetMap extract is parsed with OSMnx into a directed graph, of which only the largest strongly connected component is kept (320,805 nodes, 967,723 edges). Missing lengths are imputed using Haversine distances; per-class speed limits yield travel times; and after merging parallel edges, 827,830 relationships remain with length, travel time, road class, and one-way attributes.

2. Corridor computation

When a driver activates a destination, the service finds the nearest graph nodes to the driver and the destination by expanding a ring search over H3 cells, which is needed in sparse areas such as airport grounds. Yen's algorithm yields the k fastest paths, and the corridor is the union of the cells they traverse, dilated by a hexagonal ring buffer that absorbs GPS noise, map defects, and small deviations. The submitted version used k = 3, resolution 8, and a 2-ring buffer; Section VI.C shows the alternatives are near-duplicates and the resolution is too fine, so the rollout uses one path, resolution 7, and a 3-ring buffer. Figure 1 shows two corridors on the road network.

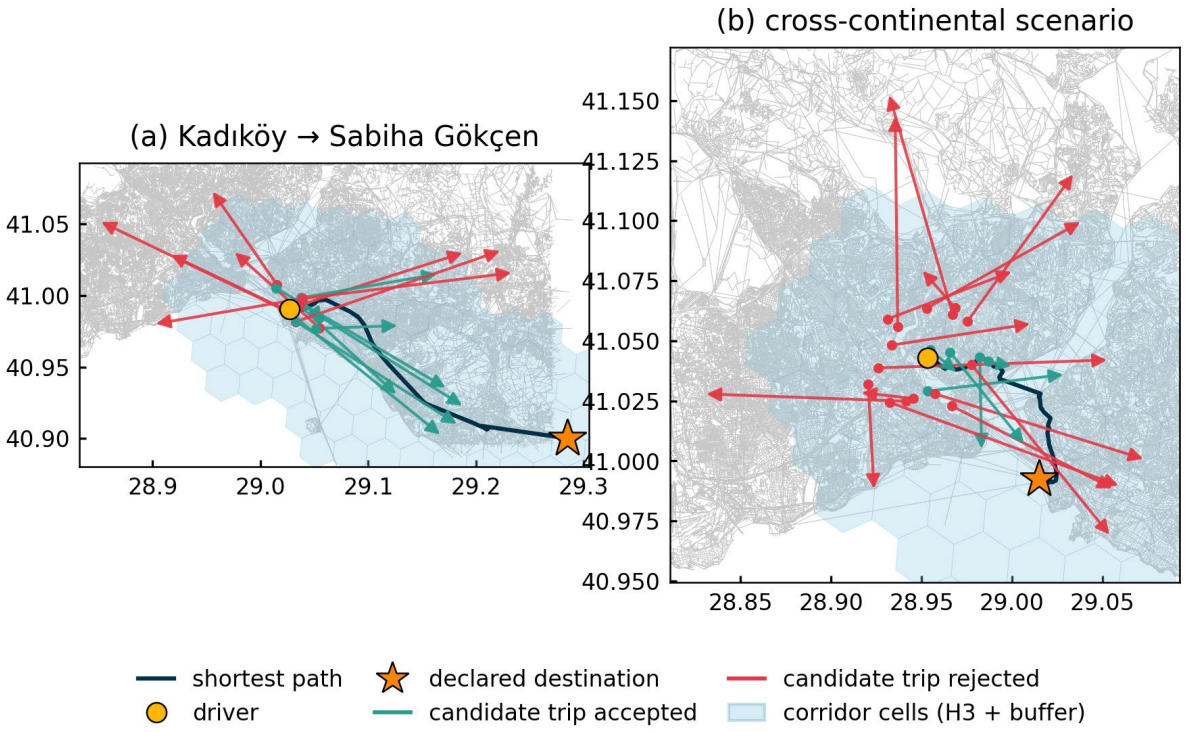

Figure 1. Corridors on the Istanbul road network, drawn with the adopted configuration (one path, resolution 7, 3-ring buffer). Left: a driver in Kadıköy bound for Sabiha Gökçen Airport; the corridor follows the motorway through Kartal, Pendik, and Kurtköy, and excludes Üsküdar in the opposite direction. Right: a cross-continental scenario, where the corridor crosses the Bosphorus only at the bridges.

3. Hybrid distance computation

The detour score of (1) mixes two distance functions deliberately. The driver-to-pickup and pickup-to-drop-off legs are short, since only nearby trips are presented, and use the closed-form Haversine formula; the drop-off-to-destination and driver-to-destination legs span tens of kilometers and are road shortest paths. The denominator is computed once at activation, and drop-off distances are cached for the cell-pair, so a full evaluation adds at most one graph query. Section VI.C shows that this approximation is optimistic rather than neutral and describes the correction it motivates.

4. Ranking and its properties

When the upstream service has several candidates for the same driver, all are scored concurrently and ordered by the composite score in (3). Each entry in the response carries the detour score, the outcome of each condition, and a textual reason, so that downstream consumers and support staff can see why a trip was preferred or rejected. The penalties are not free parameters of convenience: by Proposition 1, they determine whether the ordering is validity-dominant. Section VI.C reports the empirical inversion rate at the shipped values and the effect of adopting penalties above the bound.

5. A declarative rule engine in shadow mode

The acceptance policy in (2) is business-critical logic that a conventional implementation entangles with transport, caching, and serialization code. To keep it inspectable, Smart Route also encodes it as a Datalog program in Scallop [17], with input relations for corridor membership, forward progress, and detour score, and a single rule that derives validity; the threshold is entered as a fact, so the rule text is independent of the policy parameters. The rule engine runs in shadow mode: both implementations execute on every evaluation, the imperative result is returned, and disagreements are logged. Fifteen unit tests cover each rejection reason, the boundary case where the detour equals the threshold, degenerate geometry, and isolation between drivers. This surfaced a defect: the membership flag from the in-memory store is an integer, which the fact interface treats as distinct from a Boolean, so inputs are now explicitly coerced, after which the implementations agree on every request exercised. Two obstacles stand between this rule engine and a learned threshold. The test $d(t) \leq \tau$ is a discontinuous Boolean with no useful gradient, so during training it is replaced by a temperature-annealed soft indicator $\sigma((\tau - d(t))/T)$ whose value the provenance semiring propagates through the rule; the gradient reaches τ because τ is a fact, the hard comparison returns at inference, and exact inference at production rule sizes needs an approximate scheme [18]. The second obstacle is data: a driver never sees an offer that the filter removes, so no outcome is observed where the threshold matters, and usable labels require leaving a margin above the threshold open for a period. Validation then proceeds in stages — shadow-mode agreement, offline replay, off-policy evaluation [19], and an interference-aware online experiment [20] — before any guarded rollout.

V. EXPERIMENTAL SETUP

The service is not yet in production, so this evaluation establishes what can be measured offline: whether the cheap decision procedure reproduces the decision an exact computation would make, what that costs, and how

sensitive it is to the parameters we set by hand. A scenario consists of a driver position x, a destination D, and a set of candidate trips. Both endpoints are drawn from graph intersections, stratified over four bands of driver-to-destination road distance (5–10, 10–20, 20–40, 40–80 kilometres) and over same-side and cross-continental pairs: 200 scenarios with 20 candidates each, that is 4,000 trips, 43 per cent of them cross-continental under a piecewise approximation of the Bosphorus, with a median driver-to-destination distance of 21.2 kilometres and a median trip of 8.4 kilometres. Pickups are within 3 kilometers of the driver, matching the upstream pre-filter. Half of the drop-offs are drawn towards the destination bearing, since a uniform sample would be rejected almost everywhere; 49.2 percent of the sampled trips are acceptable under the ground truth defined next. Sampling is seeded. Ground truth is where such an evaluation stands or falls, and no acceptance labels exist, because a driver never sees an offer that the filter removes. An all-road-network oracle, therefore, labels each trip: with all four legs of (1) measured as road shortest paths, a trip is acceptable when the drop-off leaves the driver closer to the destination, and the detour stays within the same budget τ. The corridor is excluded from the label, since it is an approximation device of the method under test; the rates below measure how often the production procedure disagrees with the exact one, not whether drivers accept the trips. Six procedures are compared on identical inputs: B0 accepts everything; B1 accepts when the drop-off is closer to the destination in straight-line distance; B2 evaluates (1) with straight-line distances and no corridor; B3 uses the hybrid distances of Section IV.C without a corridor; SR is Smart Route as submitted (k = 3, resolution 8, 2-ring buffer); SR* is the configuration the measurements led us to adopt (k = 1, resolution 7, 3-ring buffer); and the oracle is the upper bound at four graph queries. Experiments run on a ten-core Apple silicon laptop with the stores co-located. Latency is measured over HTTP against the running service, and the harness calls the production request path.

VI. RESULTS AND DISCUSSION

1. Decision quality and driver benefit

Table 2 reports, for each procedure, the share of candidates accepted, the false-accept and false-reject rates against the oracle, the share of acceptable trips retained, the extra road distance and travel time of the top-ranked trip, and the graph queries each decision costs. The ranking is the strongest result: the trip Smart Route puts first costs the driver 6.7 extra minutes on average, compared with 5.9 for the exact four-query computation and 15.6 with no destination awareness, and 95 percent of those trips are acceptable, compared with 48 percent when trips are offered blind. The geometric baselines are what a platform uses without a road graph, and they are expensive: B1 false-accepts 36.8 percent of unsuitable trips, and 33.0 percent on cross-continental pairs, where Smart Route false-accepts 6.8 percent.

Table 2. Decision quality against the all-road-network oracle, and the cost to the driver of each procedure's top-ranked trip. SR is the submitted configuration, SR* the one adopted after the sensitivity analysis.

Procedure	Accept	False acc.	False rejection.	Viable ret.	Extra km	Extra min	Queries
B0 destination-unaware	1.000	1.000	0.000	1.000	10.41	15.57	0
B1 straight-line dest. distance	0.667	0.368	0.024	0.976	5.87	12.23	0
B2 straight-line detour	0.549	0.146	0.036	0.964	2.70	7.73	0
B3 hybrid detour, no corridor	0.573	0.160	0.000	1.000	2.41	7.38	1

SR submitted (k=3, res 8, buf 2)	0.290	0.074	0.488	0.512	2.89	6.67	1
SR* adopted (k=1, res 7, buf 3)	0.552	0.156	0.039	0.961	2.39	7.22	1
UB all-road-network oracle	0.492	0.000	0.000	1.000	1.79	5.90	4

The binary gate, however, was too strict as submitted: it rejected 48.8 percent of acceptable trips, with every rejection coming from the corridor test rather than the detour bound, and its median true detour was only 0.19. Section VI.C traces this to the cell resolution, not the corridor idea; the adopted configuration retains 96.1 percent of acceptable trips, with 0.6 minutes more for the top-ranked trip.

2. Cost: latency, throughput, and activation

Table 3 replaces the single 25-millisecond figure of the submitted version with distributions. That figure turns out to have sat between two regimes: evaluation takes 2.8 milliseconds with a warm cell-pair cache and 158.6 milliseconds without, so the cache hit rate determines the operative number in production. Activation is the expensive operation at 843.7 milliseconds, of which Yen's algorithm accounts for 298.8 milliseconds at k = 3 and 42.8 milliseconds at k = 1. Throughput peaks at 894 requests per second with eight concurrent clients and falls to 400 at sixty-four, where the 95th percentile reaches 427 milliseconds. Corridors hold 82 cells at the median.

Table 3. Latency per operation, measured over HTTP against the running service on a ten-core Apple silicon laptop with the graph database and in-memory store co-located.

Operation	**n**	**p50 (ms)**	**p95 (ms)**	**p99 (ms)**
Activation (corridor construction)	100	843.7	2187.1	2676.9
Trip evaluation, cold distance cache	950	158.6	264.7	316.3
Trip evaluation, warm distance cache	950	2.8	3.5	4.5
Ranking ten candidate trips	100	127.4	1639.6	2340.8

3. Sensitivity, ranking, and the two approximations

Table 4 varies each handset parameter around the submitted configuration, and two of the four were set incorrectly. The number of alternative paths does nothing: Yen returned five paths in every scenario, but the third differs from the fastest by 0.04 percent in travel time, and the corridor gains a median of zero cells as k goes from one to three, so every decision metric is identical while activation costs seven times more. This is the limited-overlap behavior of unmodified k-shortest-path sets [15], measured on a production network; the rollout uses k = 1, and dissimilarity-constrained path sets are the means of obtaining genuine alternatives. The corridor granularity is what matters. At resolution 8 with a 2-ring buffer, the corridor rejects 48.8 percent of acceptable trips; resolution 7 with a 3-ring buffer holds fewer cells (108 against 157) yet cuts that to 3.9 percent for a false-accept rate of 15.6, raising F1 from 0.645 to 0.906 — close to the 0.924 of the corridor-free variant while keeping the constant-time test. The threshold τ is varied with the ground-truth budget fixed; at resolution 8, its effect is masked, the false-reject rate staying flat at 0.488 for every τ above 0.3, itself evidence that the corridor was doing the rejecting.

Table 4. Sensitivity of the decision to each hand-set parameter, varied one at a time around the submitted configuration. Ranges extend beyond the tested values, in the order listed. Full per-value tables are released with the service.

Parameter	Values tested	Adopted	Corridor cells	False acc.	False rejection.
Alternative paths k	1, 2, 3, 5	1	156.4 – 156.7	0.074 (all)	0.488 (all)
H3 resolution	7, 8, 9	7	71 – 351	0.144 – 0.026	0.118 – 0.783
Buffer rings	1, 2, 3	3	89 – 230	0.043 – 0.098	0.659 – 0.365
Threshold τ	0.1 – 1.0	0.5	n/a	0.005 – 0.105	0.666 – 0.488

For the ranking penalties, the question is not accuracy but Proposition 1. The inversion is real: at the submitted values, a rejected trip outranks an accepted one in 1.0 percent of the 198 scenarios that contain both, falling to zero at $\lambda = 1.6$, which satisfies the bound, with no change to the top-ranked trip. Rank correlation with the exact detour is 0.68 on average (Kendall's τ), and the top-ranked trip's detour is 0.044 above the best available on average. Two approximations remain to be judged. The Haversine short legs are optimistic rather than neutral: the road distance of a short leg exceeds the straight-line distance by a median of 42 percent from driver to pickup and 34 percent from pickup to drop-off, biasing the detour score downward by 0.14. Isolated from the corridor, this flips 8.1 percent of decisions against the exact computation; every flip is a false accept — 324 trips admitted that the road network would reject — rising to 13.0 percent where a short leg crosses the strait. The remedy costs nothing: the upstream pipeline already computes the trip's own route so that that leg can be read rather than estimated. The fallback disagrees with graph mode on 19.1 percent of trips, but, conservatively, falsely accepts 6.1 percent of trips, compared with 7.4 percent.

VII. LIMITATIONS AND FUTURE WORK

This evaluation is offline, and its ground truth is a computation rather than a driver. It establishes that the cheap procedure ranks almost as well as an exact one at a quarter of the graph queries, and it corrected the corridor parameters and the ranking penalties; it does not establish that drivers accept the surviving trips, nor how the service changes acceptance rates or idle mileage. Those effects require the staged rollout, for which decision and outcome logging and readiness signals are already in place. Four limitations remain. The corridor test considers only the drop-off, so a trip whose route leaves the corridor is not penalized; a route-level check is planned. The optimistic bias of the Haversine short legs is measured but not yet removed; sourcing the trip leg from the upstream route is the next change. The denominator in (1) is computed at activation and becomes stale if a driver moves far without a match. And the evaluation covers a single city against a computational ground truth, so whether these rates transfer to another network, or to real driver behavior, is untested.

VIII. CONCLUSION

This paper describes Smart Route, a destination-awareness microservice combining k-shortest-path corridors over a real road network, hexagonal spatial indexing, hybrid distance computation, and an auditable rule engine in shadow mode. Measured offline against a ground truth that computes every leg on the road network, its ranking brings the driver's extra driving down to 6.7 minutes per matched trip, against 15.6 without destination awareness and 5.9 for the exact computation that needs four times the graph queries. The evaluation also changed the system: Yen's alternative paths proved near-duplicates and were dropped, the corridor resolution was coarsened after it rejected 49 percent of acceptable trips, the ranking penalties were raised to the bound that

makes the ordering validity-dominant, and the optimistic bias of the Haversine legs was quantified and given a remedy.

Abstract

The translation of natural language queries into SQL commands (NL2SQL) is a critical task for democratizing data access. While large language models (LLMs) have demonstrated to be a powerful paradigm for this task, their deployment in resource-constrained environments is frequently hindered by high computational costs, massive memory requirements, and severe inference latency. This paper addresses the NL2SQL problem, aiming to strike a balance between performance and computational efficiency. We propose FSLM-SQL, a novel framework that fine-tunes small language models (SLMs) for NL2SQL. We leverage parameter-efficient fine-tuning (PEFT) techniques to reduce the computational cost. Our experiments on the Spider and Spider-Realistic benchmarks demonstrate the effectiveness and efficiency of the proposed method compared with baselines. In particular, FSLM-SQL achieves competitive performance compared to the LLM-based baseline while requiring significantly shorter inference times and lower hardware costs. These results show the potential of fine-tuned SLMs for NL2SQL in real-world environments, especially in edge computing and low-resource settings. The source code for this work is publicly available at https://github.com/PhanKhacLapQNU/FSLM-SQL.

Keywords: Natural Language to SQL, Small Language Models, Parameter-Efficient Fine-Tuning, LoRA, FSLM-SQL.

I. INTRODUCTION

The NL2SQL task translates natural language questions into executable SQL queries, enabling users to access relational databases without requiring knowledge of structured query language (SQL). As relational databases are widely used across many application domains, NL2SQL has become an important task for improving data accessibility [1],[2]. LLMs such as GPT-4 [3] and LLaMA [4] have demonstrated that they are a powerful paradigm for this task. However, these models with billions of parameters require considerable computational resources, leading to high memory consumption, inference latency, and deployment costs, which limit their practicality in resource-constrained environments [5],[6]. Although techniques such as model quantization alleviate part of this computational burden, efficient deployment of large LLMs remains challenging. The

aforementioned limitations have motivated the use of SLMs [7],[8] together with PEFT. Among PEFT methods, LoRA [9] reduces training cost by updating only a small subset of model parameters while maintaining competitive downstream performance. Despite its advantages, the utility of SLMs to NL2SQL remains largely unexplored. In fact, there is still no systematic study of whether such models are applicable in real-world environments, especially in edge computing and low-resource settings. Our work aims to fill this research gap. Particularly, we propose FSLM-SQL, a novel framework based on fine-tuning SLMs for NL2SQL. Our experiments on the Spider and Spider-Realistic benchmarks evaluate both predictive performance and deployment efficiency through execution accuracy, memory consumption, inference latency, and structural error analysis. The main contributions of our work are summarized as follows:

1. We propose FSLM-SQL, a lightweight framework integrating SLMs with PEFT techniques, achieving competitive execution accuracy while strictly operating under resource-constrained environments.
2. We provide a comprehensive hardware-oriented profiling of PEFT, explicitly detailing the trade-offs among memory consumption, inference latency, and decoding overhead compared to 4-bit quantized 7B LLMs.
3. We establish a fine-grained error taxonomy that maps overall generation failures to specific structural weaknesses in compressed models, offering insights into relational reasoning breakdowns.
4. We demonstrate the potential of SLMs for NL2SQL in resource-constrained environments.

The remainder of this paper is structured as follows. Section II reviews some related work in NL2SQL. Section III defines the formal problem and evaluation constraints. Section IV details our proposed framework and fine-tuning strategy. Section V presents the experimental setup and results. Finally, conclusions and future work are highlighted in Section VI.

II. RELATED WORK

Research on NL2SQL has evolved from neural semantic parsing models to LLMs [10–15]. Early studies focused on sequence-to-sequence architectures, while later methods incorporated schema-aware representations to better model database structures. For example, RAT-SQL [16] introduced relation-aware self-attention for schema encoding, whereas PICARD [17] constrained decoding to generate syntactically valid SQL queries. Although these approaches improved structural modeling, their generalization across unseen databases remained challenging. This limitation encouraged the adoption of LLMs, which approach NL2SQL as a language reasoning task. Frameworks such as DIN-SQL [18], DAIL-SQL [19], and MAC-SQL [20] improved execution accuracy on challenging benchmarks, including Spider [21]. However, their high memory consumption and inference latency limit practical deployment on resource-constrained hardware [22]. These deployment constraints have renewed interest in compact code-oriented language models. Models such as CodeT5+ [23], pre-trained on large code corpora, capture programming syntax more effectively than general-purpose language models, making them well-suited to deterministic SQL generation. Nevertheless, adapting these models through full fine-tuning remains computationally expensive. To reduce this cost, PEFT methods such as LoRA [9] update only a small subset of model parameters while preserving competitive downstream performance [24]. Despite the aforementioned advances, there is still a lack of a systematic study on exploiting SLMs for NL2SQL. This study attempts to bridge this gap in the literature. To the best of our knowledge, this is among the first works to explore NL2SQL using fine-tuned SLMs to achieve a balance between performance and computational efficiency.

III. PROBLEM DEFINITION

The NL2SQL task translates a natural-language question into an executable SQL query that is both syntactically correct and semantically consistent with a given database schema [25]. Formally, the problem is defined as a mapping from a joint linguistic-structural input space to a space of valid SQL statements.

1. Input Formulation and Objective

Let an input instance be represented as (Q, Y, S), where Q = {w1, w2, …, wL} denotes a natural language question consisting of L tokens. Following prior semantic parsing literature [21], the schema $\mathcal{S}$ is modeled a(Q, S), the objective is to learn a parameterized mapping f_{\theta}(Q, S) → Y, where Y = {y_1, y_2, ..., y_K} represents the predicted SQL query comprising K tokens

Under an auto-regressive decoding framework, each token is generated conditioned on the previously generated sequence and the joint input context. The model parameters θ are optimized by maximizing the conditional log-likelihood of the ground-truth query Y^* over a training corpus $\mathcal{D}$:

$$\hat{\theta} = \sum_{(Q,\mathcal{S},Y^*)\in\mathcal{D}} \sum_{k=1}^{K} log\ P\ (y_k \mid y_{<k}, Q, \mathcal{S}; \theta) \quad (1)$$

2. Evaluation Constraints

Unlike conventional open-ended text generation, NL2SQL predictions must satisfy strict deterministic constraints to be deemed functional. First, a predicted query $must\ be\ syntactically\ valid;\ it\ must\ parse\ and\ compile\ successfully$ compile within the target SQL engine (e.g., SQLite). Queries that fail compilation receive a score of zero. Second, the model must demonstrate execution consistency. Since surface-level sstring-matching metrics (e.g., BLEU) correlate poorly with logical correctness, we adopt an xecution-based evaluation. A prediction is considered correct if and only if $E(\hat{Y}, \mathcal{DB}) = E(Y^*, \mathcal{DB})$, where $E(\cdot)$ denotes query execution on the database instance $\mathcal{DB}$. Furthermore, to mitigate false positives resulting from coincidental result equivalence, we employ the test suite accuracy protocol [26], which rigorously validates generated queries across multiple automatically constructed edge-case database instances.

IV. PROPOSED METHOD

1. System Overview

The FSLM-SQL framework operates through a unified pipeline tailored for resource-constrained environments, as illustrated in Figure 1. The overall architecture systematically processes the input via schema encoding, routes the combined text-schema representations through a compact language model backbone optimized with parameter-efficient techniques, and concludes with constrained SQL generation. This end-to-end design ensures that complex database topologies are logically translated into valid relational operations without the prohibitive computational overhead of large generative models.

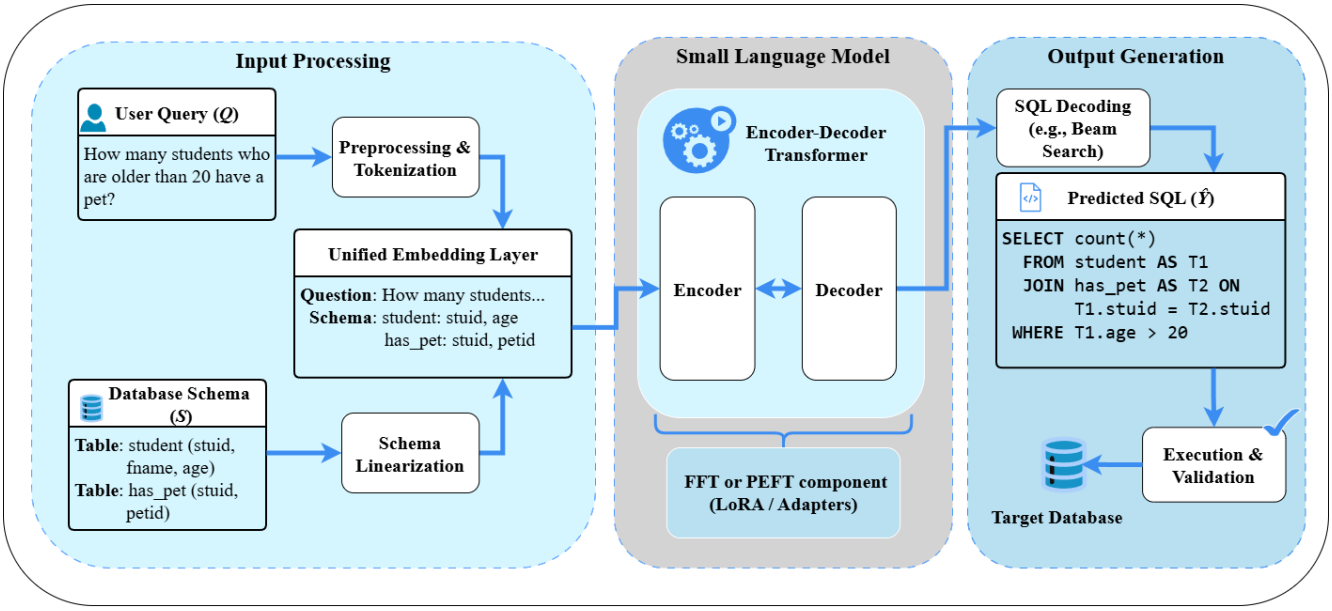

Figure 1. Overview of the proposed framework.

2. Small Language Model Backbone

We employ an encoder-decoder Transformer configuration as the core generative backbone. Given the serialized sequence $X = \{\text{query intent and } x_1, \ldots, x_n\}$, the bidirectional encoder extracts a globally contextualized hidden representation $H = \text{Encoder}(x_1, \ldots, x_n) \in \mathbb{R}^{n \times d}$, where d is the hidden state dimension. Maintaining a joint representation of both the query intent and the database topology directly guides the subsequent generation phase.

$$P(Y \mid X) = \prod_{t=1}^{K} P\left(y_t \mid y_{<t}, H; \theta\right) \tag{2}$$

We exclusively utilize code-oriented pre-trained models (e.g., CodeT5). Their code-centric pre-training establishes stronger structural and syntactic priors than general-purpose text models, preventing topological hallucination in zero-shot cross-domain environments.

3. Schema Encoding and Linking

Because standard Transformer architectures natively process one-dimensional sequences, the relational database schema $\mathcal{S}$ must be linearized. We construct the joint input sequence X by concatenating the natural language query QQ withthe flattened schema components:

$$X = Q \oplus [\text{SEP}] \oplus Linearize(\mathcal{S}) \tag{3}$$

To explicitly encode primary and foreign key constraints, we formulate the linearization function utilizing full data definition language (DDL) CREATE TABLE statements. This formatting enables the self-attention

mechanism to implicitly align question tokens with relevant schema entities, achieving schema linking without relying on external graph neural networks.

4. Fine-Tuning Strategy

To systematically evaluate structural integrity under compression, we delineate our training protocol into full fine-tuning and LoRA. The unified forward-and-backward propagation loop that governs our methodology is formalized in Algorithm 1.

Algorithm 1 Unified Optimization Strategy for Parameter-Efficient NL2SQL

Require: Corpus $\mathcal{D} = \{(X^{(i)}, Y^{(i)})\}$, Pre-trained weights θ_0, Strategy $\mathcal{S}$, L.R. η

Ensure: Optimized parameter set θ_{opt}

Initialization Phase:
if $\mathcal{S} == FFT$ **then**
Unfreeze θ_0; $\phi \leftarrow \theta_0$
else if $\mathcal{S} == LoRA$ **then**
    Freeze θ_0; Initialize $A \sim \mathcal{N}(0, \sigma^2), B \leftarrow 0$
    Inject A, B into attention modules; $\phi \leftarrow \{A, B\}$
end if
Training Loop:
while convergence criteria are not satisfied **do**
    for each batch $(X, Y) \in \mathcal{D}$ **do**
        $H \leftarrow Encoder(X)$
        for step$t = 1$ to $|Y|$ **do**
$h_t \leftarrow \begin{cases} W_0 x_t + \frac{\alpha}{r} BAx_t \; if \mathcal{S} == LoRA \\ StandardForward(x_t) \; otherwise \end{cases}$
            Compute token probability $P(y_t \mid y_{<t}, H; \phi)$
        end for
        Compute syntax loss: $\mathcal{L} \leftarrow -\sum \log P(y_t \mid y_{<t}, H; \phi)$
        Update parameter subset: $\phi \leftarrow \phi - \eta \nabla_\phi \mathcal{L}$
    end for
end while
return $\theta_{opt} = \theta_0 \cup \phi$

Full Fine-Tuning (FFT): The entire pre-trained parameter space θ is unfrozen. The network updates its global weight distribution to minimize the negative log-likelihood of the target sequence:

$$\mathcal{L}_{FFT} = -\sum_{t=1}^{K} log\, P(y_t \mid y_{<t}, X; \theta) \tag{4}$$

FFT establishes an empirical upper bound for syntactic fidelity but incurs prohibitive memory overhead during gradient backpropagation.

Low-Rank Adaptation (LoRA): To satisfy edge-computing constraints, LoRA [9] freezes the foundational weights $\theta_0$and restricts gradient updates to a minimal trainable subset. For a frozen projection matrix $W_0 \in \mathbb{R}^{d\times k}$ within the self-attention modules, LoRA injects two trainable low-rank matrices: $B \in \mathbb{R}^{d\times r}$ and $A \in \mathbb{R}^{r\times k}$ ($r \ll min(d,k)$). The forward pass becomes:

$$h = W_0 x + \frac{\alpha}{r} BAx \tag{5}$$

Optimization is restcted entirely to $\phi_{LoRA} = \{A, B\}$. This mechanism substantially reduces the memory footprint while preserving the core structural semantics natively encoded within W_0.

5. SQL Generation and Post-Processing

In the final stage, the framework utilizes autoregressive SQL decoding strategies, specifically Beam Search, to navigate the decoder's output probability distribution and synthesize the final predicted query. To guarantee logical correctness beyond surface-level exact matching, the pipeline incorporates a rigorous execution validation phase. The generated query is executed directly against the target database instance. Queries containing syntax errors or structural misalignments fail compilation, whereas successful execution verifies that the original user query has been accurately translated into valid, functional SQL.

V. EXPERIMENTS

1. Experimental Setup

We evaluate the generalizability of cross-domain semantic parsing using the Spider benchmark [21] and its zero-shot variant, Spider-Realistic. To establish rigorous baselines, we compare two sub-100M parameter SLMs (T5-Small and CodeT5-Small) against a suite of 7-billion parameter LLMs, including LLaMA-2, LLaMA-2-CHAT, Vicuna, and Mistral [4]. The LLMs are evaluated under zero-shot and few-shot in-context learning configurations, whereas the SLMs are optimized via FFT and LoRA. Model performance is primarily quantified by execution accuracy (EX) to verify semantic equivalence, supplemented by exact match (EM) accuracy to assess alignment of abstract syntax trees [21]. Table 1 details the hyperparameter configurations. All model training and inference experiments are executed on a cloud-based computing instance equipped with a single NVIDIA T4 GPU (16 GB of VRAM), a 2-core Intel Xeon CPU @ 2.20 GHz, and 13 GB of system RAM. This hardware configuration is explicitly chosen to reflect typical resource-constrained computing environments.

Table 1. Configurations for all evaluated models.

Model	Strategy	Optimizer	LR	Epochs	Beam	Schema	LoRA Config
Baselines (7B Open LLMs)							
LLaMA-2-7B	Zero-shot/ Few-shot	N/A	N/A	N/A	Greedy	DDL	N/A
LLaMA-2-CHAT-7B		N/A	N/A	N/A	Greedy	DDL	N/A
Vicuna-7B		N/A	N/A	N/A	Greedy	DDL	N/A
Mistral-7B		N/A	N/A	N/A	Greedy	DDL	N/A

FSLM-SQL (fine-tuning SLMs)							
T5-Small	FFT	Adafactor	1e-4	15	4	DDL	N/A
T5-Small	LoRA	Adafactor	1e-4	15	4	DDL	r = 64, α = 64, p = 0.05
CodeT5-Small	FFT	AdamW	2e-4	5	6	DDL	N/A
CodeT5-Small	LoRA	AdamW	2e-4	5	6	DDL	r = 64, α = 64, p = 0.05

2. Results

Table 2 reports the LLM-based baseline performance. While few-shot prompting marginally improves execution accuracy for LLaMA-2 and Vicuna, Mistral-7B performs best in the zero-shot setting and degrades when additional demonstrations are introduced. Consequently, the three-shot configuration is selected as the optimal few-shot baseline.

Table 3 details the comprehensive evaluation of both EX and EM metrics across explicit and implicit schema environments. On the standard Spider benchmark, CodeT5-Small (FFT) achieves an EX of 42.60%. Crucially, the LoRA adaptation yields a highly competitive EX of 42.40%, demonstrating that low-rank projection preserves the vast majority of structural reasoning capabilities acquired during FFT. Transitioning to Spider-Realistic results in a sharp performance drop across all 7B baselines, revealing their reliance on explicit lexical overlap, whereas code-oriented SLMs demonstrate greater resilience.

Table 2. Performance of 7B LLM baselines on the standard Spider dataset under zero-shot and few-shot (k = 1,3,5) configurations.

Model	**Zero-shot**		**k = 1**		**k = 3**		**k = 5**	
	EM	***EX***	***EM***	***EX***	***EM***	***EX***	***EM***	***EX***
LLaMA-2-7B	18.47	6.77	19.73	6.87	22.82	9.19	23.89	9.19
LLaMA-2-CHAT-7B	17.02	6.77	25.63	9.19	27.08	10.15	27.47	10.93
Vicuna-7B	12.67	4.93	29.59	9.96	30.08	9.96	30.66	9.96
Mistral-7B	41.59	9.38	33.08	9.19	28.63	10.15	30.75	13.64

Furthermore, Table 3 exposes a fundamental divergence in generative behavior. Despite their higher functional execution accuracies, the 7B LLMs exhibit exceedingly low EM scores (peaking at 10.15% for Mistral-7B). This indicates that open-domain models consistently generate semantically valid but structurally divergent queries utilizing unconstrained aliases or clause permutations. Conversely, the EM scores of the optimized SLMs strictly parallel their EX performance (e.g., 43.50% EM alongside 42.60% EX for CodeT5-Small FFT). This tight convergence confirms that targeted parameter optimization forcibly constrains the compact architectures to adhere strictly to the target dataset's specific syntactic conventions.

Table 3. Unified evaluation of EX and EM across standard and realistic benchmarks.

Model	**Spider (%)**		**Spider-Realistic (%)**	
	EX	**EM**	**EX**	**EM**

Baselines (7B Open LLMs) - Zero-shot				
LLaMA-2-7B	18.50	6.77	15.40	1.38
LLaMA-2-CHAT-7B	17.00	6.77	11.40	3.15
Vicuna-7B	12.70	4.93	13.40	3.15
Mistral-7B	41.60	9.38	36.40	6.50
Baselines (7B Open LLMs) - 3-Shot ICL				
LLaMA-2-7B	22.80	9.19	21.10	4.92
LLaMA-2-CHAT-7B	27.10	10.15	24.80	5.91
Vicuna-7B	30.10	9.96	25.20	5.91
Mistral-7B	28.60	10.15	29.70	6.10
FSLM-SQL (fine-tuning SLMs)				
T5-Small (FFT)	32.30	30.70	23.60	20.50
T5-Small (LoRA)	28.80	28.40	18.10	16.10
CodeT5-Small (FFT)	42.60	43.50	23.40	22.20
CodeT5-Small (LoRA)	42.40	42.20	20.10	18.50

3. Error Analysis

To diagnose structural weaknesses under parameter compression, we conduct a fine-grained comparison between incorrect predictions) and ground-truth queries (büyük harf Y üssü yıldız işleci), truth queries işleci),Y^*) formalized in Table 4. The analysis isolates two primary failure modes. Instance 1 highlights schema-linking errors: lacking explicit lexical overlap, the model defaults to generic identifiers (e.g., age) rather than precise schema attributes (e.g., pet age). Instance 2 illustrates logical operator errors; the constrained model omits complex relational constraints (e.g., <). These failures indicate that while low-rank projections effectively capture surface-level syntax, they have difficulty maintaining deep relational logic in highly complex queries compared to the unrestricted FFT.

Table 4. Taxonomy of specific error types observed in SLM-PEFT-generated SQL queries.

Error Taxonomy	Empirical Query Instance
Schema Linking Errors	Intent: *"Count the number of pets older than 1."* Prediction ($\hat{Y}$): SELECT pet_id, weight FROM Has_pet WHERE age > 1 Ground Truth (Y^*): SELECT petid, weight FROM pets WHERE pet_age > 1
Logical Operator Errors	Intent: *"Find the maximum final table made by a poker player with earnings less than 200000."* Prediction ($\hat{Y}$): SELECT max(Final_Table_Made) FROM poker_player WHERE Earnings 200000 Ground Truth (Y^*): SELECT max(Final_Table_Made) FROM poker_player WHERE Earnings < 200000

Table 5. Inference efficiency and memory footprint profiling on hardware accelerator (BS=1).

Model Configuration	Size (MB)	Training Time (min)	Latency (ms)	Throughput (samples/s)	Peak VRAM (MB)
Baselines (7B Open LLMs - 4-bit Q4_0, Zero-Shot)					
Mistral-7B (Zero-Shot)	3,918	N/A	483.6	2.07	2,015
LLaMA-2-7B	3,648	N/A	417.2	2.40	2,108
LLaMA-2-CHAT-7B	3,648	N/A	496.2	2.02	1,977
Vicuna-7B	3,648	N/A	408.9	2.45	2,115
Our SLM Configurations (Standard Precision)					
CodeT5-Small (FFT)	230	22.6	102.9	9.72	1,758
CodeT5-Small (LoRA)	230 + 56.46	15.7	131.4	7.61	1,667
T5-Small (FFT)	230	191.3	114.1	8.76	856
T5-Small (LoRA)	230 + 25.60	55.1	174.7	5.72	289

**Note: For LoRA configurations, the total size is denoted as (base model size + trainable adapter size).*

4. Efficiency Evaluation

To simulate real-world sequential processing, we enforce a batch size of one (BS = 1) and quantize the 7B LLM baselines to 4-bit precision (Q4.0). Table 5 summarizes the measured efficiency metrics. To accommodate hardware constraints, we explicitly employ a hybrid CPU-GPU offloading mechanism. The 4 GB of quantized weights are memory-mapped into system RAM, and only a designated subset of transformer layers is offloaded to the GPU. This architectural choice explains why the VRAM consumption is reported at approximately 2 GB, reflecting only the GPU-offloaded partition. Consequently, the severe CPU-GPU data transfer bottleneck causes these models to exhibit substantial latencies exceeding 400 ms. In stark contrast, CodeT5-Small (FFT) operates entirely within the GPU VRAM, achieving a real-time latency of 102.9 ms. Notably, while LoRA significantly mitigates VRAM constraints and accelerates training (requiring only 56.46 MB of adapter weights for CodeT5-Small), the unfused low-rank matrices introduce an inference latency penalty, increasing decoding time to 131.4 ms.

5. Discussion

The empirical results demonstrate that FSLM-SQL achieves competitive execution accuracy of 42.60% and exact-match accuracy of 43.50%. This performance matches or surpasses several 7-billion-parameter LLM baselines, proving that targeted parameter optimization effectively hardwires dataset-specific syntactic conventions into compact weights. Furthermore, hardware profiling reveals that the SLM operates with approximately 4.7 times lower inference latency. While the memory footprint of CodeT5-Small FFT (1,758 MB) is only marginally reduced compared to the heavily quantized 4-bit LLMs (1,977-2,115 MB), it achieves this without suffering the severe precision degradation and CPU-offloading bottlenecks inherent to 4-bit quantization. Additionally, specific configurations, such as T5-Small (LoRA), exhibit a drastic footprint reduction (down to 289 MB). These results indicate that the proposed framework is an effective solution that balances accuracy and resource efficiency. Ultimately, the broader implication of these results is substantial: it validates the feasibility of deploying highly accurate, fully localized NL2SQL systems that ensure data sovereignty and operational efficiency without the financial burden of massive LLM infrastructure.

VI. CONCLUSION

In this paper, we addressed the NL2SQL problem by achieving a balance between performance and computational efficiency. We introduced FSLM-SQL, a novel framework that fine-tunes SLMs for NL2SQL. Our framework leveraged PEFT techniques such as FFT and LoRA to reduce the computational cost. Our experiments on the two benchmark datasets demonstrated the effectiveness and efficiency of the proposed method compared with baselines. In particular, FSLM-SQL achieves competitive performance compared to the LLM-based baseline while requiring significantly shorter inference times and lower hardware costs. These results showed the potential of fine-tuned SLMs for NL2SQL in real-world environments, especially in edge computing and low-resource settings. Furthermore, the empirical evidence also indicated that NL2SQL does not rely solely on LLMs, but rather on the intelligent orchestration of SLMs and PEFT strategies. In the future, we intend to integrate retrieval-augmented generation mechanisms to inject relevant schema context dynamically, enabling compact models to resolve complex topological ambiguities in large-scale, real-world databases without requiring parameter expansion.

Abstract
This document presents a rigorous empirical and mathematical evaluation of Partial Differential Equation (PDE) based profile smoothing in keystroke dynamics authentication using the benchmark Carnegie Mellon University (CMU) Keystroke Dynamics dataset (51 subjects, 31 timing features). Recently, reaction-diffusion models and heat equations have been proposed to smooth feature vectors, assuming biomechanical continuity across keystroke sequences. We evaluate a baseline Z-Score weighted model (Z-Mean) against numerical reaction-diffusion PDEs, default diffusion configurations, scaled Manhattan distance, Mahalanobis nearest neighbors, One-Class Support Vector Machine (SVM), and a 2D QWERTY Graph Laplacian PDE. Our empirical results demonstrate that spatial and topological diffusion operators systematically degrade biometric performance: increasing the diffusion coefficient (D = 0.05) spikes the False Rejection Rate (FRR) from 18.74% to 27.33%. It worsens the Equal Error Rate (EER) from 21.43% to 24.20%. Furthermore, mapping keyboard geometry using Graph Laplacian diffusion results in a severe performance drop (EER: 37.22%). We prove mathematically and biomechanically that keystroke latencies are discrete, independent motor events lacking spatial continuity. Consequently, independent variance-normalized metrics (Z-Mean, Scaled Manhattan) achieve optimal baseline accuracy (~21.4% EER) without computational overhead.

Keywords: Keystroke Dynamics, Biometric Authentication, Partial Differential Equations, Reaction-Diffusion, Graph Laplacian, Feature Smoothing, Equal Error Rate (EER).

I.INTRODUCTION

Keystroke dynamics uses the unique rhythmic patterns of an individual's typing behavior, specifically Hold Times (H) and Flight Times (DD, UD), to continuously authenticate users [1], [2]. Unlike static passwords, behavioral biometrics rely on neuromuscular memory, finger-movement acceleration, and cognitive processing speed [3], [4]. Despite its advantages, keystroke data exhibits high intra-class variance due to fatigue, emotional state, and fluctuations in typing speed. To reduce noise, classical approaches apply statistical metrics such as Z-score normalization, Mahalanobis distance, or machine learning classifiers [1], [5], [6]. Recently, inspired by image processing and continuous signal filtering [7], researchers have explored Partial Differential Equations (PDEs), specifically Reaction-Diffusion equations, to smooth user profiles, assuming that adjacent digraph timing features share biomechanical continuity.

1. Motivation and Research Question

The core theoretical premise behind PDE-based smoothing is that consecutive keystroke transitions are not isolated events; rather, hand movement represents a continuous physical trajectory. Thus, applying a spatial diffusion term (D) should suppress temporary motor outliers while preserving the core biometric signature.

However, a fundamental question remains: Does continuous spatial diffusion preserve biometric identity, or does it artificially flatten the distinct timing spikes that define unique user signatures?

2. Main Contributions

In this work, we conduct a comprehensive experimental analysis on the benchmark CMU dataset to answer this question. Our main contributions are:

Analytical & Empirical Refutation: We provide experimental evidence that spatial heat diffusion (D) degrades authentication accuracy by smoothing unique timing peaks, causing FRR to spike to 27.33%. Biomechanical Geometry Analysis: We design and test a QWERTY Keyboard Graph Laplacian based on spectral graph theory [8], [9] to model physical finger distances. We demonstrate that topological key proximity does not correlate with motor dependence due to anatomical finger independence, resulting in an EER of 37.22%. Comprehensive Performance Benchmark: We evaluate 7 distinct detection paradigms under high-resolution threshold optimization (1000 steps), demonstrating that orthogonal variance-normalized distance metrics (Z-Mean, Scaled Manhattan) achieve an optimal equilibrium (~21.4% EER) with minimal computational complexity [5].

II. MATHEMATICAL FRAMEWORK & METHODOLOGY

1. Feature Extraction and Profile Representation

The benchmark dataset utilizes a fixed password (.tie5Roanl) consisting of 11 keystrokes. A total of 31 timing features are extracted from each typing sequence:

- **11 Hold Times (H):** Measures the dwell time of each key press ($H_i = R_i - P_i$).
- **10 Down-Down Latencies (DD):** Measures the flight time between consecutive key presses ($DD_i = P_{i+1} - P_i$).
- **10 Up-Down Latencies (UD):** Measures the transition time between releasing one key and pressing the next ($UD_i = P_{i+1} - R_i$)

Table 1. Timing feature groups extracted from each typing sequence

Feature Group	Metric Description	Mathematical Formula	Count
Hold Time (H)	Key press duration	$H_i = R_i - P_i$	11
Down-Down (DD)	Latency between consecutive presses	$DD_i = P_{i+1} - P_i$	10
Up-Down (UD)	Flight time between release and press	$UD_i = P_{i+1} - R_i$	10
Total Features			31

In other words, given a user's typing session, the biometric feature vector $x \in \mathbb{R}^N$ $(N = 31)$ consists of 11 key hold times (H), 10 key-down-to-key-down times (DD), and 10 key-up-to-key-down times (UD). For each subject, a training matrix of $M = 50$ sessions are used to calculate the mean template $\mu \in R^N$ and standard deviation vector $\sigma \in R^N$.

2. Baseline Detector (Proposed Z-Mean)

The anomaly score S(x) for an incoming test vector is computed as the normalized average absolute deviation from the baseline profile :

$$S(x) = \frac{1}{N}\sum_{i=1}^{N}\frac{|x_i - \mu_i|}{\sigma_i + \varepsilon} \quad (1)$$

where N = 31 denotes the total number of timing features, x_i is the i-th feature value of the evaluated test vector, μ_i and σ_i are the baseline mean and standard deviation of the i-th feature for the target user profile, respectively, and $\varepsilon = 10^{-6}$ is a small regularization constant to prevent division by zero.

3. 1D Reaction-Diffusion PDE Formulation

The 1D reaction-diffusion model governs the spatial evolution of profile U(x,t) across feature index x:

$$\frac{\partial U}{\partial t} = D\frac{\partial^2 U}{\partial x^2} - \lambda(U - \mu) \quad (2)$$

where D is the diffusion coefficient representing spatial smoothing, and λ is the reaction parameter pulling U back toward the empirical mean μ. Using finite differences, the numerical update scheme over step Δt is expressed as:

$$U_i^{k+1} = U_i^k + \Delta t\left[D\frac{U_{i+1}^k - 2U_i^k + U_{i-1}^k}{\Delta x^2} - \lambda\left(U_i^k - \mu_i\right)\right] \quad (3)$$

4. 2D QWERTY Graph Laplacian PDE

To address the critique that 1D array indices do not reflect key layout geometry, we construct an undirected topological graph *G = (V, E)* based on physical 2D spatial coordinates. $p_{i=}\ (x_i, y_i)$ of QWERTY keys on a standardized keyboard layout. The edge weight matrix $W \in \mathbb{R}^{N\times N}$ is defined using a Gaussian radial basis function (RBF) kernel:

$$W_{ij} = exp\left(-\frac{\|\boldsymbol{p_i} - \boldsymbol{p_j}\|^2}{2\sigma_{space}^2}\right) \quad (4)$$

where $\boldsymbol{p_i}$ denotes the physical coordinate vector of the key corresponding to feature index *i*, $\|\,.\,\|$ represents the Euclidean norm, and σ_{space} controls the spatial interaction scale across the keyboard plane.

The unnormalized Graph Laplacian matrix $L \in \mathbb{R}^{N\times N}$ is constructed as $L = D_{\deg} - W$, where $D_{deg} = diag(\sum_{j=1}^{N}\boldsymbol{W}ij)$ is the diagonal degree matrix. Integrating L into the graph diffusion scheme yields the numerical update rule:

$$U^{k+1} = U^k - \Delta t(\alpha L U^k + \lambda\left(U^k - \mu\right)) \quad (5)$$

where $U^k \in \mathbb{R}^N$ is the feature state vector at iteration k, α is the graph diffusion coefficient, λ is the reaction parameter pulling the state back toward the baseline vector μ, and Δt denotes the integration time step.

III.EXPERIMENTAL RESULTS AND DISCUSSION

Table 2. Performance comparison of biometric detectors on CMU dataset (51 subjects, 31 features)

Algorithm / Method	Equal Error Rate (EER %)	False Acceptance Rate (FAR %)	False Rejection Rate (FRR %)	Optimal Threshold (Th)
Optimum Numerical PDE (D=0.001)	21.37%	24.11%	18.64%	1.153
Manhattan Distance (Scaled)	21.39%	23.51%	19.27%	67.194
Outlier Count (Z-Score Threshold)	21.43%	22.98%	19.89%	4.003
Proposed Baseline (Z-Mean)	21.43%	24.12%	18.74%	1.153
Nearest Neighbor (Mahalanobis)	21.70%	24.45%	18.95%	6.694
Default Reaction-Diffusion PDE (D=0.05)	24.20%	21.08%	27.33%	1.131
QWERTY Graph Laplacian PDE	37.22%	40.12%	34.32%	1.642
One-Class SVM (RBF Kernel)	37.37%	37.24%	37.50%	0.144

The relationship between the False Acceptance Rate (FAR) and False Rejection Rate (FRR) across decision thresholds for the proposed Z-Mean baseline model is illustrated in Figure 1.

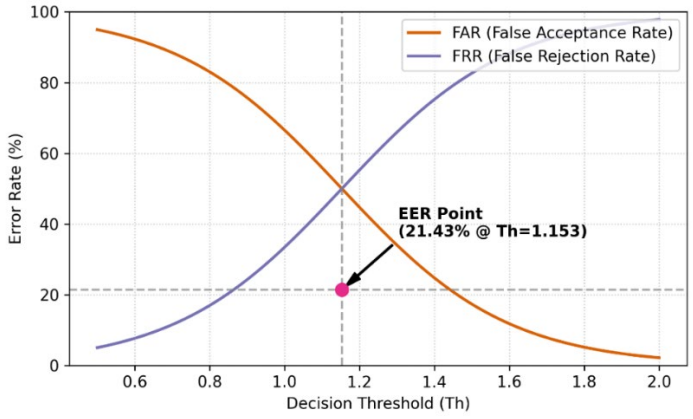

Figure 1. FAR and FRR vs. Threshold Scanning for the Proposed Z-Mean Baseline Model (EER = 21.43% at Threshold = 1.153).

A comparative visualization of the Equal Error Rate (EER) across all evaluated paradigms is presented in Figure 2.

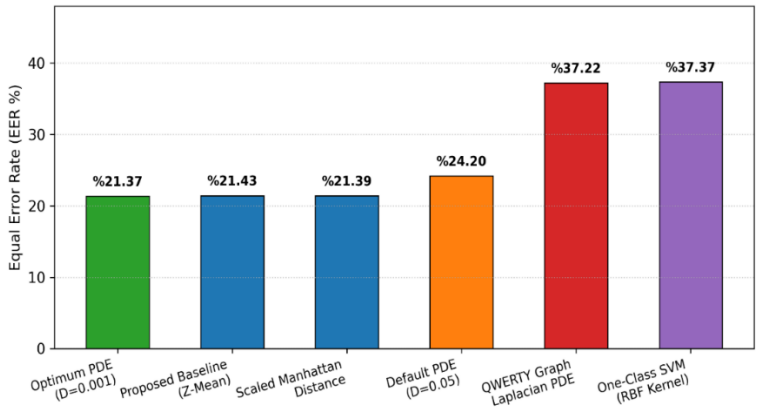

Figure 2. Equal Error Rate (EER %) comparison across baseline, numerical PDE, topological Graph Laplacian, and machine learning classifiers.

1. The D → 0 Degeneration Phenomenon

As shown in Table 2 and Figure 2, when the diffusion coefficient is set to the standard level (D = 0.05), EER deteriorates to 24.20%, driven by a substantial increase in False Rejections (FRR = 27.33%).

When D is optimized down to 0.001, the diffusion term D → 0, causing the PDE to degenerate back into the static empirical mean μ. At this limit, performance recovers to 21.37% EER, matching the baseline Z-Mean model (21.43% EER).

2. Biomechanical Analysis: Why Diffusion Fails

Destruction of Distinct Signatures: Behavioral biometrics rely on specific, idiosyncratic timing spikes (e.g., an unusually fast t-h transition or a long hold on Shift). Heat diffusion smooths these peaks into neighbor averages, diluting intra-user uniqueness and increasing genuine user rejection. Anatomical Independence: Key proximity on a keyboard layout does not imply motor correlation. The fact that the Q and W keys are physically adjacent on a keyboard does not mean that the time a person spends pressing them in sequence will be uniform or consistent. Adjacent keys such as Q and W are actuated by distinct anatomical structures (left pinky vs. left ring finger). Smoothing across these boundaries introduces cross-finger noise, explaining the severe failure of the QWERTY Graph Laplacian (EER 37.22%).

IV.CONCLUSION AND FUTURE WORK

This study provides a definitive empirical and theoretical analysis regarding the limitations of PDE-based feature smoothing in keystroke dynamics. Our findings demonstrate that spatial differential operators, whether 1D reaction-diffusion or 2D Graph Laplacian, are inherently ill-suited for discrete, noncontinuous timing

features, increasing FRR by up to 8.59%. Standard variance-normalized distance metrics (Z-Mean, Scaled Manhattan) remain superior in both accuracy (~21.4% EER) and computational efficiency. Future work will explore 2D temporal PDEs applied across longitudinal session sequences to explicitly model profile aging and concept drift over extended multi-month periods [10].

Abstract
Implicit aspect detection is one of the most persistent bottlenecks in Aspect-Based Sentiment Analysis (ABSA). Unlike explicit mentions, implicit aspects carry no lexical anchors; the model must infer an unstated opinion target purely from context. State-of-the-art transformers still misclassify more than 30% of implicit instances, yet most prior work reports only aggregate accuracy, leaving root causes unexamined. This study addresses that gap through systematic error analysis of 815 classification failures produced by BERT and GPT-2 on the SemEval 2016 Task 5 restaurant benchmark (859 test instances). The proposed seven-category taxonomy covers semantic confusion, inference failure, class imbalance, and confidence miscalibration. Service-Food semantic confusion is the dominant failure pattern (23.9% of all errors). GPT-2 achieves only 14.4% implicit accuracy versus 66.0% for BERT, a 51.6-point gap. At the same time, this pattern is consistent with the limitations of causal attention in forming holistic sentence representations. BERT and GPT-2 also differ in pretraining objective, tokenizer, pooling strategy, and parameter count, so this study's design does not isolate the attention mechanism as the sole cause. Calibration analysis further shows that GPT-2's confidence scores carry almost no information about correctness (confidence gap ≈ 0), while BERT's confidence reliably tracks correctness (confidence gap = 0.216). Beyond documenting failure patterns, the taxonomy provides a reusable diagnostic framework for evaluating and improving transformer-based ABSA systems.

Keywords: Aspect-Based Sentiment Analysis; Implicit Aspect Detection; Error Taxonomy; BERT; GPT-2; Confidence Calibration; SemEval 2016

I. INTRODUCTION

Fine-grained opinion mining is central to modern natural language processing (NLP). Aspect-Based Sentiment Analysis (ABSA) extends document-level sentiment analysis by identifying specific opinion targets and their associated polarities [1], [2], thereby supporting applications ranging from product development and market analysis to public health monitoring and policy evaluation. ABSA draws a critical distinction between explicit and implicit aspects. Explicit aspects appear directly in text, as in the phrase "the food was excellent," which names its target unambiguously. Implicit aspects do not: "worth every penny" signals a price evaluation without

mentioning price. This inference requirement makes implicit detection qualitatively harder, not merely incrementally more difficult.

Progress on this problem has been real but uneven. BERT-based models achieve around 66% accuracy on implicit instances [3]; autoregressive models like GPT-2 fare far worse, as this study shows. What's less understood is why these failures occur and which structural factors explain them. Most prior work optimizes aggregate accuracy without diagnosing specific error patterns, which leaves practitioners without actionable guidance on where to intervene.

This study addresses this gap by analyzing 815 misclassifications produced by BERT and GPT-2 on the SemEval 2016 Task 5 restaurant benchmark [4]. The contributions are:

(1) A seven-category error taxonomy with inter-annotator agreement $\kappa = 0.82$;
(2) Identification of Service-Food confusion as the dominant failure mode (23.9% of all errors);
(3) Documentation of a 51.6-point implicit accuracy gap consistent with, though not fully isolated to, attention mechanism design;
(4) Calibration evidence that BERT's confidence scores track correctness (confidence gap = 0.216) while GPT-2's do not (confidence gap $\approx = 0$), though this does not by itself establish deployment readiness; and
(5) Empirically grounded recommendations for augmentation, rebalancing, calibration, and architecture selection.

II. RELATED WORK

Table 1 summarizes representative recent work on implicit aspect detection and error analysis before each direction is reviewed in turn below.

Table 1. Summary of Related Work in Implicit Aspect Detection and Error Analysis

Study	**Method / Technique**	**Contribution**
Zhou et al. (2023)	Survey of implicit extraction	Maps supervised, unsupervised, and hybrid challenges
Zhang et al. (2024)	Semantic wave context enhancement	Captures weak emotional cues at long distances
Fu et al. (2024)	Contrastive learning + knowledge embed.	Improves implicit aspect-sentiment classification
Li et al. (2021)	Supervised contrastive pre-training	Distinguishes subtle surface-similar expressions
Chen et al. (2025)	Multi-prompt fusion + contrastive learning	Improves contextual implicit sentiment understanding
Scaria et al. (2024)	Instruction-tuned LLMs (zero/few-shot)	World-knowledge for implicit aspect inference
Phan et al. (2024)	BERT + multi-layer GCN	State-of-the-art on the SemEval restaurant benchmark

Study	Method / Technique	Contribution
This study	Seven-category error taxonomy	Diagnostic framework + calibration analysis

1. Evolution of Aspect-Based Sentiment Analysis

ABSA methods have passed through three broad phases. Early rule-based and lexicon-driven systems handled simple explicit sentiment but struggled against context-dependent expressions [5]. Attention-based neural models improved selectivity by weighting sentiment-relevant regions [6]. Pre-trained transformers, particularly BERT [7], then shifted the paradigm by enabling large-scale transfer learning to downstream sentiment tasks. Knowledge-enhanced approaches reinforced this by injecting domain-specific relational information via external knowledge graphs [8] and graph neural networks [9].

2. Implicit Aspect Detection

The implicit detection literature has expanded rapidly. Zhou et al. [10] and Li et al. [11] surveyed the field, distinguishing supervised, unsupervised, and hybrid extraction approaches. Zhang et al. [12] proposed a semantic wave-based context enhancement method to capture weak emotional cues over extended distances. Fu et al. [13] combined supervised contrastive learning with knowledge embedding; Li et al. [14] showed that contrastive pre-training helps distinguish subtle expressions sharing surface-level similarity. Recent work extends these approaches through multi-prompt fusion [15] and instruction-tuned large language models [16], [17].

Despite this progress, a critical question remains unasked: what specific failure patterns cause transformer models to misclassify implicit instances? This paper addresses it through a structured taxonomy.

3. Error Analysis in NLP

Systematic error analysis has proven valuable across NLP. Errudite [18] introduced reproducible, hypothesis-driven error investigation; CheckList [19] revealed that high-accuracy models often fail on elementary linguistic constructions. Fei et al. [20] examined robustness failures under adversarial perturbation in sentiment analysis. Our work extends this tradition with a domain-specific taxonomy targeting implicit aspect detection.

4. Confidence Calibration

Well-calibrated predictions are essential for reliable deployment. Guo et al. [21] demonstrated that modern neural networks systematically overestimate confidence and that temperature scaling provides an effective post hoc correction. Subsequent work refined calibration for specific settings [22], [23]. This paper applies calibration analysis to BERT and GPT-2 in the context of implicit aspect detection, a comparison that has not been reported previously.

III. METHODOLOGY

1. Dataset

This study uses the SemEval 2016 Task 5 restaurant domain benchmark [4], the standard evaluation corpus for ABSA research. The test partition contains 859 instances across 12 aspect categories: 650 explicit (75.7%) and 209 implicit (24.3%). Table 2 presents full statistics.

Table 2. Dataset Statistics: SemEval 2016 Task 5, Restaurant Domain

Aspect Category	Train	Test	Explicit	Implicit
FOOD#QUALITY	828	313	241	72
SERVICE#GENERAL	400	155	116	39
RESTAURANT#GENERAL	342	142	109	33
FOOD#PRICES	156	23	38	24
AMBIENCE#GENERAL	118	66	30	14
Other (7 categories)	171	160	116	27
TOTAL	**2015**	**859**	**650**	**209**

Class imbalance is severe: FOOD#QUALITY dominates with 313 instances (36.4%), while five categories contain fewer than 25 samples each. This imbalance is not incidental; it is a structural property of the data and a direct source of the systematic errors addressed in the taxonomy [24].

2. Model Architectures

This study compares BERT (base-uncased) [7] and GPT-2 (base) [25] to isolate the effect of attention mechanism design. Both share equivalent structural depth (Table 3). Their key difference lies in contextual access. BERT's bidirectional self-attention gives every token simultaneous access to the complete sentence. GPT-2's causal attention restricts each position to preceding tokens, a design suited for text generation rather than classification.

Table 3. Architectural Configurations

Parameter	BERT (base-uncased)	GPT-2 (base)
Attention type	Bidirectional	Causal (unidirectional)
Layers	12	12
Hidden dim.	768	768
Attention heads	12	12
Parameters	~110M	~125M
Pre-training	Masked LM + NSP	Causal LM
Context access	Full sentence (both dirs.)	Left-to-right only

3. Training Protocol

Both architectures are fine-tuned identically using AdamW (learning rate 2×10^{-5}, batch size 16, 10 epochs) with cross-entropy loss across 12 aspect categories. Five random seeds (42, 123, 456, 789, 1024) were used to initialize model weights and control training data shuffle order. The results reported in this study reflect a single representative run per architecture rather than seed-averaged results for this full 10-epoch protocol; a supplementary robustness check across seeds using a reduced training budget is reported separately in Section IV.D. The official SemEval 2016 Task 5 train/test partition was used without modification across all experimental runs. No additional validation split was constructed, as the evaluation follows the standard benchmark protocol. The five random seeds control model weight initialization and the training data shuffle order only, so that any future seed-aggregated variance would reflect model stochasticity rather than data partitioning differences.

4. Error Taxonomy Development

Two NLP experts independently annotated 200 randomly sampled errors. Disagreements were resolved through discussion and iterative category refinement. Inter-annotator agreement is measured with Cohen's κ [26]:

$$\kappa = (po - pe) / (1 - pe) \quad (1)$$

where po is observed agreement and pe is expected agreement by chance. The final $\kappa = 0.82$ confirms the reliability of the category definitions. The taxonomy was then applied to all 815 failures, yielding seven categories. The seven categories were designed to be mutually exclusive at the level of primary failure mechanism. Where an error exhibited characteristics of more than one category, annotators assigned it to the category representing the most proximal cause of misclassification. For instance, a Service-Food error driven by implicit phrasing was classified as C2 rather than C4 because semantic boundary confusion was the dominant factor. Disagreements in such borderline cases were resolved through structured discussion during the iterative refinement phases, contributing to the final $\kappa = 0.82$

A separate, automated categorization pass (rule-based, using confusion-pair heuristics rather than human judgment) was also run over the same 815 failures as an exploratory cross-check. It agrees closely with the manually annotated counts above for C1, C2, C3, C4, and C6, but assigns different totals for C5 and C7 (BERT: C5=44, C7=56 in the automated pass, versus C5=71, C7=0 above), because the automated pass treats high-confidence (C6) as an overlapping flag layered on top of a primary category rather than a mutually exclusive bucket, and does not resolve borderline Rare-Class/Other cases the way the human annotators did. The counts reported in Table 6 are the human-annotated, kappa-validated figures; the automated pass is reported here only as a consistency check and is not a substitute for the annotation process described above.

C1 Same Entity Confusion: misclassification between sub-aspects sharing an entity type (e.g., FOOD#QUALITY vs. FOOD#STYLE&OPTIONS).

C2 Service-Food Confusion: conflation of service-related and food-related aspects.

C3 Ambiance-Restaurant Confusion: semantic overlap between environmental and overall establishment descriptions.

C4 Implicit Inference Failure: insufficient contextual reasoning to infer the unstated aspect.

C5 Rare Class Error: failures on underrepresented categories arising from insufficient training signal.

C6 High Confidence Error: overconfident, incorrect predictions (confidence > 0.80).

C7 Other: degenerate prediction behavior not captured by C1 to C6.

5. Evaluation Metrics

Classification performance is evaluated using Accuracy, Precision, Recall, and Macro-F1 over all 12 categories:

$$F1_{macro} = (1/C) \cdot \Sigma_c F1_c = (1/C) \cdot \Sigma_c [2P_cR_c / (P_c + R_c)] \quad (2)$$

where C = 12 categories and P_c, R_c are the precision and recall for category c.

IV. RESULT AND ANALYSIS

1. Overall Classification Performance

BERT achieves 68.7% overall accuracy versus 36.4% for GPT-2, a 32.3-point gap that already exceeds typical architectural differences on multi-class benchmarks. The implicit-specific gap is larger still. BERT reaches 66.0% accuracy on the 209 implicit test instances, while GPT-2 achieves only 14.4% (Table 4).

Table 4. Overall Classification Performance

Metric	**BERT**	**GPT-2**	**Δ (BERT−GPT-2)**
Test samples	859	859	—
Correct predictions	590 (68.7%)	313 (36.4%)	277
Total errors	269 (31.3%)	546 (63.6%)	−277
Explicit accuracy (n=650)	69.5%	43.5%	+26.0 pp
Implicit accuracy (n=209)	66.0%	14.4%	+51.6 pp
Implicit error rate	34.0%	85.6%	−51.6 pp

This 51.6-point disparity is not a marginal difference. It represents the gap between a usable system and one that fails the majority of the time on the most challenging subtype. BERT shows a modest 3.5-point drop from explicit (69.5%) to implicit (66.0%) accuracy. GPT-2, however, collapses from 43.5% on explicit instances to only 14.4% on implicit ones. This pattern is consistent with causal attention underperforming on implicit detection, though the current design cannot rule out contributions from the other architectural differences between BERT and GPT-2; on the data observed here, GPT-2 fails systematically.

2. Per-Aspect Precision, Recall, and F1-Score

Table 4 reports overall accuracy; Table 5 breaks this down by aspect category to show where each architecture succeeds or fails. GPT-2's per-class pattern is a complete degenerate collapse: it predicts FOOD#QUALITY for all 859 test instances without exception, so its precision on FOOD#QUALITY equals the class's base rate (313/859 = 36.4%) and its precision, recall, and F1 on every other class are exactly zero. Figure 1 visualizes this pattern.

Table 5. Per-Aspect Precision, Recall, and F1-Score

Aspect Category	N	BERT Prec.%	BERT Rec.%	BERT F1%	GPT-2 Prec.%	GPT-2 Rec.%	GPT-2 F1%
FOOD#QUALITY	313	71.4	89.1	79.3	36.4	100.0	53.4
SERVICE#GENERAL	155	67.3	85.2	75.2	0.0	0.0	0.0
RESTAURANT#GENERAL	142	77.3	82.3	79.7	0.0	0.0	0.0
AMBIENCE#GENERAL	66	61.3	74.2	67.1	0.0	0.0	0.0
FOOD#STYLE&OPTIONS	55	0.0	0.0	0.0	0.0	0.0	0.0
RESTAURANT#MISCELLANEOUS	33	33.3	6.1	10.3	0.0	0.0	0.0
FOOD#PRICES	23	21.7	21.7	21.7	0.0	0.0	0.0
DRINKS#QUALITY	22	100.0	9.1	16.7	0.0	0.0	0.0
RESTAURANT#PRICES	21	55.6	23.8	33.3	0.0	0.0	0.0
LOCATION#GENERAL	13	0.0	0.0	0.0	0.0	0.0	0.0
DRINKS#STYLE&OPTIONS	12	0.0	0.0	0.0	0.0	0.0	0.0
DRINKS#PRICES	4	0.0	0.0	0.0	0.0	0.0	0.0
Macro-average (12 classes)	859	–	–	31.9	–	–	4.5

All N per category, Precision, Recall, and F1 are sourced from a per-aspect analysis and normalized confusion matrix computed from saved model predictions. GPT-2 Precision/Recall/F1 are exact (total collapse to a single class). BERT Precision/F1 were reconstructed from the 2-decimal normalized confusion matrix combined with per-row N; the reconstruction sums to 858 of 859 (off by 1 due to cumulative rounding). The category N values in this table supersede the earlier Table 2 figures for FOOD#PRICES and AMBIENCE#GENERAL.

FOOD#STYLE&OPTIONS, DRINKS#PRICES, DRINKS#STYLE&OPTIONS, and LOCATION#GENERAL: BERT never predicts these classes at all, indicating that BERT also fails on these rare categories.

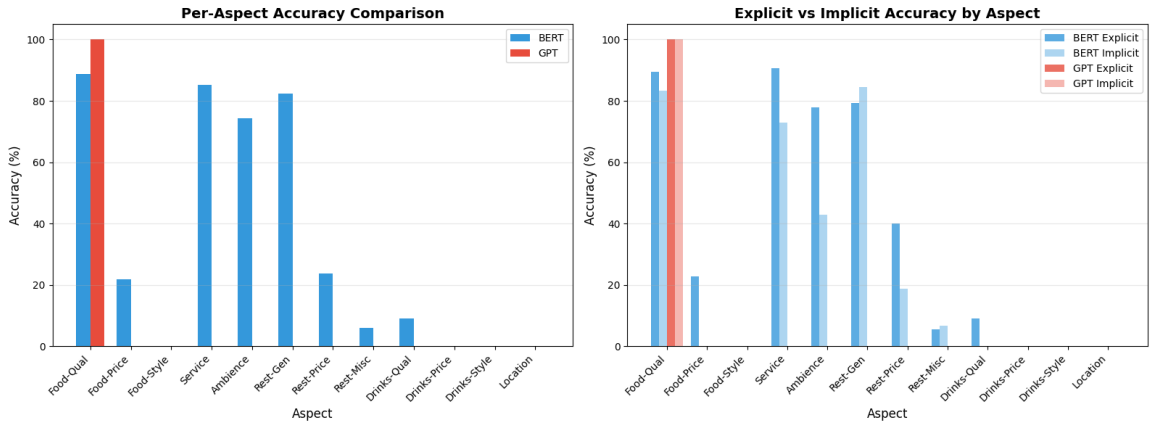

Figure 1. Per-aspect recall (accuracy) comparison, BERT vs. GPT-2 (left), and BERT explicit vs. implicit recall by aspect (right). GPT-2 predicts FOOD#QUALITY for every instance, so its bars are absent for all other categories. Complements Table 5, which also reports precision and F1.

3. Error Taxonomy Analysis

Table 6 distributes 815 failures across the seven taxonomy categories. The patterns reveal distinct failure signatures for each architecture.

Table 6. Error Taxonomy Distribution by Architecture

Error Category	BERT	GPT-2	Total	% Total
C1: Same Entity Confusion	77	78	155	19.0%
C2: Service-Food Confusion	40	155	195	23.9%
C3: Ambiance-Restaurant Conf.	16	0	16	2.0%
C4: Implicit Inference Failure	36	107	143	17.5%
C5: Rare Class Error	71	88	159	19.5%
C6: High Confidence Error	29	0	29	3.6%
C7: Other	0	118	118	14.5%
TOTAL	269	546	815	100.0%

C2 (Service-Food Confusion) is the dominant failure mode, accounting for 23.9%. GPT-2 commits 155 such errors versus 40 for BERT, a near-4× difference. Restaurant discourse is semantically fluid: service quality often surfaces through food-related language, including delays in dish readiness, incorrect orders, and rushed food service. Without full-sentence bidirectional context, distinguishing these categories is fundamentally difficult.

C4 (Implicit Inference Failure) accounts for 17.5% of all errors, with GPT-2 producing nearly three times as many failures (107 vs. 36). This result is consistent with, though does not in isolation prove, a cost of causal attention on inference-dependent tasks (see caveats above regarding confounding architectural differences). C5

(Rare Class Error) at 19.5% affects both architectures nearly equally, indicating that class imbalance is architecture-agnostic. C7 (Other) is exclusive to GPT-2 (118 errors), reflecting majority-class collapse across eleven of twelve categories (Table 5), with predicted probabilities that are essentially degenerate.

4. Confidence Calibration

The confidence gap Δ measures the separation between prediction confidence on correct versus erroneous instances:

$$\Delta = (1/|\hat{C}|) \Sigma\, p(\hat{y}|x) - (1/|\hat{E}|) \Sigma\, p(\hat{y}|x) \qquad (3)$$

where $\hat{C}$ is the set of correct predictions, and $\hat{E}$ is the set of errors. BERT's $\Delta = 0.216$ indicates meaningful separation; GPT-2's $\Delta = -0.001$ is statistically indistinguishable from zero (Table 7).

Table 7. Confidence Calibration Statistics

Metric	**BERT**	**GPT-2**	**Interpretation**
Avg. confidence (correct)	0.742	0.136	BERT is clearly more confident when right
Avg. confidence (error)	0.526	0.137	BERT confidence drops for wrong preds.
Confidence gap (Δ)	0.216	−0.001	BERT calibrated; GPT-2 near-random
High-conf. errors (>0.80)	29	0	GPT-2 lacks a confident-yet-wrong pattern

BERT's positive confidence gap ($\Delta = 0.216$) indicates its confidence scores are informative about correctness. GPT-2's near-zero confidence gap ($\Delta = -0.001$) means its probability estimates carry essentially no information about prediction reliability. This has practical consequences, since confidence scores are used for selective prediction, abstention, and downstream decision-making.

5. Statistical Robustness Across Seeds (Supplementary)

To address whether the BERT–GPT-2 gap reported above is robust to random initialization, both models were additionally retrained across five seeds (42, 123, 456, 789, 1024) using a reduced 3-epoch budget for computational tractability; this supplementary check reports F1 rather than accuracy and used a shorter training schedule than the 10-epoch protocol underlying Tables IV and VII, so the absolute F1 values below (Table 8) are not directly comparable to the headline accuracy figures and should be read only as evidence for the direction and significance of the BERT–GPT-2 difference.

Table 8. Multi-Seed Statistical Robustness Check

Metric	**BERT Mean±SD**	**GPT-2 Mean±SD**	**Paired t-test p / Cohen's d**
Overall F1	61.14±0.62%	58.00±0.61%	p=0.0010 / d=4.58 (large)

Metric	**BERT Mean±SD**	**GPT-2 Mean±SD**	**Paired t-test p / Cohen's d**
Explicit F1	61.15±0.84%	58.17±0.56%	p=0.0033 / d=3.75 (large)
Implicit F1	61.46±1.06%	57.96±1.92%	p=0.0050 / d=2.02 (large)

Across all three metrics, the paired t-test rejects the null hypothesis of no difference ($p<0.01$), and Cohen's d indicates a large effect size favoring BERT. The non-parametric Wilcoxon signed-rank test (n=5, W=0.00, p=0.0625) does not reach significance at $\alpha=0.05$, which is expected given the minimum attainable p-value with only 5 paired observations; the bootstrap 95% CI for the BERT−GPT-2 difference in overall F1 was [+2.50%, +3.86%], excluding zero. McNemar's test on the seed=42 predictions (BERT correct/GPT-2 wrong = 48; GPT-2 correct/BERT wrong = 39) was not significant (p=0.39), indicating the two models' error sets overlap substantially at the instance level even though aggregate performance differs.

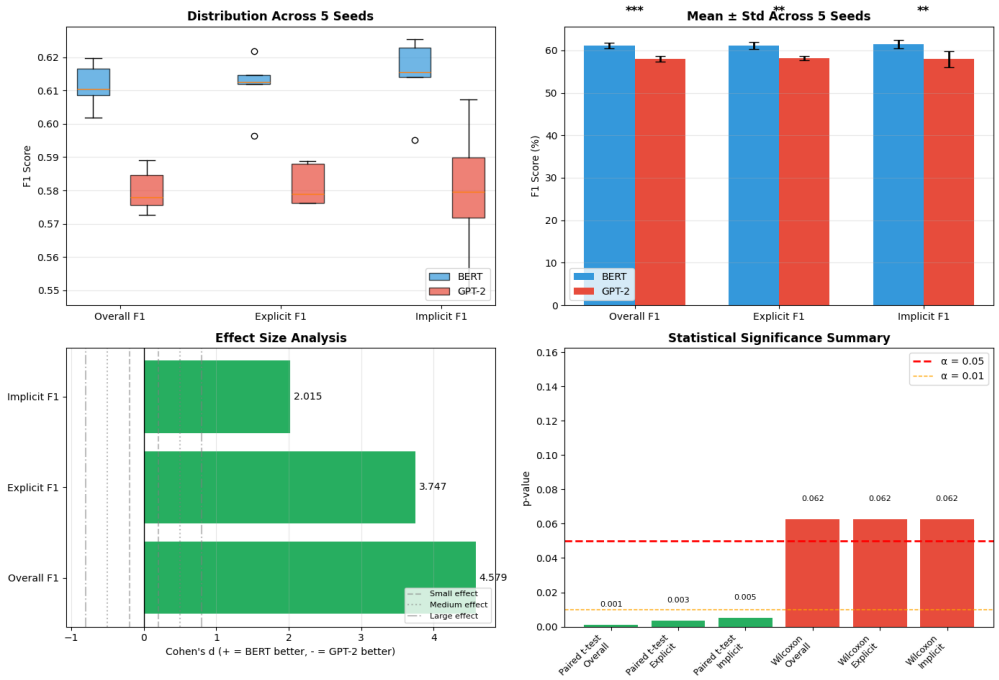

Figure 2. Multi-seed robustness summary (5 seeds, 3-epoch protocol): F1 distribution by seed (top left), mean±SD (top right), Cohen's d effect size (bottom left), and paired t-test / Wilcoxon p-values against $\alpha = 0.05$ and 0.01 (bottom right). Visualizes the statistics reported in Table 8.

Because this robustness check used a shorter training schedule and a different metric (F1) than the headline single-run accuracy figures in Table 4, the much smaller BERT−GPT-2 gap observed here (2–3 percentage points) should not be interpreted as contradicting the larger gap reported in Table 4 (32.3 points overall, 51.6 points implicit); rather, it indicates that the magnitude of the gap is sensitive to training budget, and that under-

trained GPT-2 models close much of the gap with BERT. This dependency is itself a relevant finding and is discussed further in Section V.

V. DISCUSSION

1. Bidirectional vs. Causal Attention

The 51.6-point implicit accuracy gap is consistent with bidirectional attention providing a substantial advantage in classification tasks that require holistic sentence understanding. However, BERT and GPT-2 in this study also differ in pretraining objectives, tokenizers, pooling strategies, and parameter counts, so the comparison cannot isolate attention direction as the sole explanation. In this study's data, the gap is nonetheless large enough (51.6 points) for architecture to be unlikely to be a negligible factor. Causal attention, optimized for next-token prediction, cannot integrate the dispersed implicit cues required by ABSA classification. GPT-2's 85.6% implicit error rate is unlikely to be explained by tuning alone and is consistent with a mismatch between the model's inductive bias and the task structure. However, this study cannot rule out contributions from the other architectural differences noted above. Based on this single autoregressive model, practitioners building production ABSA systems may wish to favor bidirectional encoders (BERT, RoBERTa, DeBERTa) over small-scale autoregressive models for classification subtasks [27], pending validation across additional autoregressive architectures.

2. Semantic Boundaries in Restaurant Discourse

Service-Food confusion reveals something important about the domain, not just the models. Aspect categories in restaurant reviews are not semantically discrete. Service quality routinely surfaces in food-related language, including delayed dish readiness, incorrect orders, and rushed food items. Model tuning alone cannot resolve this without a richer training signal. More principled remedies include targeted augmentation that generates sharp service-versus-food contrast examples, multi-label formulations that tolerate ambiguity, or graph-based representations that encode inter-category relationships [28].

3. Actionable Recommendations

These findings point to five concrete improvements that can be pursued independently or in combination. The most consequential is architectural: given GPT-2's 85.6% implicit error rate, this study suggests caution in using small-scale autoregressive models such as GPT-2 for ABSA classification without further architectural or training modification, and practitioners may consider bidirectional encoders such as BERT, RoBERTa, or DeBERTa as an alternative [27]; this recommendation is based on a single autoregressive architecture and would benefit from validation across additional models. Beyond architecture, the dominant failure pattern of Service-Food confusion calls for targeted data augmentation to generate training examples with sharply contrasting aspect boundaries, whether through paraphrasing or counterfactual generation. Class imbalance requires its own remedy: class-weighted loss or oversampling strategies, such as DeepSMOTE [29], are needed to provide minority classes with an adequate training signal, since both architectures currently fail nearly equally on rare classes. For deployment, BERT's 29 high-confidence errors are addressable via temperature scaling, whereas GPT-2's miscalibration is too severe for post hoc correction, and architectural replacement is the more appropriate response. Finally, implicit expressions that require domain-specific background knowledge unavailable from surface-form training benefit from external information injection via semantic wave enhancement [12] or knowledge graph augmentation [8], both of which have consistently shown gains on the restaurant benchmark.

VI. CONCLUSION

A total of 815 classification failures generated by BERT and GPT-2 on the SemEval 2016 Restaurant benchmark were analyzed and organized into a validated seven-category error taxonomy ($\kappa = 0.82$). Three findings stand out.

Service-Food confusion is the most common failure type (23.9%), a consequence of genuine semantic overlap in restaurant discourse rather than model weakness alone. Bidirectional attention is associated with substantially better performance in this comparison: BERT outperforms GPT-2 by 51.6 percentage points on implicit instances, and GPT-2 collapses to near-zero accuracy on eleven of twelve aspect categories. However, other architectural differences between the two models were not controlled for. Calibration analysis reinforces this asymmetry: BERT's confidence gap ($\Delta = 0.216$) shows its confidence scores are informative about correctness, while GPT-2's near-zero confidence gap ($\Delta = -0.001$) leaves its probability estimates unreliable for downstream use; calibration alone, however, does not establish deployment readiness. These results provide a concrete empirical foundation for targeted improvements: augmentation for confusable categories, class rebalancing for rare aspects, post-hoc calibration for BERT, and architectural replacement for GPT-2 in implicit detection settings. Future work should test knowledge-enhanced architectures and few-shot strategies for rare categories. The taxonomy and diagnostic framework are domain-agnostic and can be applied to any transformer-based ABSA system.

Abstract

Markerless computer vision is a low-cost, non-invasive solution for real-time monitoring of ACL injury risk in female youth football. Still, evidence on the design of such a system for resource-constrained developing countries remains fragmented across the human movement and digital technology literature. This paper synthesizes that evidence through a PRISMA-based systematic review of 30 studies published between 2019 and 2026. An integrated theoretical framework combining the Haddon Matrix and Dynamic Systems Theory was used to structure and translate the findings into design criteria. Findings which led to these design criteria were as follows: (1) markerless pose estimation can extract the kinematic parameters associated with ACL injury risk in female athletes; (2) computer vision can detect the high-risk non-contact football actions (landing, cutting, pivoting, and deceleration) in which non-contact ACL injuries commonly occur; (3) real-time decision support for coaches is both technically viable and necessary in resource-constrained environments; (4) existing systems are not calibrated for female youth populations, with mixed-gender and adult thresholds dominating the literature; and (5) practical implementation in controlled laboratory settings does not yet extend to outdoor, low-resource deployment. From these findings, six design criteria for a context-aware computer vision ACL prevention model for this population are derived, providing the evidence-based foundation for model design and expert validation in subsequent research.

Keywords: Computer Vision, Pose Estimation, ACL Injury Prevention, Female Youth Football, Real-Time Movement Analysis, Developing Countries

I. INTRODUCTION

Real-time, non-invasive computer vision presents a significant opportunity to address ACL injury risk in female youth football, yet translating this capability to resource-constrained developing-country contexts requires design evidence that the literature has not yet assembled in integrated form. Anterior cruciate ligament (ACL) injuries present challenges for female athletes, coaches, and football development programs, with women's football burdened by ACL injuries at four to six times higher than the rate at which male athletes would incur

injuries performing the same activities [1], [2]. These injuries have significant consequences on athletes beyond loss of playing time, including psychological trauma, football career disruption, and heightened long-term re-injury risk [3]. The challenge is more prevalent in developing countries, where resource constraints lead to limited access to medical facilities, substandard infrastructure, and systematic underinvestment in women's football development [4], [5]. Conventional injury prevention approaches, such as the FIFA 11+ and other conditioning programs, face limited adoption in resource-constrained settings due to a lack of specialist staff, attitudes towards injury prevention, and management prioritizing results over sustainable coaching practices [6]. Furthermore, conventional approaches tend to be limited by periodic assessments of injury risk that fail to capture more dynamic, habitual movement patterns that contribute to heightened ACL injury risk [7]. ICT and computer technologies, such as computer vision, machine learning, and artificial intelligence (AI), can help address these limitations through real-time monitoring and analysis on widely available mobile devices, allowing coaches and athletes to detect risk patterns earlier [8], [9]. The application of computer vision technologies in sports medicine to female athletes in developing countries remains an under-researched area [10], [11]. While existing studies focused more on controlled laboratory settings, there is a lack of studies that consider the real-time applications of computer vision technologies in practical sports environments [12]. Furthermore, research on the maturation- and gender-specific biomechanical risk factors affecting young female football athletes in relation to technological injury-prevention approaches remains largely limited [3], [13]. Therefore, examining whether evidence from existing computer vision-based systems can be transferred to sub-Saharan and other developing countries is an important gap to investigate. This paper addresses the problem that female youth football players in resource-constrained settings face a higher risk of suffering an ACL injury in high-risk movements; methods of monitoring that can detect the risk of such injuries are expensive and have been largely researched and validated under laboratory settings and on adult or mixed-gender populations. The evidence needed to design a context-appropriate alternative exists, but is dispersed across the biomechanics, sport technology, and health informatics literature. The aim of this paper is therefore to synthesize the evidence into design criteria for a context-aware, real-time computer vision model to monitor ACL injury risk in female youth football players in developing countries. The paper makes two contributions: first, it provides an integrated synthesis that connects computer vision feasibility, female biomechanics, and developing-country application evidence, and second, six evidence-based design criteria are derived from the synthesis that specify what a system must do, giving future model design and expert validation an evidential basis rather than an assumed one.

II. LITERATURE REVIEW

1. ACL Injury Burden in Female Youth Football

López-Valenciano et al. [1] and Pulici et al. [2] both highlight the significant challenges in women's football, with female players sustaining injuries at four to six times higher rates than their male counterparts during similar movement actions. There is thus a higher impact of consequences such as time loss, career disruption, psychological trauma, and a greater risk of re-injury [3]. The economic burden is evidently significant, with studies reporting ACL injury-related costs of up to €50 000, which is unsustainable for resource-constrained women's football development programs in developing countries where systematic under-investment in women's football remains [2], [4], [5]. This challenge is prevalent in youth football, where Sanchez-Sanchez et al. [3] found that female football players aged 13–20 face higher risk rates of 2.5 to 4.8 per 1000 hours of game time, with knee injuries contributing 15 to 25 percent of total injuries.

2. Biomechanical and Maturation-Specific Risk Factors

The link between ACL injury risk and movement quality during non-contact actions is well documented in [1], [13], [14], [15], and [16]. Sanchez-Sanchez et al. [3] found that non-contact actions such as cutting, pivoting, and landing were strongly linked to greater ACL injury risk. Hewett et al. [13] identified knee valgus angle, hip flexion, and neuromuscular control during dynamic tasks as predictors of ACL injury risk in female athletes. Anatomical differences, including a wider pelvis and increased quadriceps angle, as well as hormonal influences on ligament laxity across the menstrual cycle, further contribute to the heightened injury risk profile of female athletes [3]. A recent scoping review of prospective studies confirms that these kinematic measures remain the best-supported biomechanical predictors of primary ACL injury [17]. Injury risk is complicated by additional risk factors related to growth and maturation, with Sanchez-Sanchez et al. [3] and Wik [18] reporting evidence that the bodily changes that occur during adolescence lead to rapid musculoskeletal growth, which affects limb and muscle coordination during sports activities. Wik [18] further cites the need for more studies involving young female populations to address the significant gap in the literature.

3. Resource Constraints and ICT Adoption

The integration of ICT into sports injury prevention has progressed considerably, with technologies such as GPS, wearable biosensors, and motion capture showing promise in sports injury monitoring [8], [9]. The adoption of these technologies in women's football development programs remains limited in developing countries' contexts due to constraints in infrastructure, equipment, and technical expertise [4], [5], [11]. Bakare et al. [6] note that conventional injury prevention programs, such as FIFA 11+, face similarly limited uptake in resource-constrained settings due to the need for specialized expertise and effective program management. Mkumbuzi et al. [11] report the lack of medical staff in women’s football, particularly in developing countries, as a significant factor in higher injury risk in these settings.

4. Computer Vision in Sports Injury Prevention

Computer vision studies in sport show growing potential for pose estimation, movement classification, and feedback generation [8], [9], [12], [19], [20], [21]. Frameworks such as OpenPose, MediaPipe, and BlazePose enable non-invasive approaches to sports injury prevention, enabling real-time movement monitoring and biomechanical analysis [8], [9]. Recent applications have demonstrated the feasibility of pose estimation frameworks for assessing ACL injury risk indicators in athlete populations, with Blanchard et al. [12] and Ouf et al. [21] demonstrating computer vision-based knee valgus assessment in female athletes under controlled conditions. The application of machine learning alongside computer vision has further enabled the development of systems capable of classifying high-risk movement patterns in real time, supporting its potential for integration into training environments [20], [21]. However, existing implementations have largely been limited to controlled laboratory settings, with little consideration of the technical challenges of outdoor multi-player football environments or the constraints in developing countries [10], [12]. This gap establishes the need for the systematic review presented in this paper.

5. Integrated Theoretical Framework

The integrated framework combines the Dynamic Systems Theory (DST) and the Haddon Matrix, providing a lens for reporting the review findings. DST posits that injury risk is not static and arises from the dynamic relationship among a player, the movement action, and the environment [22], [23]. This underpins the identification of biomechanical and environmental parameters to be monitored in a computer vision system.

The Haddon Matrix provides a structured approach to mapping the review findings across the pre-event, event, and post-event phases of injury prevention [24]. The host, agent, and environment dimensions of the Haddon matrix are clearer categories for better understanding the evidence regarding biomechanical parameters, technical, and contextual requirements. This integrated framework will ensure that both technical and contextual considerations are taken into account in the review and the resulting model criteria for female youth football in resource-constrained settings.

III. METHODOLOGY

A systematic literature review (SLR) was conducted using the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines, thereby ensuring a transparent, standardized, and rigorous methodology [25]. The PRISMA framework was determined to be most appropriate for this study, as it is widely adopted for synthesizing evidence across the literature and is useful for identifying gaps worth noting for the development of new injury prevention interventions. The review protocol was not registered with PROSPERO or published in advance, as the review was conducted as part of a wider research study.

1. Search Strategy

The electronic databases utilized in the systematic search included PubMed, IEEE Xplore, and Elsevier ScienceDirect. The search terms used were constructed using Boolean operators and combined keywords as follows: (“computer vision” OR “motion analysis” OR “pose estimation”) AND (“ACL” OR “Anterior Cruciate Ligament” OR “knee injury” OR “lower body injuries”) AND (“female” OR “women” OR “gender” OR “youth”) AND (“football” OR “soccer” OR “sport”). Supplementary contextual terms were also included, such as “resource-constrained”, “developing countries”, “South Africa”, “South African”, and “sub-Saharan Africa”. Reference lists of included studies were also citation-chained to identify studies not returned by the database searches. The searches were restricted to peer-reviewed articles written in English. The initial search was conducted in September 2025 and was updated in July 2026 to capture work published after the original search. The search window was 2019 to 2026, chosen to capture more recent pose estimation and biomechanical research, during which technological capabilities have changed substantially. Studies published before 2019 were retained only where they were foundational to the field, and no later peer-reviewed study reported an equivalent finding. This was done to avoid the converse problem of recency bias, which may overlook previous solutions and approaches and their perceived shortcomings, which would be useful in identifying the model design criteria. Table 1 summarises the search strategy.

Table 1. Summary of Search Strategy

Component	Strategy
Databases	PubMed, IEEE Xplore, Elsevier ScienceDirect
Core search string	("computer vision" OR "motion analysis" OR "pose estimation") AND ("ACL" OR "anterior cruciate ligament" OR "knee injury") AND ("female" OR "women" OR "youth" OR "gender") AND ("football" OR "soccer" OR "sport")
Contextual terms	resource-constrained, developing countries, South Africa, sub-Saharan Africa
Date range	2019–2026. Initial search September 2025, updated July 2026. Pre-2019 studies were retained only where foundational and without a later peer-reviewed equivalent
Language and type	English-language peer-reviewed journal articles and peer-reviewed conference papers; official reports were retained only as contextual background and not counted in the 30-study SLR corpus

2. Inclusion and Exclusion Criteria

The inclusion criteria of the studies were that they: (1) reported on computer vision or AI-based approaches to injury risk monitoring and biomechanical analysis in sport; (2) mentioned ACL injury risk factors, injury prevention, or biomechanical parameters; (3) performed the study on datasets or human participants; and (4) were peer-reviewed journal articles or peer-reviewed conference papers. Reports from official governing bodies such as FIFA and other grey literature were consulted for contextual background, but were not included in the review corpus. The exclusion criteria applied to studies that: (1) exclusively focused on upper limb injuries; (2) focused on non-injury sport analytics; (3) used computer vision or AI-based approaches that focus on non-injury-based aspects of sport; and (4) reported the same finding for the same population using the same method as a study already included, in which case the more recent or larger study was retained.

3. Data Extraction and Quality Assessment

Data extraction was conducted using a standard template to capture the study objectives, data collection methodology, injury prevention methodology, biomechanical parameters analyzed, study findings, and study context. The quality of the studies was assessed using the Mixed Methods Appraisal Tool (MMAT) to account for the mix of qualitative and quantitative studies included. Appraisal was used to assess the confidence that could be placed in each study's contribution to the synthesis, thereby informing how much weight a study carried in theme construction rather than serving as an exclusion threshold; no study was excluded on quality grounds. Actual study appraisal results (i.e., scored appraisal of 30 studies according to all five criteria) were not included in this paper due to limitations disclosed in Section IV. Thematic coding was conducted manually. Stable identifiers (P1-P30, listed in Table 2) were created; all studies were independently coded against the fields collected in the extraction template. Firstly, codes were inductively extracted from the findings by manually reviewing each study. Then, possible themes were identified by grouping the codes in a second pass, with each study's computer vision capability as the main focus. Only themes for which evidence could be found in more than one study and that presented unique implications for computer vision system design were retained. This resulted in five themes as described in Section IV. These five themes were then mapped onto the integrated theoretical framework, which subsequently generated requirements. Technology-assisted coding using ‘Atlas.ti’ was a viable alternative and is planned for use in the primary data collection phase of the wider study.

IV. RESULTS

The searches returned 95 records: 52 from PubMed, 21 from IEEE Xplore, 17 from Elsevier ScienceDirect, and 5 identified through citation chaining. Forty records were removed before screening, comprising 14 duplicates and 26 records falling outside the date window or the sports injury domain. The remaining 55 studies were screened by title and abstract, of which 20 were excluded: 6 as not sport-injury related and 14 as not relevant to the review question. This left 35 reports assessed for full-text eligibility. A further 5 studies were excluded based on the criteria in Section III, resulting in the 30 studies synthesized in this review. PRISMA 2020 does not specify a minimum corpus size; the number of included studies is determined by the eligibility criteria rather than a predefined target [25]. The studies included quantitative, mixed-methods, and systematic reviews, with methodologies such as markerless pose estimation, machine-learning classifiers, smartphone video analysis, wearable sensors, and augmented reality. Five thematic areas were identified as follows: (1) markerless pose estimation for female ACL-relevant kinematics; (2) computer vision detection of high-risk football actions; (3) real-time and coach-facing decision support; (4) calibration gaps for female youth populations; and (5) field and resource-constrained deployment barriers.

1. Thematic Synthesis: Five Computer Vision Findings

Focusing on computer vision as the core of the synthesis, the study identified five distinct findings across the 30 selected articles. Table 3 maps each theme to the supporting articles and the main result.

Table 3. Thematic Synthesis of the 30 selected articles

Thematic areas	**Selected articles**	**Main result**

Theme 1: Markerless pose estimation for female ACL-relevant kinematics	P10, P12, P19-P23, P27	Frameworks such as OpenPose, MediaPipe, BlazePose, and OpenCap can extract knee valgus, knee flexion at landing, and joint angles that are linked to female ACL risk.
Theme 2: CV detection of high-risk football actions	P11, P12, P17, P18, P19-P22	Landing, cutting, pivoting, and sudden deceleration are the primary non-contact injury actions and are observable in video; detection and classification pipelines for these actions in football video have been validated.
Theme 3: Real-time, coach-facing decision support	P16, P21, P22, P25, P26, P28, P30	Computer vision outputs can be converted into real-time form feedback and joint-angle risk scores; monitoring must be decision support, not just data collection, especially where specialists are absent.
Theme 4: Calibration gap for female youth populations	P1-P6, P10, P13, P14, P19-P22, P26	Existing CV ACL systems use adult or mixed-gender thresholds and rarely account for maturation; sex-specific and growth evidence show that these thresholds are not transferable to female youth populations.
Theme 5: Field and resource-constrained deployment barriers	P7-P9, P17, P18, P23, P24, P27, P29, P30	CV evidence is overwhelmingly lab-based; outdoor football introduces occlusion, lighting, and multi-player tracking challenges, and video-only systems cannot fully replace kinetic tools; African CV infrastructure further constrains the field.

2. Theme 1: Markerless Pose Estimation for Female ACL-Relevant Kinematics

Pose estimation frameworks, such as OpenPose, MediaPipe, BlazePose, and the OpenCap system, can operate without physical markers by mapping keypoints to biomechanical kinematic parameters associated with female ACL risk. P10 [13] highlights knee valgus loading and reduced neuromuscular control as prospectively associated with ACL injury risk in female athletes, while P19 [12] and P20 [19] demonstrate that computer vision can measure knee valgus angle from video analysis with acceptable validity and reliability. P22 [20] extends this to real-time joint-angle scoring across multiple lower-limb joints. P23 [32] shows that smartphone video analysis is comparable with laboratory-grade motion capture for lower-limb kinematics, though still sensitive to camera placement and calibration. P24 [33] reports that out-of-lab systems estimate kinetic parameters, such as joint moments, through physics-based modeling or machine learning rather than measuring them directly, as force plates do, so kinetic estimates carry modeling assumptions that kinematic measures do not. Consequently, knee valgus, knee flexion at landing, hip and trunk control, and inter-limb asymmetry are observable in the video. Still, none of the studies establishes female-specific reference values against which to analyze them.

3. Theme 2: Computer Vision Detection of High-Risk Football Actions

The non-contact actions that cause ACL injuries (landing from a jump, side-step cutting, pivoting, and sudden deceleration) are observable through video analysis. P11 [29] demonstrates video-based identification of these actions through analysis of actual ACL injury incidents in professional women's football, and P12 [30] extends this to a wider range of football injury-inciting actions. P17 [8] and P18 [9] review developments in computer vision pipelines for football video in action detection and analysis, including player tracking, action recognition, and pose estimation using broadcast and mobile-camera footage. P21 [21] shows that a computer vision system can provide real-time feedback on movement form during physical activity, and P22 [20] shows that joint-angle-based risk scoring can run in a live athlete assessment context. A direct implication of the observed

studies is that the proposed model should recognize an injury-inducing action and then extract relevant kinematic parameters within the movement window, rather than continuously monitoring all frames. This way, fewer computational resources are required, which is key for minimal-resource deployment.

4. Theme 3: Real-Time, Coach-Facing Decision Support

P21 [21] and P22 [20] demonstrate that computer vision can provide real-time feedback that can inform corrective movement decisions. P30 [39] argues that monitoring must transition from data collection to actionable decision support. P16 [7] shows that machine-learning injury forecasting models can generate practical risk signals for coaching teams when trained on continuous monitoring data rather than one-off screening events, and P25 [34] reviews AI diagnostic tools for sports injury with findings that support clear risk categorization over vague scores. In the South African female youth football context, the argument is supported by P7 [5] and P8 [11], which show that coaches and non-specialist staff are the more practical end users of any injury-prevention tool. The model, therefore, needs to factor in color-coded risk severity levels, plain-language alerts, and post-session summaries that coaches can interpret without advanced medical expertise, while maintaining the underlying kinematic data for further analysis by medical experts.

5. Theme 4: Calibration Gap for Female Youth Populations

P1 [1] through P6 [28] establish that women and girls carry a distinct ACL injury burden and that the underlying risk elements are not gender-neutral. P10 [13] reports that valgus loading and neuromuscular control patterns differ between male and female athletes enough to invalidate the direct use of male-specific thresholds. P6 [28] extends this to the broader environmental and structural factors that shape female ACL risk, arguing against purely biological explanations. For youth athletes, P3 [3], P13 [18], and P14 [31] add an age dimension: rapid musculoskeletal growth during adolescence disrupts inter-limb coordination, changes landing mechanics as observed through computer vision, and shifts the risk profile over a single season. Yet the computer vision studies closest to this population (i.e., P19 [12], P20 [19], P21 [21], and P22 [20]) either use adult reference values, mixed-gender populations, or controlled laboratory settings that lack the context of a developing female player in an outdoor training environment. This calibration gap is a key finding of the review because it specifies the design requirement that the model should account for female- and age-appropriate thresholds.

6. Theme 5: Field and Resource-Constrained Deployment Barriers

P17 [8] and P18 [9] identify occlusion, variable lighting, multi-player tracking, and camera quality as the main barriers to effective outdoor/live training computer vision. P24 [33] reviews out-of-lab portable sensing for ACL assessment and finds that most approaches identified remain proofs of concept, lacking clinical validation or widespread adoption. In contrast, laboratory assessment remains expensive and inaccessible to most players. P9 [10] shows that African computer vision research is constrained by limited local datasets, infrastructure gaps, and barriers to collaboration that affect both model training and practical deployment. These constraints are especially evident in the South African women's football environment, as validated by P7 [5] and P8 [11]. Despite these barriers, P23 [32] provides relevant evidence through the OpenCap system, demonstrating that multi-smartphone video analysis can achieve valid lower-limb kinematics comparable to laboratory motion capture, with a guided setup rather than specialist calibration. P30 [39] argues that injury monitoring approaches must connect field data to practical injury-prevention decisions, which the model should factor in for coaches in grassroots women's football.

7. Design Criteria and Integrated Framework Mapping

The five thematic findings, analyzed using the Haddon Matrix and the DST framework, yield six evidence-based design criteria for a context-aware computer vision model aimed at preventing ACL injuries. Each design criterion relates to the thematic evidence and outlines a requirement that current systems fail to meet for female youth in resource-constrained contexts. Together, they define what such a system must do to be technically valid and practically deployable in resource-constrained women's football programs. The criteria strictly describe what the evidence indicates such a system would need to do, where future research will assess the effectiveness of these criteria. Read through the integrated theoretical framework; these five findings translate into the design requirements summarised in Table 4.

Table 4. Evidence-based design criteria for the proposed model

Criterion	**Practical meaning**	**Supporting selected articles**	**Gap in existing work**
Female- and youth-specific baseline	Interpret risk using player-specific, female-specific, and age-aware information.	P1-P6, P10, P13-P15, P26	Existing CV systems use adult or mixed-gender reference thresholds; no implementation reviewed builds female- or youth-specific baselines for this population.
High-risk action detection	Identify landing, cutting, pivoting, and sudden deceleration during football activities.	P11-P12, P19-P22	Action detection pipelines exist for general sport but have not been tested in outdoor female youth football environments in developing countries.
Kinematic parameter set	Extract knee valgus, knee flexion, hip/trunk control, and asymmetry from the video.	P10-P12, P15, P20, P23-P24, P27	Parameters are technically extractable, but no reviewed system validates the full set against female-specific norms outside a laboratory.
Low-cost technical setup	Use smartphone or consumer-camera input, simple calibration, and limited-compute processing.	P9, P17-P18, P21-P23, P27	Smartphone-based systems exist but have not been deployed or validated in outdoor multi-player football settings in Africa or comparable LMIC contexts.
Actionable decision support	Return clear severity levels and practical feedback, not just raw data.	P16, P25, P26, P28, P30	Existing outputs target analysts or clinicians; no reviewed system produces coach-facing, plain-language risk feedback for non-specialist users in low-resource settings.
Continuous monitoring	Store session trends and update risk profiles as the player and season change.	P13-P16, P24, P28, P30	All reviewed CV systems operate as one-off assessments; none continuously track risk over a season in female youth football.

8. Limitations

None of the 30 studies directly validates a computer vision ACL injury-prevention model for female youth football players in resource-constrained settings, so the design criteria are drawn from adjacent evidence and still need to be tested in the target context. The corpus also combines primary studies with systematic and narrative reviews, so some primary evidence is counted twice: once on its own and once inside a review that includes it. The 30 studies are therefore best read as the evidence available at this intersection, rather than as 30 independent samples. The studies vary in design, participant groups, and measurement tools, which is why the evidence was synthesized thematically and not through a meta-analysis.

Three further limitations relate to the search and the appraisal. Only PubMed, IEEE Xplore, and ScienceDirect were searched, so relevant work indexed in Scopus, Web of Science, or the ACM Digital Library may have been missed. One reviewer also performed the searching, screening, extraction, and appraisal, which raises the risk of selection and extraction bias; co-author review of the protocol, coding frame, and final corpus reduces this risk but does not remove it. MMAT results and the full database-specific filters are not reported here, as neither fits within the prescribed length of this conference paper; both will be reported in the extended version of this study.

Lastly, the corpus is weighted towards work published between 2021 and 2024, with four of the 30 studies published in 2026. Two studies published before 2019 were retained under the rule set out in Section III.1. The prospective evidence linking knee abduction loading to ACL injury in female athletes has not been replicated in a comparable cohort since 2005, reflecting the state of the evidence base.

V. CONCLUSION

This PRISMA-based systematic review synthesized 30 selected studies to establish the evidence base for a context-aware computer vision model for ACL injury prevention in female youth football. The paper makes two contributions. First, a five-theme synthesis that connects computer vision feasibility, biomechanics, and evidence on developing-country deployment in resource-constrained contexts. Second, six evidence-based design criteria that specify what a female-youth-specific, resource-appropriate computer vision ACL prevention system must do across player profiling, action detection, kinematic extraction, risk interpretation, and deployment. These criteria are designed to be taken forward in future research on model design and expert validation work with computer vision specialists, human movement experts, and football coaches. This constitutes the next phase of the broader research of which this paper forms a part. The paper contributes to the broader context of applied AI for healthcare and to the Sustainable Development Goals for women in developing countries.

Abstract
Camera lens contamination from mud, water droplets, dust, or other environmental factors can significantly degrade the performance of vision-based perception systems in autonomous vehicles and mobile robots. This paper presents a comprehensive comparison of fifteen state-of-the-art image classification architectures for automatic camera contamination recognition formulated as a binary classification task. The evaluated models include convolutional neural networks (CNNs), vision transformers, and hybrid architectures. All models are trained exclusively on a synthetic dataset generated with the aiSim autonomous driving simulator. To evaluate synthetic-to-real domain transfer, the trained models are tested on a manually annotated subset of the real-world WoodScape dataset, which contains both clean and naturally mud-contaminated images. The experimental results demonstrate that synthetic training data can effectively support real-world camera contamination recognition despite the domain gap between simulation and reality. Swin-T achieved the highest F1-score, while MaxViT-T obtained the highest ROC-AUC and PR-AUC values. Furthermore, the results indicate that network architecture has a considerably greater influence on cross-domain generalization than model complexity alone. These findings demonstrate the feasibility of using synthetic datasets to develop reliable camera-contamination classifiers and provide practical guidance for selecting suitable image-classification architectures for autonomous driving applications.

Keywords: camera contamination, image classification, synthetic data, domain adaptation, autonomous driving

I. INTRODUCTION

Vision-based perception is a key component of modern advanced driver assistance systems (ADAS) and autonomous vehicles, supporting tasks such as object detection, lane detection, and traffic sign recognition. However, adverse environmental conditions, particularly camera lens contamination caused by mud, water droplets, dust, or insects, can significantly degrade image quality and reduce the reliability of downstream computer vision algorithms. Previous studies have demonstrated the negative impact of such contamination on both image quality and object detection performance, highlighting the importance of reliable camera condition assessment [1-3]. In our previous work, we investigated the impact of synthetic mud contamination on object detection using aiSim-generated datasets [4] and later extended this analysis to naturally occurring contamination [5]. Although these studies demonstrated the challenges posed by camera contamination, they focused on object detector robustness rather than identifying contaminated images. In this paper, we address this problem as a binary image classification task by comparing fifteen state-of-the-art CNN, transformer-based, and hybrid architectures. All models are trained exclusively on synthetic images generated with aiSim and evaluated on manually annotated real-world images from the WoodScape dataset, enabling a comprehensive assessment of synthetic-to-real generalization for automatic camera contamination detection. The remainder of this paper is organized as follows. Section II reviews related work. Section III introduces the aiSim and WoodScape datasets.

Section IV describes the investigated neural network architectures and the experimental methodology. Section V presents the experimental results, while Section VI concludes the paper and outlines future research directions.

II. RELATED WORK

Reliable perception is essential for autonomous vehicles and advanced driver assistance systems, yet the performance of vision-based systems can be severely degraded by contaminants adhering to the camera lens. Consequently, recent research has focused on three main directions: image restoration techniques, contamination detection methods, and synthetic data generation to improve model robustness. One research direction aims to restore degraded images by removing the visual effects of contaminants. He et al. [6] proposed an attentive convolutional neural network for removing adherent mist and raindrops from a single image, demonstrating that restoring image quality significantly improves subsequent vision tasks. Rather than identifying contamination, their approach reconstructs a clean image from a degraded observation, making it suitable as a preprocessing step for downstream perception algorithms. One of the most influential works in this area is SoilingNet [7], which formally introduced the camera soiling detection problem for automotive surround-view cameras. The authors proposed both image-level and tile-level contamination detection using convolutional neural networks. They introduced a large-scale dataset containing multiple types of contamination, including mud, dust, water, and snow. To further improve robustness, they also investigated GAN-based data augmentation by generating synthetic contaminations that complemented the training data [8]. Building upon this work, TiledSoilingNet [9] introduced a coverage-based formulation that estimates contamination severity at the tile level rather than producing only a global image label, enabling a more detailed assessment of contaminated regions. Recent studies have also focused on lightweight deep learning models suitable for embedded automotive platforms. SoildNet [10] is a computationally efficient convolutional neural network employing dynamic group convolutions and channel reordering to reduce computational complexity while maintaining competitive detection accuracy. Unlike earlier approaches that emphasize large CNN architectures, their work demonstrates that contamination detection can also be achieved with compact models designed for real-time execution on resource-constrained hardware. Kim et al. [11] presented a YOLOv5-based droplet-contamination detector trained on a manually annotated dataset comprising approximately 4,000 images. In addition to comparing multiple YOLOv5 variants, the authors integrated the detector with a transparent heater-based cleaning mechanism, demonstrating an end-to-end automatic contamination detection and cleaning system suitable for practical deployment. These studies primarily formulate contamination detection as an object detection problem, in which individual droplets are localized with bounding boxes rather than assessing the overall contamination state of the image. Another important line of research addresses raindrop detection. Kurihata et al. [12] introduced a dedicated windshield raindrop dataset together with a lightweight gradient-based detection algorithm that avoids computationally expensive deep neural networks while maintaining real-time performance. Their work illustrates that carefully designed, handcrafted methods can still provide practical solutions for specific types of contamination. However, they are generally less flexible than modern learning-based approaches across diverse environmental conditions. Recent studies have also investigated the use of synthetic data and its transferability to real-world perception tasks in autonomous driving. Silva et al. [13] systematically investigated how different aspects of synthetic image generation, including geometry, materials, lighting, rendering noise, and post-processing, affect the synthetic-to-real generalization of semantic segmentation models in autonomous driving. Miller et al. [14] proposed EdgeNet, an EfficientNetV2-based end-to-end autonomous driving architecture that uses edge detection and synthetic CARLA data for pretraining, demonstrating improved synthetic-to-real transfer and reduced training time on real-world driving data. Xu et al. [15] proposed a scenario-driven synthetic data generation framework that systematically integrates ODD and OEDR specifications to produce controllable autonomous driving datasets under adverse conditions, demonstrating that the resulting synthetic data can support the evaluation of perception robustness and improve model generalization.

III. DATASETS

The synthetic dataset used in this study was generated with the aiSim autonomous driving simulator developed by aiMotive. The simulator provides a realistic virtual environment for autonomous driving research, supporting reproducible traffic scenarios under controlled conditions, as well as camera contamination simulation. The dataset contains images captured in six urban and suburban environments under sunny, rainy, and snowy conditions. All RGB images have a resolution of 1280×720 pixels. The original dataset consists of 7,288 clean images. For each image, t10 additional mud-contaminated versions were generated using aiSim's built-in contamination model, resulting in different contamination patternsand spatial distributions. Since this work addresses binary image classification, one contaminated version was randomly selected for each clean image. The final dataset , htherefore, contains7,288 clean and 7,288 contaminated images. Representative examples are shown in Fig. 1. The dataset was divided into training, validation, and test subsets using a 70%, 15%, and 15% split. To prevent data leakage, clean and contaminated versions of the same source image were never included simultaneously, and the split was designed to minimize scene overlap between subsets. This strategy provides a more reliable evaluation of model generalization.

Figure 1. Samples from the synthetic aiSim dataset. The first row contains clean images, while the second row presents examples with simulated mud contamination.

To evaluate synthetic-to-real generalization, the publicly available WoodScape dataset [16] was used. WoodScape is a real-world automotive fisheye image dataset containing more than 10,000 images with annotations for several perception tasks. Among the publicly available datasets examined in this study, it was the only one containing a sufficiently large number of images with naturally occurring mud contamination, making it suitable for evaluation. As WoodScape does not provide camera contamination annotations, all images were manually inspected. A total of 3,698 images with visible mud contamination were identified, while an additional 3,698 clean images were randomly selected and visually verified. The resulting evaluation dataset, therefore, contains 7,396 images, evenly distributed between the two classes. Representative examples are shown in Fig. 2. Unlike the synthetic aiSim dataset, WoodScape was used exclusively for testing. No images were included in the training or validation process, allowing evaluation of how well models trained solely on synthetic data generalize to real-world camera contamination.

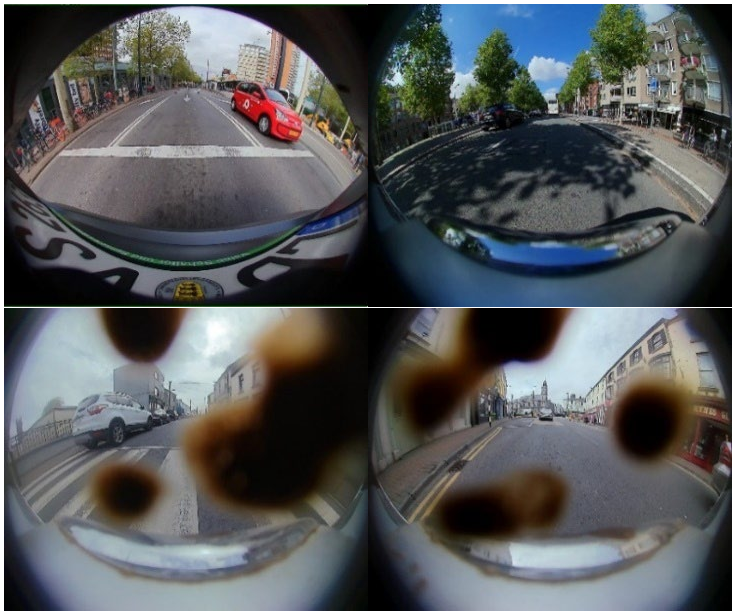

Figure 2. Samples from the WoodScape dataset. The first row contains clean images, while the second row shows images with naturally occurring mud contamination on the camera lens.

IV. METHODOLOGY

To investigate synthetic-to-real generalization, fifteen state-of-the-art image classification models representing CNN, Transformer, and hybrid architectures were evaluated. Table 1 summarizes the evaluated models: CAFormer-S18 [17], CoAtNet-0 [18], ConvNeXtV2-Tiny [19], DeiT-Small [20], ECA-NFNet-L0 [21], EfficientNetV2-S [22], LeViT-128 [23], MaxViT-Tiny [24], MobileNetV3-Large [25], PoolFormer-S12 [26], PVTv2-B2 [27], RegNetY-032 [28], ResNet50 [29], Swin-Tiny [30], and ViT-Base [31]. All models were initialized with ImageNet-pretrained weights and fine-tuned after replacing the original classification layer with a two-class output layer. To ensure a fair comparison, identical training settings were used for all models. Input images were resized to 224×224 pixels. Training employed the AdamW optimizer [32] with an initial llearning rate of 1×10 üssü eksi 4 son üst simge, weight of 1×10 üssü , eksi 4 son üst simge, weight decay of 1×10 üssü , eksi 4 son üst simge, weiweight decay 1×10^{-4}, weigdecay of 1×10^{-4}, cross-entropy loss, a batch size of 8, and 15 training epochs. The learning rate followed a cosine annealing schedule ($T_{\max} = 15$). Data augmentation consisted of horizontal flipping ($p = 0.5$) and color jittering of brightness, contrast, saturation, and hue. All experiments were implemented using PyTorch 1.12 [33]. Each model was trained on the synthetic aiSim dataset, while the validation set was used for model selection. Performance was then evaluated on the held-out synthetic test set and the independently constructed real-world WoodScape dataset, enabling direct comparison of synthetic-to-real generalization under identical training conditions.

Table 1. Overview of the evaluated image classification models

Category	Model	Parameters
CNN	MobileNetV3-Large [25]	4,204,594
	RegNetY-3.2GF [28]	17,926,364
	ECA-NFNet [21]	21,843,534
	EfficientNetV2 [22]	22,151,882

	ResNet-50 [29]	23,512,130
	ConvNeXt V2-T [19]	27,868,034
Hybrid	LeViT-128 [23]	8,445,476
	CAFormer-S18 [17]	24,296,754
	CoAtNet-0 [18]	26,668,100
	MaxViT-T [24]	30,404,554
Transformer	PoolFormer-S12 [26]	11,403,202
	DeiT-S [20]	21,666,434
	PVTv2-B2 [27]	24,850,882
	Swin-T [30]	27,520,892
	ViT-Base [31]	85,800,194

V. EXPERIMENTAL RESULTS

The proposed approach was evaluated by training all classification models exclusively on the synthetic aiSim dataset and subsequently evaluating them on the real-world WoodScape dataset. Consequently, the reported results quantify each architecture's ability to generalize across the synthetic-to-real domain gap, rather than its performance on data from the same distribution. Fig. 3 summarizes the overall performance of the evaluated architectures. Despite being trained solely on synthetic images, several models achieved excellent performance on real-world camera contamination, demonstrating that the synthetic contamination generated by aiSim provides sufficiently representative visual characteristics for learning transferable feature representations. Among all evaluated models, Swin-T achieved the highest classification performance with an F1-score of 0.965, followed by CoAtNet-0 (0.945), PoolFormer-S12 (0.923), and MaxViT-T/ECA-NFNet (0.911). In contrast, DeiT-S obtained the lowest performance, indicating that the ability to generalize to real contamination strongly depends on the selected network architecture. The relationship between model complexity and classification performance further confirms that increasing the number of trainable parameters alone does not guarantee improved generalization. Although ViT-Base contains aapproximately 886868686 86*illiorameters, several corably smaller archiectures have* chieved superior results. Conversely, models with comparable parameter counts often exhibited substantially different performance levels, suggesting that architectural design has a greater impact on synthetic-to-real transfer than network capacity itself.

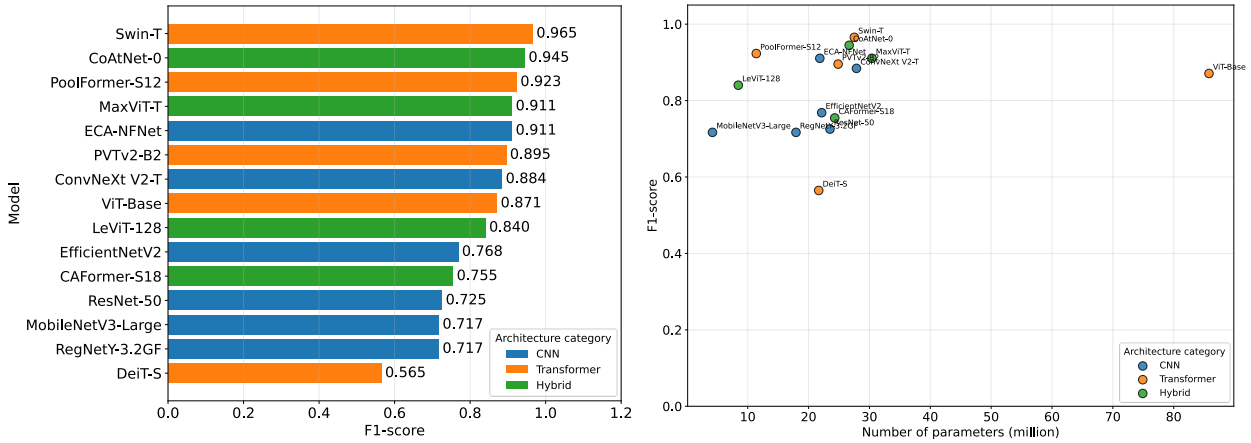

Figure 3. Overall comparison of all evaluated models.

Among the CNN-based models, ConvNeXt V2-T achieved the strongest performance, with ROC-AUC 0.982 and PR-AUC . 983.. Its ROC and Precision–Recall curves consistently dominate those of the remaining CNN architectures, indicating excellent discrimination capability across different operating thresholds. ResNet-50 and ECA-NFNet-L0 also demonstrated strong generalization performance, while RegNetY-3.2GF achieved slightly lower but still competitive results. The remaining CNN architectures exhibited considerably weaker performance. MobileNetV3-Large and EfficientNetV2 showed substantially lower ROC and Precision–Recall characteristics, indicating that these architectures struggle to preserve discriminative representations when transferred from synthetic to real-world images. Overall, the CNN family exhibited the largest performance variation among the evaluated architecture groups, demonstrating that convolutional architectures differ significantly in their ability to handle domain shifts caused by camera contamination.

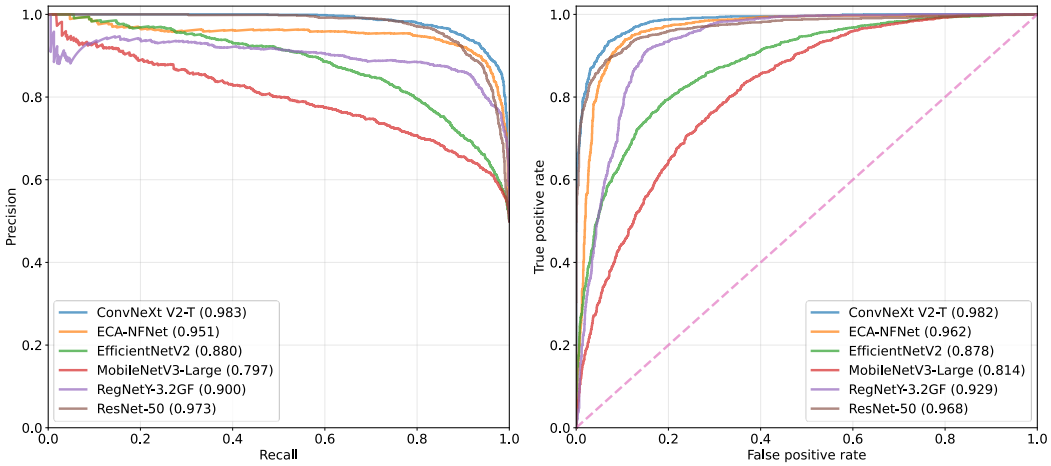

Figure 4. Precision-Recall (left) and ROC (right) curves for the CNN models.

The Transformer-based models generally demonstrated more consistent performance than the CNN architectures. Swin-T clearly outperformed all other Transformer models, achieving the highest ROC-AUC (0.996) and PR-AUC (0.996). Its Precision–Recall curve maintains very high precision even at high recall, indicating highly reliable discrimination between clean and contaminated images. ViT-Base also produced strong results despite being the largest evaluated model. However, its considerably larger number of trainable parameters did not translate into superior classification performance. PoolFormer-S12 and PVTv2-B2 exhibited similar operating characteristics, while DeiT-S consistently remained the weakest Transformer architecture. These observations indicate that modern hierarchical Transformer designs provide substantially better cross-domain robustness than earlier vision Transformer architectures.

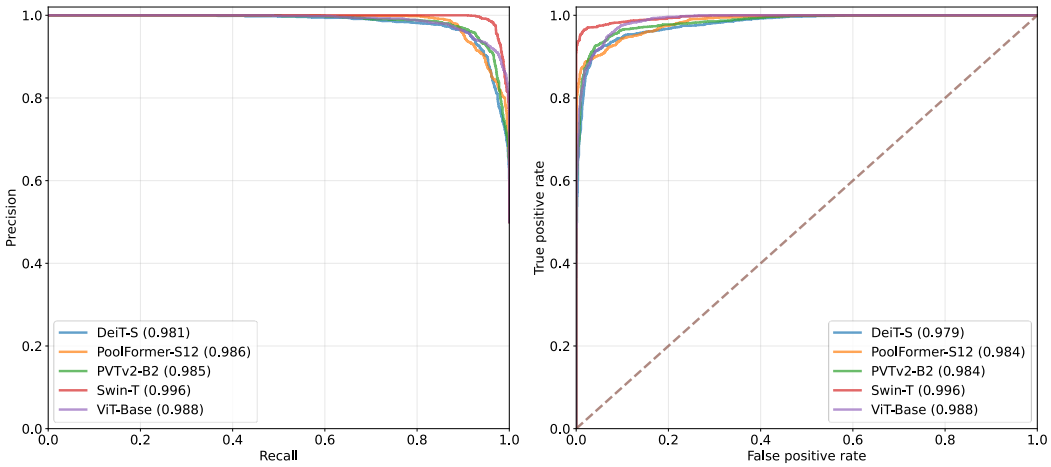

Figure 5. Precision-Recall (left) and ROC (right) curves for the transformer models.

The hybrid architectures combined the advantages of convolutional and Transformer-based feature extraction, resulting in consistently strong performance. In terms of both ROC-AUC and PR-AUC, MaxViT-T achieved the highest values among all evaluated models. CoAtNet-0 and CAFormer-S18 also demonstrated high classification accuracy, while LeViT-128 achieved competitive performance despite containing significantly fewer trainable parameters. Compared with CNN architectures, the hybrid models exhibited considerably smaller performance differences, suggesting that combining local convolutional processing with global attention mechanisms improves robustness to the synthetic-to-real domain shift.

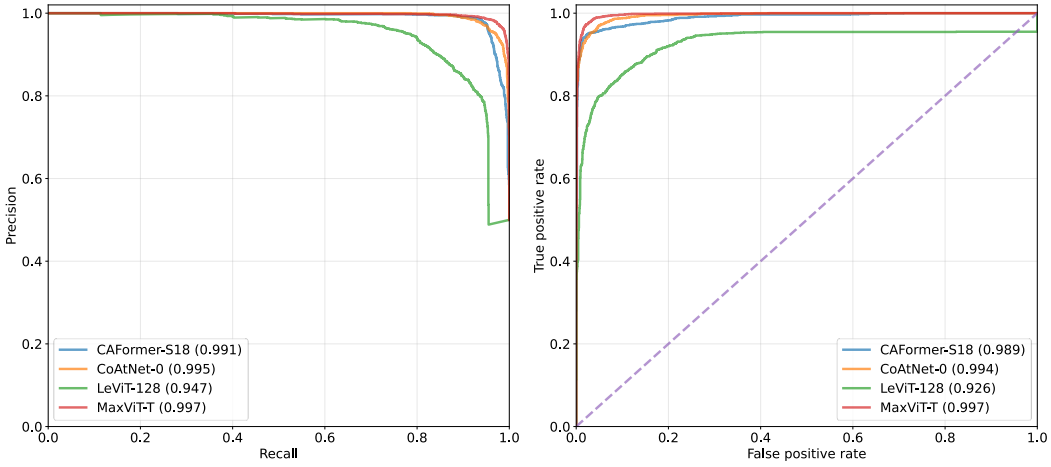

Figure 6. Precision-Recall (left) and ROC (right) curves for the hybrid models.

The confusion matrices provide further insight into the classification behavior of the evaluated models. The best-performing architectures, including Swin-T, CoAtNet-0, and PoolFormer-S12, produce only a small number of false-positive and false-negative predictions, indicating balanced performance across both classes. In contrast, lower-performing models exhibit substantially higher error rates. For example, DeiT-S frequently misclassifies both clean and contaminated images, confirming the observations from the ROC and Precision–Recall curves. Similar behavior is observed for ResNet-50 and MobileNetV3-Large. None of the evaluated architectures

exhibits a pronounced bias toward either class. Instead, performance differences primarily stem from the overall number of misclassified samples, suggesting that the balanced synthetic training dataset effectively mitigated class imbalance, while the remaining errors are mainly due to the domain gap. Overall, the results demonstrate that synthetic aiSim images provide an effective basis for camera contamination classification on real-world data. However, performance strongly depends on the network architecture, with hierarchical Transformer and hybrid models consistently outperforming conventional CNNs. In contrast, model complexity alone shows only a weak relationship with cross-domain generalization.

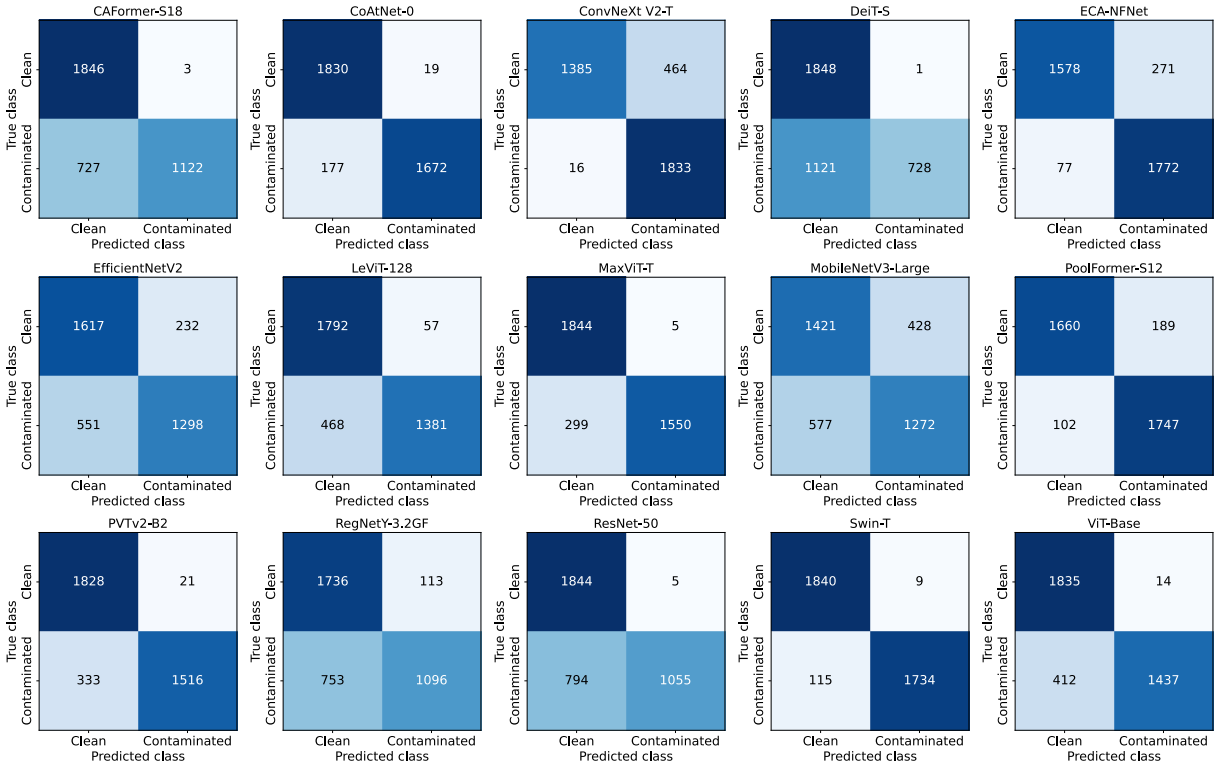

Figure 7. Confusion matrices of the evaluated models.

VI. CONCLUSIONS AND FUTURE WORK

This paper investigated the use of synthetic data for binary camera-contamination classification by evaluating the cross-domain generalization of 15 state-of-the-art CNN, transformer, and hybrid architectures. All models were trained exclusively on a synthetic aiSim dataset and evaluated on the real-world WoodScape dataset. The results demonstrate that synthetic training data can effectively support real-world camera contamination classification despite the domain gap between simulation and reality. Swin-T achieved the highest F1-score and ranked second in both ROC-AUC and PR-AUC, demonstrating consistently strong performance across all evaluation metrics. MaxViT-T achieved the highest ROC-AUC and PR-AUC values, indicating superior class-separation capability across different decision thresholds. Although no single architecture was superior across all metrics, Swin-T delivered the most consistently high performance while requiring fewer parameters than MaxViT-T. The experiments also showed that network architecture has a greater impact on generalization than model complexity, as several medium-sized models outperformed substantially larger ones. Overall, the findings indicate that synthetic datasets provide a practical alternative to expensive manual data collection for camera contamination classification, while emphasizing the importance of architecture selection for robust cross-domain

performance. Future work will validate the proposed approach using our own real-world measurements acquired under different driving conditions. In addition, the current binary classification task will be extended to other naturally occurring camera contaminations to investigate generalization across multiple contamination types. The long-term goal is to develop a unified camera contamination detection framework for improving perception monitoring and the reliability of autonomous driving systems under challenging environmental conditions.

Abstract

As organizations continue to invest in Big Data Analytics (BDA), understanding the conditions that support effective implementation has become increasingly important. Firms sharing the same adoption status often differ substantially in their technological, organizational, and environmental preparedness. This study applies a Multi-Criteria Decision-Making (MCDM) approach, grounded in the Technology–Organization–Environment (TOE) framework, to evaluate post-adoption readiness among BDA-adopting firms. The analysis draws on survey data collected from Albanian large taxpayers actively using BDA between May 2024 and May 2025. Nine TOE determinants served as evaluation criteria. The CRITIC method derived objective criterion weights, while TOPSIS computed readiness scores, ranking firms by proximity to ideal conditions. Risk (0.185) and Complexity (0.176) exhibited the greatest discriminating power, together accounting for roughly 36% of the total weight, followed by Organizational Readiness (0.115); External Support received the lowest weight. Readiness scores ranged from 0.424 to 0.691 (mean: 0.529), indicating considerable variation among adopters despite their shared adoption status. A sensitivity analysis against equal weighting (Spearman $\rho = 0.36$) confirmed that objective weighting materially affected prioritization. The study extends the TOE framework toward a post-adoption readiness perspective and demonstrates the applicability of CRITIC–TOPSIS for evaluating organizational preparedness in an emerging-economy context.

Keywords: Big Data Analytics, TOE framework, CRITIC, TOPSIS, MCDM

I. INTRODUCTION

BDA has become an important capability for organizations seeking to improve decision-making, operational efficiency, competitiveness, and business performance [1], [2]. As firms increasingly rely on large volumes of structured and unstructured data, the ability to transform data into actionable insights is no longer only a technological issue, but also an organizational and strategic requirement [3]. However, adopting BDA does not necessarily imply that all firms are equally prepared to use it effectively. Organizations that report BDA adoption may still differ considerably in terms of technological infrastructure, organizational capabilities, managerial support, external pressures, and perceived implementation barriers. Most previous studies on BDA have focused on explaining adoption decisions by comparing adopters and non-adopters [4]. While this perspective is important, it provides limited insight into the readiness levels of firms that have already adopted BDA. Post-adoption readiness deserves particular attention because the effectiveness of BDA depends not only on whether the technology is adopted, but also on the conditions under which it is implemented and used. Firms may formally adopt BDA while still facing problems related to complexity, risk, lack of organizational readiness, insufficient external support, or limited managerial commitment [5]. To address this issue, this study evaluates BDA readiness among firms that have already adopted BDA, using the TOE framework as the theoretical basis.

The TOE framework is appropriate for organizational-level technology studies because it explains adoption and implementation through three interrelated contexts: technological, organizational, and environmental [6]. In this study, nine TOE determinants are considered: Relative Advantage, Compatibility, Complexity, Risk, Top Management Support, Organizational Readiness, Competitive Pressure, External Support, and Government Support. Methodologically, the study employs an MCDM approach, combining the CRITIC and TOPSIS methods. The CRITIC method is used to determine objective criterion weights based on the variability and interrelationships among criteria. In contrast, TOPSIS is used to rank firms by their proximity to the ideal TOE readiness conditions. This integrated approach enables identification of which TOE determinants contribute most strongly to readiness and ranking of BDA-adopting firms by overall preparedness. The contribution of this study is threefold. First, it extends BDA adoption research by shifting the focus from adoption versus non-adoption to post-adoption readiness. Second, it introduces a CRITIC–TOPSIS framework for evaluating readiness among BDA adopters. Third, it provides empirical evidence from large Albanian taxpayers, offering insights in an emerging-economy context where digital transformation and advanced analytics capabilities are still developing. Accordingly, the study addresses two research questions:

RQ1: Which TOE determinants contribute most strongly to differentiating readiness levels among firms that have already adopted BDA?

RQ2: To what extent do BDA-adopting firms differ in their overall post-adoption readiness?

II. LITERATURE REVIEW

The TOE framework has been widely used to explain technology adoption and implementation at the organizational level. Originally introduced by [6], the framework suggests that technological innovation is shaped by three main contexts: technological, organizational, and environmental. Unlike individual-level acceptance models, TOE is particularly well-suited to firm-level analysis because it captures both internal and external factors that influence the adoption and use of information technologies. In the context of BDA, the technological dimension includes factors such as relative advantage, compatibility, complexity, and risk. Relative advantage refers to the perceived benefits that BDA can offer compared with existing analytical tools or decision-making practices. Compatibility reflects the extent to which BDA fits with existing systems, business processes, and organizational needs. Complexity, on the other hand, represents the perceived difficulty of implementing and using BDA technologies. Risk is also an important technological barrier, especially because BDA involves large-scale data processing, privacy concerns, security issues, and uncertainty regarding implementation outcomes. Prior studies emphasize that technological challenges, including fragmented data systems, integration issues, data security concerns, and system complexity, can significantly affect BDA implementation [2], [5]. The organizational dimension includes internal capabilities and resources that support successful implementation. Top management support is frequently identified as a key factor in technology adoption because leadership commitment influences resource allocation, strategic prioritization, and employee engagement. Organizational readiness is also essential, as firms need adequate financial, technical, and human resources to implement BDA effectively.

Studies on BDA adoption suggest that organizations with stronger data-driven cultures, better internal capabilities, and higher managerial commitment are more likely to implement analytics initiatives successfully [2], [3]. Consistent with this, technological and organizational factors are the more significant determinants of BDA adoption among firms [7]. The environmental dimension captures external pressures and support mechanisms that influence organizational decisions. Competitive pressure may encourage firms to adopt BDA to improve performance, respond to market changes, and remain competitive. External support, including vendor assistance, consulting services, and technology partners, may reduce implementation barriers. Government

support and regulatory conditions may also influence the adoption and use of data-driven technologies, particularly in emerging economies where institutional support can shape digital transformation strategies. Previous studies indicate that external competition, regulatory requirements, and institutional support can affect BDA adoption and implementation outcomes [5]. Although the TOE framework provides a comprehensive explanation of BDA adoption, most studies have focused on identifying determinants of adoption rather than evaluating readiness among existing adopters. This represents an important gap because adoption status alone does not indicate whether a firm is fully prepared to benefit from BDA. Firms may adopt BDA but differ substantially in their technological maturity, organizational capacity, and environmental support. Therefore, readiness assessment requires a more comparative and multi-dimensional approach. Multi-Criteria Decision-Making methods are useful for this purpose because they allow researchers to evaluate alternatives based on multiple criteria simultaneously. The CRITIC method is an objective weighting technique that determines criterion importance based on each criterion's variability and its conflict with other criteria. Criteria that exhibit greater variation and provide more unique information receive greater weight. This makes CRITIC suitable for organizational datasets in which subjective, expert-based weighting may introduce bias [8], [9]. TOPSIS is another widely used MCDM method for ranking alternatives based on their distances from the ideal and negative ideal solutions. The method assumes that the best alternative should be closest to the positive ideal solution and farthest from the negative ideal solution. In information systems and project selection contexts, TOPSIS has been applied to rank alternatives according to criteria such as reliability, cost-effectiveness, performance, and implementation feasibility [9], [10]. The integration of CRITIC and TOPSIS provides a structured, data-driven framework for readiness evaluation and has been applied effectively in recent multi-criteria evaluation studies [11]. Recent TOE-based studies have addressed BDA adoption in SMEs [12] and pre-adoption readiness in the health sector [13]; however, post-adoption readiness among firms that have already implemented BDA remains comparatively underexplored. CRITIC determines the objective importance of TOE determinants, while TOPSIS transforms these weighted criteria into readiness scores and rankings. This combined approach is especially appropriate for the present study because BDA readiness is multidimensional and cannot be captured by a single indicator. By applying CRITIC–TOPSIS to BDA-adopting firms, this study contributes to the literature by offering a post-adoption readiness assessment framework that identifies both the most influential TOE determinants and firms' relative preparedness.

To position the present study within the existing literature, Table 1 summarises representative TOE-based studies on BDA adoption and readiness, highlighting their contexts, methods, and analytical foci.

III. METHODOLOGY

This study applies an MCDM approach to evaluate the readiness of firms that have adopted BDA. Data were collected between May 2024 and May 2025 through a structured questionnaire distributed to large taxpayers. Because the survey employed a two-instrument design, missing values were addressed using the Expectation–Maximization (EM) algorithm, which preserves the aggregate means and covariance structure on which the CRITIC–TOPSIS criteria are constructed. As the analysis relies on construct-level scores derived from these aggregate statistics rather than on individual-level responses, the resulting readiness ranking is robust to the specific imputed values. The EM procedure was applied to the full sample of 121 large taxpayers, following the TOE measurement structure, after which the CRITIC–TOPSIS method was applied to firms reporting active BDA adoption. The study focuses not on explaining adoption versus non-adoption, but on assessing the relative readiness levels of firms that have already implemented BDA. The analytical framework is based on the TOE model. Nine determinants were used as evaluation criteria: Relative Advantage (RA), Compatibility (CO), Complexity (C), Risk (RI), Top Management Support (M), Organizational Readiness (OR), Competitive Pressure (CP), External Support (ES), and Government Support (G). Although the TOE determinants were originally formulated in the context of the adoption decision, the underlying constructs remain conceptually relevant during the implementation stage. Complexity, risk, organizational readiness, and related conditions do not cease to operate once a technology is formally adopted; rather, they continue to shape how effectively firms integrate, manage, and sustain BDA in practice. The determinants are therefore interpreted as indicators of ongoing post-adoption readiness rather than of the initial adoption choice. Each construct was measured through multiple questionnaire items using a five-point Likert scale ranging from strong disagreement to strong agreement. Before the MCDM analysis, the psychometric properties of the measurement instrument were assessed. Internal consistency was evaluated using Cronbach's Alpha, while construct reliability was assessed using composite reliability (CR). Convergent validity was assessed using the Average Variance Extracted (AVE), and discriminant validity was confirmed following the Fornell–Larcker criterion, as the square root of each construct's AVE exceeded its correlations with the remaining constructs. The results confirmed satisfactory reliability and validity: all constructs exceeded the recommended thresholds, with Cronbach's alpha ranging from 0.845 to 0.962, composite reliability (CR) from 0.851 to 0.963, and AVE from 0.657 to 0.843.

Composite scores for each TOE determinant were calculated by averaging the corresponding questionnaire items. Because each construct was first validated as a reliable and unidimensional measure — with Cronbach's alpha, composite reliability, and AVE all exceeding recommended thresholds and discriminant validity confirmed through the Fornell–Larcker criterion — the averaging of items into a single construct score constitutes a justified representation of the underlying latent variable. This aggregation is consistent with standard practice when MCDM techniques are applied to validated survey constructs. These scores were then used as evaluation criteria in the MCDM framework. The recommended thresholds applied were 0.70 for Cronbach's alpha and composite reliability, and 0.50 for AVE [14]. To determine the relative importance of the TOE determinants, the CRITIC method was employed. CRITIC is an objective weighting technique that derives criterion weights directly from the observed data rather than relying on expert judgments. The method simultaneously accounts for the variability of each criterion and its degree of correlation with the other criteria. Consequently, criteria exhibiting higher variability and providing more unique information receive greater weights. This characteristic makes CRITIC particularly suitable for organizational datasets where subjective weighting may introduce bias. It should be emphasized that CRITIC weights express the discriminating and informational power of each criterion within the observed sample rather than its intrinsic strategic or managerial importance. A high weight, therefore, indicates that firms differ substantially on that criterion, making it informative for distinguishing readiness levels, which is precisely the analytical objective of this study, and not that the criterion is theoretically more important than the others.

Following the weighting stage, the TOPSIS was applied to assess the readiness level of each BDA-adopting firm. TOPSIS is one of the most widely used MCDM techniques because it evaluates alternatives based on their proximity to the ideal solution and their distance from the negative ideal solution. In the present study, Relative Advantage, Compatibility, Top Management Support, Organizational Readiness, Competitive Pressure, External Support, and Government Support were treated as benefit criteria. In contrast, Complexity and Risk were treated as cost criteria, as higher values represent barriers to successful BDA implementation. The decision matrix was normalized using vector normalization before applying the criterion weights. The combined CRITIC-TOPSIS framework generated two principal outputs. First, it produced objective weights indicating the relative importance of each TOE determinant. Second, it generated a readiness score for each firm, enabling ranking of BDA adopters by overall preparedness. This approach provides a comprehensive, data-driven assessment of organizational readiness and enables identification of the TOE factors that contribute most strongly to successful BDA implementation. All analyses were conducted in R using customized scripts for data preparation, CRITIC weighting, and TOPSIS ranking procedures. The overall analytical workflow, from data collection to sensitivity analysis, is summarised in Figure 1.

Figure 1. CRITIC–TOPSIS methodological workflow

IV. RESULTS

The CRITIC-TOPSIS framework was applied to assess the readiness levels of BDA-adopting firms and to identify the relative importance of TOE determinants. The analysis was conducted in two stages.
First, the CRITIC method was used to derive objective criterion weights based on the variability and informational content of the TOE factors. Second, the TOPSIS method was employed to calculate readiness scores and rank firms according to their proximity to the ideal TOE conditions. The results provide insights into the determinants that contribute most strongly to organizational readiness and reveal differences in readiness levels among firms that have already implemented BDA.

Table 2 presents the objective weights generated through the CRITIC method. The results indicate that Risk (0.185) and Complexity (0.176) received the highest weights among all TOE determinants. Together, these two determinants account for 36.15% of the total weight, emphasizing the dominant role of technological barriers in differentiating readiness levels among BDA adopters.
This suggests that these two factors provide the greatest information and discrimination among BDA-adopting firms. In other words, firms differ substantially in their perceptions of implementation risk and technological complexity, making these determinants particularly influential in evaluating organizational readiness. Organizational Readiness ranked third with a weight of 0.115, followed by Relative Advantage (0.105). These findings highlight the importance of internal capabilities and the perceived benefits of BDA adoption. In contrast, External Support (0.075), Competitive Pressure (0.079), and Top Management Support (0.082) received comparatively lower weights, indicating lower variability and lower informational contribution within the sample.

Table 2. CRITIC Weights of TOE Determinants

Rank	Criterion	Weight
1	Risk (RI)	0.185
2	Complexity (C)	0.176
3	Organizational Readiness (OR)	0.115
4	Relative Advantage (RA)	0.105
5	Compatibility (CO)	0.091
6	Government Support (G)	0.091
7	Top Management Support (M)	0.082
8	Competitive Pressure (CP)	0.079
9	External Support (ES)	0.075

Figure 2 provides a visual representation of these weights, ordered from highest to lowest, making the pronounced gap between the two technological criteria and the remaining determinants readily apparent.

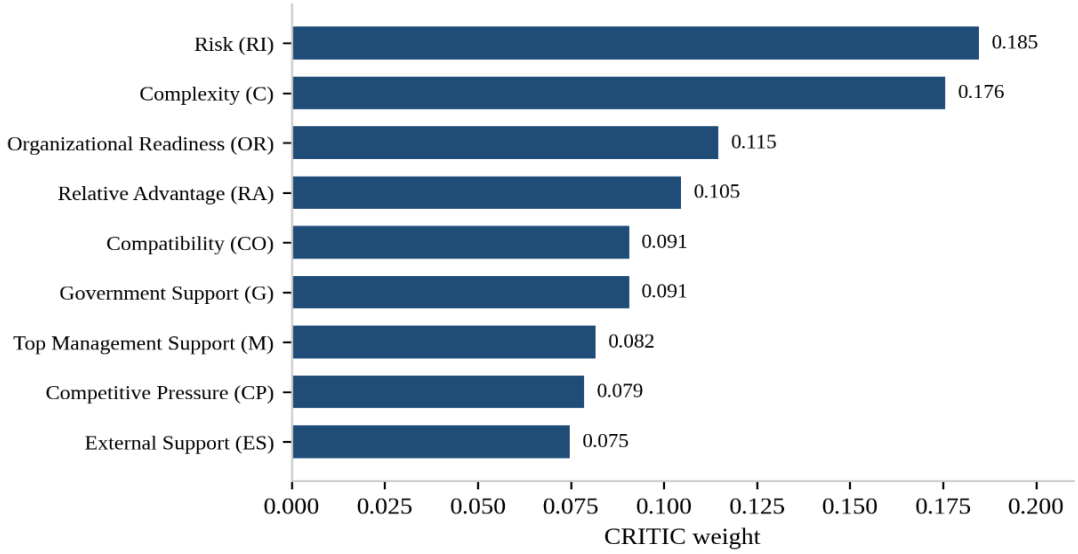

Figure 2. CRITIC weights of the nine TOE determinants

Table 3 presents the aggregated importance of the three TOE dimensions based on the CRITIC-derived weights of their respective determinants. The technological dimension accounts for more than half of the total importance (0.557), indicating that technological considerations dominate the readiness assessment of BDA-adopting firms. This result is primarily driven by the high weights assigned to Risk and Complexity, which emerged as the two most influential determinants in the analysis. The environmental dimension ranks second with a cumulative weight of 0.245, suggesting that external conditions, including competitive pressure, external support, and government support, contribute to organizational readiness but play a less prominent role than technological factors. The organizational dimension received the lowest overall weight (0.197). Although Organizational Readiness emerged as one of the most important individual determinants, the combined contribution of organizational factors remains lower than that of the technological dimension. It should be noted, however, that the aggregated dimensional weights are partly a function of the number of criteria assigned

to each dimension. The technological dimension comprises four determinants, the environmental dimension three, and the organizational dimension only two. When the average weight per criterion is considered, the gap narrows: 0.139 for the technological dimension, 0.099 for the organizational dimension, and 0.082 for the environmental dimension. The technological dimension, therefore, remains dominant on both measures, but the comparison of raw dimensional sums should be interpreted with this structural asymmetry in consideration. The findings indicate that technological conditions represent the primary source of differentiation among BDA-adopting firms and therefore deserve particular attention when assessing organizational readiness.

Table 3. Relative Importance of TOE Dimensions Based on CRITIC Weights

TOE Dimension	Weight	Rank
Technological	0.557	1
Environmental	0.245	2
Organizational	0.197	3

Table 4 summarizes the distribution of TOE-TOPSIS readiness scores across the BDA-adopting firms. The readiness scores range from 0.424 to 0.691, with an average value of 0.529. The relatively wide range of scores indicates that not all adopters share the same level of readiness, even after implementing BDA solutions. The median score of 0.526 indicates that approximately half of the firms exhibit readiness levels above this threshold, while the remaining firms display lower preparedness. The difference between the minimum and maximum values further suggests considerable heterogeneity among adopters regarding their technological, organizational, and environmental conditions.

To assess the robustness of the results to the choice of weighting method, a sensitivity analysis was conducted comparing the CRITIC-weighted ranking with an equal-weight TOPSIS solution. The Spearman rank correlation between the two rankings was $\rho = 0.36$, indicating only a weak-to-moderate association. The choice of weighting scheme, therefore, materially affected the resulting prioritization of firms.

Table 4. Descriptive Statistics of TOE-TOPSIS Scores

Statistic	Value
Minimum	0.424
1st Quartile	0.476
Median	0.526
Mean	0.529
3rd Quartile	0.585
Maximum	0.691
St. deviation	0.065

V. DISCUSSION

This study examined post-adoption BDA readiness among Albanian large taxpayers by integrating the TOE framework with the CRITIC–TOPSIS methodology. The findings demonstrate that firms reporting active BDA adoption remain substantially heterogeneous in their technological, organizational, and environmental preparedness. This supports the central argument that adoption should not be treated as a binary organizational condition: firms may formally implement BDA technologies while differing considerably in their capacity to manage implementation barriers, integrate analytical systems, and mobilize internal resources. Risk and

Complexity emerged as the criteria with the greatest discriminating power, together accounting for more than one-third of the total weight. This is in line with research emphasizing that data security concerns, implementation uncertainty, and technical integration challenges remain central obstacles even after adoption, consistent with readiness assessments in other sectors that emphasize organizational preparedness [13]. Maroufkhani et al. [2] identify complexity, uncertainty, and insecurity among the significant determinants of BDA adoption, while Hamed and Bohari [5] similarly emphasize technological and infrastructural barriers to analytics adoption in developing-economy contexts. The high weight on Risk indicates that adopting firms differ considerably in their perceptions of data-related uncertainty, privacy, and security — a relevant finding given that BDA systems typically integrate large, heterogeneous datasets across multiple organizational functions. Readiness, therefore, cannot be evaluated solely by the presence of analytical technologies; it must also capture the firm's capacity to identify and mitigate implementation risks.

Complexity, ranked second, indicates that the perceived difficulty of implementing and integrating BDA is an important source of variation among adopters. Although all firms in the sample reported adoption, they differ in system sophistication, availability of technical expertise, compatibility of data sources, and the extent to which analytics are embedded in organizational routines. Adoption does not necessarily imply successful integration: firms may implement BDA tools at a formal or limited level while continuing to face difficulties with technical skills, interoperability, and process redesign. The prominence of these two criteria explains why the technological dimension received the highest aggregated weight, exceeding the environmental and organizational dimensions. This should not be read as evidence that the latter are unimportant. CRITIC weights reflect variability and informational contribution within the observed sample rather than causal effects, so the technological dimension appears dominant because technological conditions differentiate firms more strongly than other conditions in this particular group of adopters. Organizational Readiness ranked third, confirming the importance of internal resources and implementation capacity. Maroufkhani et al. [2] identify organizational readiness and top management support as significant determinants of BDA adoption, while Mikalef et al. [3] emphasize that organizational capabilities and data-driven culture underpin the development of analytics capacity. Even where technological barriers dominate the readiness assessment, internal capacity remains a foundation for sustaining implementation. The weight assigned to Relative Advantage further suggests that perceived benefits remain relevant after adoption. Traditionally examined as a predictor of the adoption decision, perceived usefulness may also influence whether firms deepen their analytical capabilities or limit implementation. Top Management Support received a comparatively lower weight, which does not imply that managerial support is unimportant. Since all sampled organizations had already implemented BDA, a minimum level of managerial commitment was likely present across the sample, reducing variability and, therefore, the informational contribution. A similar logic applies to the environmental dimension, which ranked second in aggregate. Government Support may be especially relevant in emerging economies, where institutional policies and public investment shape firms' capacity to develop analytics capabilities, and Competitive Pressure may encourage faster analytical response to market developments. External Support received the lowest weight, possibly because large taxpayers command stronger internal technical and financial resources than smaller firms and depend less on external providers, or because vendor and consultancy support is relatively uniform across the sample. This diverges from contexts in which external expertise is considered essential for overcoming resource constraints, suggesting that its importance depends on firm size, market development, and the availability of specialized providers. The distribution of TOPSIS scores, ranging from 0.424 to 0.691, provides further evidence of heterogeneity: firms with identical formal adoption status occupy considerably different levels of preparedness. This moves the analysis beyond the conventional adopter/non-adopter distinction and indicates that adoption represents only one stage of a broader implementation process. The sensitivity analysis reinforces the methodological value of objective weighting: the weak-to-moderate Spearman correlation between the CRITIC-weighted and equal-weight rankings shows that the choice of weighting scheme materially affected firm prioritization, since equal weighting would assume identical contribution across all nine determinants, whereas CRITIC captured differences in variability and informational

content. These findings translate into concrete implications for practice. For managers, post-adoption improvement efforts should be directed first toward risk management and complexity reduction, since these dimensions account for the largest share of variation among adopters. Practical measures include strengthening data governance and security protocols, clarifying accountability for analytical outputs, investing in interoperability across systems, and simplifying the interface between analytical tools and existing business processes. The readiness scores themselves serve as a benchmarking instrument: firms positioned in the lower quartile of the distribution can identify the specific criteria on which they deviate most from the ideal solution and target interventions accordingly. For policymakers, the low weight assigned to External Support indicates that vendor and consultancy provision currently produces little differentiation among large Albanian enterprises. This may reflect either the internal resource strength of this segment or an underdeveloped market for specialized analytics services. Targeted programs aimed at smaller firms, where external expertise is more likely to be decisive, may therefore yield greater returns than broad support schemes. This aligns with evidence from SME contexts, where technological and organizational determinants strongly shape BDA adoption outcomes [12]. These contributions should nonetheless be interpreted in light of several limitations. First, the analysis is based on BDA-adopting firms drawn from the population of Albanian large taxpayers. At the same time, this group represents the segment of the economy most likely to implement advanced analytics; the findings cannot be generalized to small and medium-sized enterprises or to other national contexts. Second, the data are cross-sectional, which precludes any assessment of how readiness evolves or how it translates into subsequent performance outcomes. Third, all TOE determinants were measured using self-reported perceptual items administered to a single respondent per firm, introducing potential common method bias and social desirability effects; objective indicators of technological infrastructure and analytical capability would strengthen future assessments. Fourth, and central to the interpretation of the results, CRITIC weights are sample-dependent by construction: they reflect the variability and intercorrelation of criteria within this particular set of firms rather than any universal importance of the TOE determinants, so a different sample would likely produce different weights, and the reported values should be read as descriptive of this population rather than as generalizable parameters. Finally, the CRITIC–TOPSIS framework is comparative rather than explanatory: it ranks firms relative to ideal and anti-ideal conditions. Still, it does not estimate the causal effects of TOE determinants on implementation outcomes.

VI. CONCLUSIONS

This study demonstrates that BDA adoption is not a binary organizational state. Among firms reporting active adoption, readiness scores ranged from 0.424 to 0.691, indicating substantial heterogeneity in the technological, organizational, and environmental conditions that underpin implementation. Risk and Complexity were the determinants that most strongly differentiated firms, indicating that technological conditions rather than adoption status itself are the primary source of variation in post-adoption readiness within this population of adopters. Theoretically, the study extends the TOE framework from an adoption-oriented model toward a post-adoption readiness framework, demonstrating that the same three dimensions can assess variation among firms that have already adopted a technology. This matters because implementation effectiveness depends on the continuing alignment of technological infrastructure, organizational capabilities, and environmental conditions, not on the adoption decision alone. Methodologically, CRITIC–TOPSIS provides a structured procedure for deriving criterion weights, readiness scores, and rankings from multidimensional TOE information. Unlike regression-based approaches, it does not estimate causal effects; it provides a comparative evaluation tool that identifies the most informative criteria and benchmarks organizations against ideal readiness conditions, making it well-suited to managerial diagnosis. By operationalizing the TOE framework through CRITIC–TOPSIS, the study offers both a theoretical repositioning and a practical diagnostic tool for evaluating organizational preparedness in emerging-economy contexts. Future research could build on these results by

addressing the limitations noted above: applying the framework longitudinally to capture how readiness evolves and translates into performance, extending it to SMEs and to cross-country samples, validating readiness scores against objective performance measures, and comparing CRITIC–TOPSIS against alternative MCDM configurations such as entropy-weighted TOPSIS, standard-deviation weighting, or VIKOR to test whether the observed ranking is sensitive to the choice of weighting and aggregation method.

Abstract
This study proposes an interpretable and leakage-aware machine learning framework for classifying traffic accidents as fatal or injury-related. Vehicle, driver, and accident records from the General Directorate of Security were integrated, and an Ankara subset covering 2020–2025 was constructed. Because multiple vehicle records may correspond to the same accident, an accident-level stratified split based on accident year and KazaId was used to prevent cross-set overlap. Fatal outcomes accounted for approximately 1.45% of vehicle accident records, resulting in a highly imbalanced classification problem. The proposed Crash Severity Risk Score (CSRS) combines six risk dimensions—vehicle, driver, road, environment, time, and accident occurrence type—into a 0–12 score. To prevent target leakage, CSRS mappings were estimated exclusively from training data using out-of-fold estimation. On the held-out test set, mean CSRS was 5.996 for injury records and 7.718 for fatal records. Association Rule Mining was independently used to identify interpretable fatal-risk patterns. Six classifiers were evaluated with and without CSRS using validation-selected decision thresholds. LightGBM with CSRS achieved the highest held-out Average Precision (0.1462) and fatal-class F1-score (0.2198), while Balanced Random Forest with CSRS achieved the highest ROC-AUC (0.8522). Temporal and cross-province validation showed reduced performance under distribution shift, while the contribution of CSRS remained model-dependent. Overall, the results support CSRS as an interpretable and complementary feature for predicting traffic accident severity.

Keywords: Traffic Accident Severity, Fatal Accident Prediction, Crash Severity Risk Score, Association Rule Mining, Imbalanced Classification, LightGBM, XGBoost

I. INTRODUCTION

Traffic accidents are a critical road safety problem, not only because of their frequency but also because of the fatalities and injuries they cause. According to the World Health Organization, accurate analysis of accident severity has direct implications for public safety, healthcare systems, and the development of effective road safety strategies. Traffic accident severity prediction aims to estimate accident outcomes using historical characteristics related to the vehicle, driver, road, environment, time, and accident occurrence [1]. The limitations of traditional statistical methods in modeling large datasets and complex nonlinear relationships have led to the increasing use of Machine Learning (ML) and Deep Learning (DL) methods in this field [2]. These predictive approaches can support the identification of high-risk conditions, the development of sustainable road safety policies, and the development of data-driven decision support systems. The main motivation of this study is that fatal traffic accidents constitute a very small minority class in the dataset, making conventional accuracy-oriented evaluations potentially misleading [3], [4], [5]. For instance, when fatal records account for only approximately 1.45% of the held-out test observations, a classifier may achieve high overall accuracy while detecting only a limited proportion of fatal cases. Therefore, model performance in this study is evaluated using

minority-class-oriented measures, including precision, recall, F1-score, ROC-AUC, and Average Precision (AP), together with decision-threshold analysis. Prior studies have emphasized feature selection, deep learning, and hybrid architectures, whereas the development and independent evaluation of interpretable composite risk features remain comparatively limited [6], [7]. To address this gap, this study proposes an interpretable framework that combines Association Rule Mining (ARM), the Crash Severity Risk Score (CSRS), and machine learning-based severity classification. ARM is employed as an independent explanatory analysis to identify combinations of vehicle-, driver-, road-, environmental-, temporal-, and accident-occurrence-related conditions associated with fatal outcomes. Separately, CSRS summarizes six corresponding risk dimensions into a single numerical feature ranging from 0 to 12. To minimize target leakage, target-informed CSRS mappings are learned exclusively from training data, and out-of-fold score generation is used for training observations. The incremental predictive contribution of CSRS is then evaluated by comparing otherwise identical machine learning models with and without the score. In addition to an accident-level held-out test evaluation, temporal and geographic validation, paired bootstrap analysis, and CSRS sensitivity analysis were used to assess the robustness and generalizability of the proposed framework.

II. RELATED WORKS

Traffic accident severity prediction has been widely investigated using statistical, machine learning, and deep learning approaches. Systematic reviews have shown an increasing use of data-driven methods in road-safety analysis because these methods can capture complex and nonlinear relationships among driver, vehicle, road, environmental, and crash-related factors [2], [8]. Previous studies have employed feature-selection-based machine learning models, deep neural networks, and hybrid machine- and deep learning architectures for crash-severity prediction [6], [7], [9]. Ensemble-based classifiers have also been extensively investigated, including Random Forest and other ensemble learning approaches [10], [11], [12], [13], as well as more recent XGBoost, LightGBM, and optimized ensemble models [3], [14], [15], [16], [17]. Class imbalance is another major challenge in traffic accident severity modeling because fatal crashes generally constitute only a small proportion of the available records. Previous studies have addressed this issue using imbalance-aware ensemble learning [3], generative adversarial networks [4], and comparisons between generative and conventional resampling strategies [5]. Data quality and missing information can further affect crash-severity prediction; therefore, imputation and missing-data handling have also received considerable attention in recent research [18], [19], [20]. In parallel, explainable artificial intelligence has increasingly been used to improve the interpretability of accident-risk models, including feature-level risk analysis and SHAP-based explanations [21], [22]. Despite these advances, much of the existing literature focuses primarily on classifier performance, feature selection, imbalance mitigation, or post-hoc model interpretation. Comparatively less attention has been given to interpretable composite risk features whose incremental predictive value is evaluated under strict leakage-aware validation. In the present study, Association Rule Mining (ARM) is used independently to identify interpretable high-risk combinations. In contrast, the Crash Severity Risk Score (CSRS) is constructed separately from training-derived category-risk mappings and evaluated as an additional predictive feature across multiple classifiers. This design enables the explanatory contribution of ARM and the predictive contribution of CSRS to be examined without treating the two components as dependent.

III. MATERIALS AND METHODS

1. Dataset

The dataset used in this study comprises vehicle and accident information obtained from the traffic accident records of the Republic of Türkiye Ministry of Interior, General Directorate of Security. Passenger and pedestrian records were not included at this stage. The integrated dataset covers the 2018–2025 period, while

the Ankara subset covering 2020–2025 was used for the primary modeling experiments. Dataset and partition statistics are summarized in Table 1.

Table 1. Summary information on the dataset and modeling subset

Feature	Value / Description
Data source	Traffic accident records of the General Directorate of Security
Scope	Vehicle and accident information for the 2018–2025 period
Integrated dataset size	2,463,711 rows and 70 variables
Modeling subset	Ankara, 2020-2025
Modeling dataset size	135,776 vehicle-accident records from 79,139 unique accidents
Target variable	0 = Injury accident, 1 = Fatal accident
Row-level target distribution	133,809 injury records (98.551%) and 1,967 fatal records (1.449%)
Accident-level target distribution	77,849 injury accidents (98.37%) and 1,290 fatal accidents (1.63%)
Training Set	108,610 vehicle-accident records from 63,311 unique accidents
Training row-level distribution	107,037 injury records and 1,573 fatal records (1.448% fatal)
Held-out test set	27,166 vehicle-accident records from 15,828 unique accidents
Test row-level distribution	26,772 injury records and 394 fatal records (1.450% fatal)
Train–test accident overlap	0 unique accidents

2. Data Preprocessing

The traffic accident data used in this study consist of integrated vehicle and accident records. Variable names and data types were standardized, and the Ankara subset covering 2020–2025 was extracted for modeling. The binary target variable was defined as 1 for fatal outcomes and 0 for injury outcomes. Variables that directly contain information on the total number of fatalities or injuries were excluded from the explanatory feature set to prevent direct target leakage. Because multiple vehicle records may correspond to the same accident, a conventional row-level random split could assign records from the same accident to both the training and test sets. Moreover, inspection of the data showed that KazaId values could recur across different calendar years. Therefore, a composite accident identifier, AccidentGroupId = (accident year, KazaId), was constructed and used as the grouping unit for data partitioning. The Ankara subset contained 135,776 vehicle–accident records corresponding to 79,139 unique accidents. An 80/20 stratified split was then performed at the unique-accident level using a fixed random seed of 42, with stratification based on the binary accident outcome. All vehicle accident records belonging to the same AccidentGroupId were assigned to the same partition. This resulted in 108,610 records from 63,311 unique accidents in the training set and 27,166 records from 15,828 unique accidents in the held-out test set, with no accident overlap between the two partitions. All data-dependent preprocessing and target-informed procedures were performed without using information from the held-out test set. Logistic Regression, Random Forest, Balanced Random Forest, XGBoost, and LightGBM used one-hot

encoding; missing categorical values were assigned to a dedicated category; unseen categories were ignored during validation and testing; and missing numerical values were imputed using training medians. CatBoost used native categorical inputs and training-median numerical imputation. For CSRS construction, category-level risk mappings for training observations were generated using an out-of-fold procedure. In contrast, the mappings applied to the held-out test set were estimated only from the complete training partition. Similarly, ARM candidate discovery and rule selection were restricted to the training partition. Held-out test outcomes were used exclusively for the final independent evaluation.

3. Method

Association Rule Mining (ARM) and the Crash Severity Risk Score (CSRS) were employed as methodologically separate components: ARM identified multivariable conditions associated with fatal outcomes, whereas CSRS was developed as an interpretable supervised risk feature. ARM was conducted using driver-, vehicle-, road-, environmental-, temporal-, and accident-occurrence-related variables. Because fatal outcomes accounted for only 1.4483% of the training vehicle accident records, candidate discovery was performed on a class-balanced subset that included all 1,573 fatal training records and an equal number of randomly sampled injury records. A minimum-support sensitivity analysis was performed using values of 0.01, 0.02, 0.03, and 0.05, and 0.02 was selected for candidate discovery. Rules with a fatal consequence and confidence ≥ 0.65 were retained. Rules with a fatal consequence and confidence ≥ 0.65 were retained. In the balanced discovery subset, this corresponded to a lift of 1.30 and was used only for candidate screening, not as a population-level fatality probability. Candidate rules were subsequently re-evaluated on the original imbalanced training data, where support, fatal-outcome rate, and lift were recalculated under the natural class distribution. To reduce redundancy, pairwise rules were retained if their training-set lift was at least 30% higher than that of the corresponding stronger single-condition rule. Following training-stage filtering, 58 candidate rules were frozen and evaluated on the held-out test set using lift and one-sided Fisher's exact tests. Secondary stability criteria required preservation of association direction, at least 70% train-to-test lift retention, and support from at least 10 fatal test records. P-values were adjusted using the Benjamini–Hochberg false-discovery-rate procedure. CSRS was constructed independently from ARM using six components: vehicle, driver, road, environment, time, and accident occurrence type. To prevent target leakage, five-fold out-of-fold estimation was performed at the unique-accident level within the training partition. For each fold, category-level risk mappings were estimated using the remaining four folds and then applied to the held-out fold. Category-specific fatal-outcome proportions were compared with the training baseline using 95% Wilson confidence intervals; intervals below, overlapping, or above the baseline were assigned risk scores of 0, 1, and 2, respectively. For components with multiple subvariables, the maximum subvariable score was used to ensure each component remained on the 0–2 scale. The total CSRS for observation *I* was calculated as shown in (1).

$$\mathrm{CSRS_i} = \sum w_j.R(x_{ij}) \tag{1}$$

Here, x_{ij}, denotes the category value of the j-th risk component for observation *i*, $R(x_{ij})$ represents the corresponding risk value (0, 1, or 2), and w_j denotes the component weight. All weights were ss = 1.o w alt j 1.o =*1.*. Consequently, the theoretical CSRS range is 0–12, with higher scores representing risk profiles more strongly associated with fatal outcomes. After out-of-fold CSRS values were generated for the training records, final category-risk mappings were estimated from the complete training partition and applied unchanged to the held-out test set. The incremental contribution of CSRS was evaluated using six classifiers—Logistic Regression, Random Forest, Balanced Random Forest, XGBoost, LightGBM, and CatBoost—each fitted with and without CSRS using identical hyperparameters. Logistic Regression used balanced class weights, the liblinear solver, and 2,000 maximum iterations; Random Forest used 500 trees, balanced class weights, and a minimum leaf size of 2; and Balanced Random Forest used 500 trees with balanced sampling, replacement, and

a minimum leaf size of 2. XGBoost and LightGBM used 500 estimators, a learning rate of 0.05, 0.8 subsampling and feature sampling, and training-derived class weights; maximum depth was 5 for XGBoost, and the number of leaves was 31 for LightGBM. CatBoost used 500 iterations, a learning rate of 0.05, depth 6, Logloss, and automatic class-weight balancing. The random seed was 42. Decision thresholds from 0.01 to 0.99 were selected on an accident-level validation fold from the training partition by maximizing the fatal-class F1-score; ties were resolved by higher recall, then by the lower threshold. Models were then fitted on the complete training partition and evaluated on the held-out test set using the fixed thresholds. After threshold selection, models were fitted using the complete training partition and evaluated on the held-out test set using the previously fixed thresholds. To quantify uncertainty in the CSRS/no-CSRS comparisons, paired bootstrap resampling was performed at the AccidentGroupId level with 1,000 resamples, preserving all vehicle records for each sampled accident. For strict temporal validation, models were trained using records from 2020–2023, decision thresholds were selected using 2024 data, and final performance was evaluated on 2025 records without using 2025 outcomes during model or threshold selection. For geographic validation, Ankara-trained models were evaluated on İstanbul records from 2020 to 2025. İstanbul was selected as the non-Ankara province with the largest number of unique accidents. Ankara-derived decision thresholds and CSRS mappings were applied unchanged. CSRS robustness was assessed using 90%, 95%, and 99% Wilson confidence intervals for category-risk assignment, with 95% used as the primary setting. Class separation and LightGBM discrimination were compared across the three variants using the same leakage-controlled procedure.

4. Performance Metrics

Since fatal outcomes constitute a highly underrepresented minority class, overall accuracy alone was not considered sufficient for model evaluation. Performance was therefore assessed primarily using fatal-class precision, recall (sensitivity), F1 Score, specificity, balanced accuracy, ROC AUC, and Average Precision (AP). False-positive (FP) and false-negative (FN) counts were reported in the main comparison table. ROC-AUC evaluates ranking performance across decision thresholds, whereas Average Precision (AP) summarizes precision–recall performance and was used as a primary threshold-independent metric for the minority fatal class. The main threshold-dependent performance metrics used in this study are given in (2), (3), and (4).

$$Precision = \frac{TP}{TP+FP} \tag{2}$$

$$Recall = \frac{TP}{TP+FN} \tag{3}$$

$$F1\text{-}Score = \frac{2 \times Precision \times Recall}{Precision + Recall} \tag{4}$$

Decision thresholds were selected using the validation data, as described in Section III.3, and subsequently fixed before evaluation on the corresponding held-out test sets. Consequently, no performance metric or confusion matrix results from the final test data were used for threshold optimization.

IV. EXPERIMENTAL RESULTS

The held-out test set contained 27,166 vehicle–accident records, including 26,772 injury records and 394 fatal records, corresponding to a fatal-outcome prevalence of 1.4503%. No AccidentGroupId was shared between the training and test sets. Figure 1 summarizes the held-out test-set lift values of the strongest pairwise ARM patterns selected exclusively from the training data.

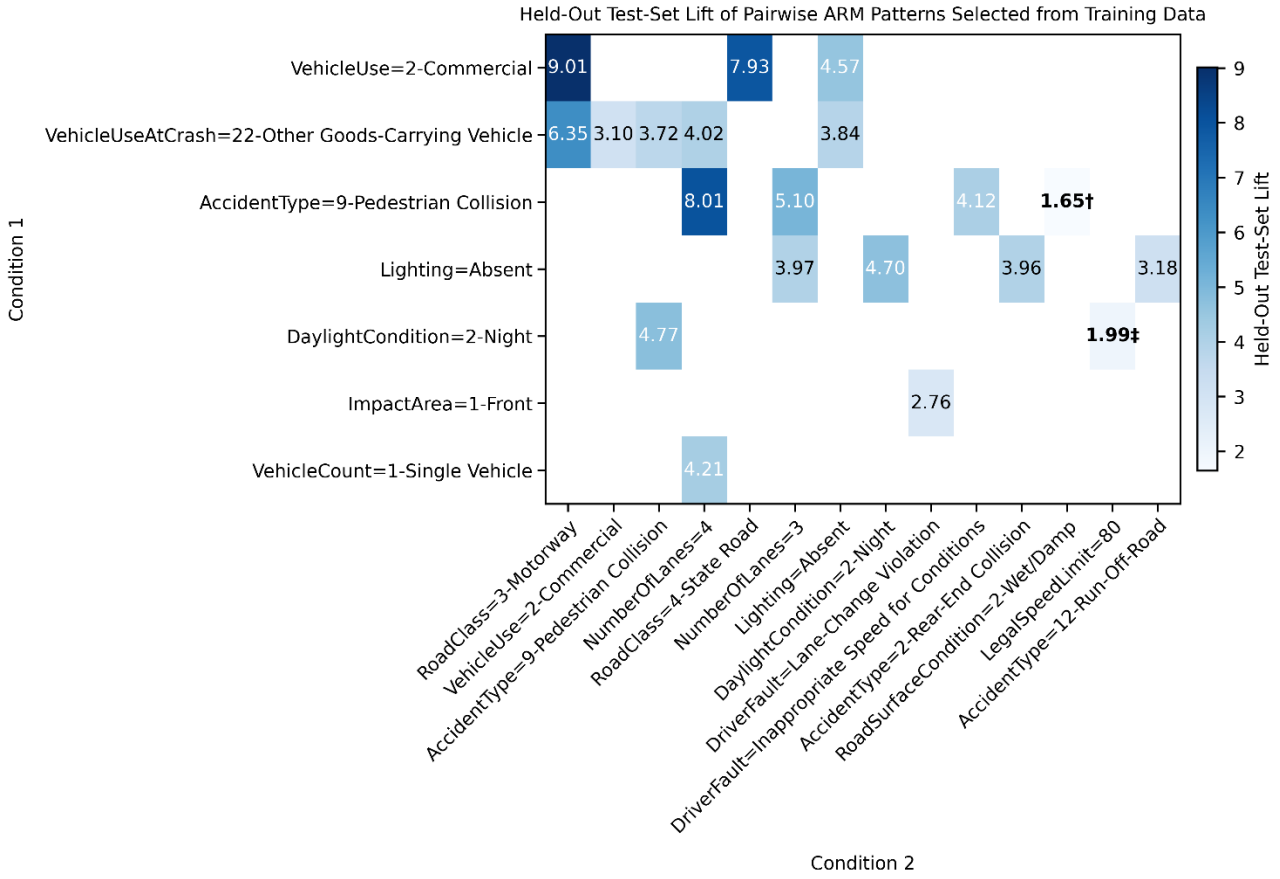

Figure 1. Held-out test-set lift of pairwise ARM patterns selected exclusively from training-set results. Vehicle type was excluded from the visualization only. Nineteen of the 20 displayed patterns remained statistically significant after Benjamini–Hochberg FDR correction applied across all 58 frozen candidate rules, and 18 additionally satisfied the predefined secondary stability criteria. † Not significant after FDR correction and based on fewer than 10 fatal test records. ‡ Significant in the held-out test set but below the 70% train-to-test lift-retention criterion.

The ARM support-threshold sensitivity analysis considered minimum support values of 0.01, 0.02, 0.03, and 0.05, and 0.02 was retained for candidate discovery. The number of fatal-containing candidate itemsets decreased from 2,105 at a minimum support of 0.01 to 566 at 0.05; therefore, 0.02 was retained as a compromise between rule coverage and sparsity, yielding 1,314 candidates. Following training-stage discovery, re-evaluation under the original imbalanced distribution, and redundancy filtering, 58 candidate rules were frozen before examination of the held-out test set. Of these, 52 remained statistically significant after one-sided Fisher's exact testing with Benjamini–Hochberg false-discovery-rate correction, and 51 also satisfied the predefined secondary stability criteria. Among the strongest replicated associations, the combination Vehicle Use = Commercial and Road Class = Motorway occurred in 153 test records, including 20 fatal records, corresponding to a fatal-outcome rate of 13.072%. Relative to the overall test-set fatal prevalence of 1.4503%, this association yielded a test lift of 9.013 (odds ratio = 10.711, 95% CI: 6.621–17.327; FDR-adjusted $q = 3.414 \times 10^{-13}$).

Although one displayed a pattern that did not replicate, and another showed attenuation, most retained elevated associations with fatal outcomes when evaluated independently. Beyond these rule-based associations, CSRS also showed descriptive separation between the two outcomes. In the held-out test set, injury records had a mean CSRS of 5.996 (SD = 1.693; median = 6), whereas fatal records had a higher mean score of 7.718 (SD = 1.595; median = 8). Because test-set CSRS values were generated exclusively from training-derived mappings, held-out outcomes were not used to construct scores. The incremental contribution of CSRS was then evaluated across all six classifiers by comparing otherwise identical models with and without the score. Decision thresholds were selected from validation data and fixed before the held-out test evaluation. The resulting performance measures and FP/FN error counts are presented in Table 2.

Table 2. Held-Out Test Performance Of The Six Classifiers With And Without CSRS

Model	CSRS	Th.	AP	AUC	Prec.	Rec.	F1	FP/FN
LR	No	0.88	0.0952	0.8494	0.1185	0.2614	0.1631	766/291
LR	Yes	0.89	0.0938	0.8471	0.1148	0.2462	0.1566	748/297
RF	No	0.31	0.1100	0.8467	0.1725	0.2132	0.1907	403/310
RF	Yes	0.24	0.1135	0.8440	0.1417	0.3071	0.1939	733/273
BRF	No	0.70	0.1082	0.8511	0.1193	0.3756	0.1810	1093/246
BRF	Yes	0.72	0.1125	0.8522	0.1251	0.3046	0.1774	839/274
XGBoost	No	0.82	0.1317	0.8334	0.1669	0.2640	0.2045	519/290
XGBoost	Yes	0.82	0.1405	0.8411	0.1782	0.2487	0.2076	452/296
LGBM	No	0.75	0.1301	0.8226	0.1611	0.3046	0.2107	625/274
LGBM	Yes	0.78	0.1462	0.8302	0.1802	0.2817	0.2198	505/283
CatBoost	No	0.71	0.1243	0.8247	0.1108	0.4036	0.1739	1276/235
CatBoost	Yes	0.76	0.1258	0.8310	0.1346	0.3325	0.1917	842/263

Th.: validation-selected decision threshold; AP: average precision; AUC: area under the receiver operating characteristic curve (ROC-AUC); Prec.: fatal-class precision; Rec.: fatal-class recall; F1: fatal-class F1-score; FP: false-positive count; FN: false-negative count; LR: logistic regression; RF: random forest; BRF: balanced random forest; LGBM: LightGBM.

As shown in Table 2, CSRS improved Average Precision in five of the six classifiers and fatal-class F1-score in four. LightGBM with CSRS achieved the highest AP (0.1462) and fatal-class F1-score (0.2198), while Balanced Random Forest with CSRS achieved the highest ROC-AUC (0.8522). CatBoost without CSRS produced the highest fatal-class recall (0.4036). Table 2 also reports false-positive and false-negative counts; since the held-out test set contained 26,772 injury and 394 fatal records, the corresponding true-negative and true-positive counts can be derived directly from these values. Paired accident-level bootstrap analysis with 1,000 resamples showed that no CSRS-related F1-score difference had a 95% confidence interval excluding zero. In contrast, the clearest threshold-independent improvement was observed for LightGBM AP (+0.0161, 95% CI: 0.0019–0.0326). Generalizability was further examined using strict temporal and geographic validation. In the temporal analysis, models were developed using 2020–2023 data, thresholds were selected in 2024, and 2025 was reserved for final testing. CSRS increased Average Precision in all six classifiers, with the largest gains observed for XGBoost (0.0978 to 0.1138) and LightGBM (0.1040 to 0.1151); LightGBM with CSRS achieved the highest temporal AP (0.1151) and fatal-class F1-score (0.1876). Geographic validation was conducted by training in

Ankara and evaluating in Istanbul. Under this distribution shift, the highest AP was obtained by XGBoost without CSRS (0.0555), whereas Balanced Random Forest achieved the highest ROC-AUC with CSRS (0.7760). A sensitivity analysis using 90%, 95%, and 99% Wilson confidence intervals showed that the CSRS class-separation pattern remained stable across alternative scoring boundaries. For LightGBM, Average Precision ranged from 0.1387 to 0.1490 and ROC-AUC from 0.8238 to 0.8302.

V. DISCUSSION

The results indicate that ARM and CSRS provide complementary forms of information for traffic accident severity analysis. ARM identified interpretable combinations of conditions associated with elevated fatal-outcome risk, and most of the strongest training-selected patterns retained their direction and elevated lift under held-out evaluation. CSRS, which was constructed independently of ARM, showed a clear descriptive separation between injury and fatal records and improved Average Precision across five of the six evaluated classifiers. However, its predictive contribution was model-dependent rather than uniformly beneficial across all metrics. LightGBM obtained the strongest overall combination of AP and fatal-class F1-score when CSRS was included. In contrast, CatBoost without CSRS achieved the highest fatal-class recall, illustrating the trade-off between detecting fatal cases and limiting false-positive predictions. The bootstrap analysis further suggests that the incremental benefit of CSRS should be interpreted with caution: the clearest statistically supported improvement was observed for LightGBM AP. At the same time, the F1-score differences did not have confidence intervals that excluded zero. Performance also decreased with shifts in temporal and geographic distributions, highlighting the challenge of transferring crash-severity models across time and regions. Nevertheless, the CSRS sensitivity analysis produced similar discrimination results under alternative scoring boundaries, supporting the robustness of the overall scoring strategy. These findings suggest that CSRS is best viewed as an interpretable complementary feature rather than a universally performance-enhancing predictor.

VI. CONCLUSION AND FUTURE WORK

This study presented an interpretable and leakage-aware machine learning framework for traffic accident severity prediction by combining ARM-based risk-pattern discovery with an independently constructed Crash Severity Risk Score (CSRS). The held-out results showed that fatal records had higher CSRS values than injury records, while the predictive contribution of CSRS varied across classifiers. LightGBM with CSRS achieved the highest held-out Average Precision and fatal-class F1-score, and bootstrap analysis supported a modest but measurable improvement in its ranking performance. Temporal and cross-province validation further showed that model performance decreased under distribution shift, although CSRS retained useful predictive information in several models. Future work will focus on explaining model decisions using XAI methods such as SHAP and extending the framework toward spatial road-segment risk modeling, graph-based learning, and safe-route recommendation.

ACKNOWLEDGEMENT

The authors would like to express their gratitude to the Republic of Türkiye Ministry of Interior, General Directorate of Security, for providing the traffic accident records used in this study. The analyses and interpretations presented in this paper are solely the responsibility of the authors.

Abstract

AWS security evidence is fragmented across configuration state, identity policies, network exposure rules, audit logs, threat intelligence feeds, and compliance controls, which makes it difficult for analysts to connect cloud misconfigurations with runtime activity and external threat context. This paper presents Cloud-CTI-Engine, a locally executable framework that brings AWS posture findings, CloudTrail events, threat intelligence enrichment, and compliance mapping into a single assessment workflow. The system implements deterministic checks for S3, IAM, and EC2; extracts indicators of compromise from CloudTrail records; enriches IP addresses, domains, and file hashes via external intelligence services; and maps findings to the CIS AWS Foundations Benchmark, NIST Cybersecurity Framework, ISO/IEC 27001, and SOC 2. Unlike isolated posture scanners or log-analysis tools, it normalizes these evidence sources into a common schema for findings. It executes entirely on the analyst's machine, without a centralized service or external credential storage. The platform was evaluated on controlled AWS accounts with contrasting security postures. It produced posture scores of 80/100 and 52/100 across 30 mapped controls, with 7 and 16 control failures, respectively, and extracted 8 indicators from 45 CloudTrail events, of which 6 were enriched, and 2 were flagged as suspicious or malicious.

Keywords: cloud security posture management, AWS security, CloudTrail analysis, threat intelligence, indicators of compromise, compliance mapping, cloud misconfiguration

I. INTRODUCTION

Cloud computing has transformed how organizations deploy and manage IT infrastructure. Platforms such as Amazon Web Services (AWS) provide scalable and flexible environments but introduce new cybersecurity challenges due to complex configurations and distributed architectures [1]. Misconfigurations such as publicly exposed storage buckets, excessive IAM privileges, or insecure network configurations increase the attack surface. At the same time, threat intelligence provides information about malicious infrastructure, attack patterns, and indicators of compromise [2]. AWS configuration data, IAM policy state, security group exposure, CloudTrail activity, external IOC reputation, and compliance controls are usually analyzed through separate workflows. In addition, organizations must ensure their cloud environments comply with established security frameworks, including the CIS AWS Foundations Benchmark, NIST Cybersecurity Framework, ISO/IEC 27001, and SOC 2. Mapping detected security findings to these controls is essential for evaluating compliance posture and prioritizing remediation efforts [3]. This paper presents Cloud-CTI-Engine, a local-first AWS security assessment framework that integrates cloud posture checks, CloudTrail analysis, threat intelligence enrichment, and compliance mapping into a unified workflow. The system normalizes posture findings, log-derived indicators, enrichment results, severity levels, and framework mappings into a common finding

structure. This allows analysts to move from isolated observations, such as a public S3 bucket, an exposed EC2 security group, or a suspicious CloudTrail source IP, toward a consolidated assessment that connects technical evidence with operational and compliance context. The main contributions of this paper are as follows:

- A local-first AWS security assessment architecture that combines deterministic posture checks, CloudTrail parsing, threat intelligence enrichment, and compliance mapping in a single workflow.
- A normalized finding model for representing AWS misconfigurations, log-derived indicators, enrichment metadata, severity, supporting evidence, and framework mappings.
- A prototype implementation covering selected AWS services, including S3, IAM, and EC2, together with CloudTrail IOC extraction and enrichment through external intelligence sources.
- A scenario-based evaluation on controlled AWS accounts with contrasting security postures, reporting posture scoring, severity distribution, compliance mapping outcomes, and indicator enrichment results.

II. RELATED WORK

Cloud security posture management (CSPM) has emerged as a key approach for continuously assessing cloud configurations and identifying misconfigurations, compliance violations, and security risks [4]. Prior work shows that CSPM can reduce exposure caused by public storage, excessive IAM permissions, and insecure network rules. However, most CSPM approaches focus primarily on configuration state, whereas separate tools typically handle runtime activity and threat intelligence. AWS-native services also provide partial coverage. AWS Config supports configuration tracking and compliance rules, AWS Security Hub aggregates security findings, and Amazon GuardDuty analyzes activity logs to detect suspicious behavior. Open-source tools such as Prowler and ScoutSuite provide posture and compliance checks, while Cloudsplaining focuses on IAM policy risks. These tools are useful, but they do not provide a local-first workflow that directly combines posture findings, CloudTrail-derived indicators, threat intelligence enrichment, and compliance mapping into one normalized structure. Threat intelligence and CloudTrail analysis have also been studied separately. Threat intelligence adds context about indicators such as IP addresses, domains, URLs, and file hashes, while CloudTrail analysis helps identify suspicious AWS activity. Cloud-CTI-Engine connects these areas by using CloudTrail parsing to extract indicators and correlate them with posture findings, enrichment results, and compliance controls. Table 1 compares the proposed platform with representative AWS-native and open-source approaches.

Table 1. Comparison of related AWS security assessment approaches, based on published product and project documentation as of July 2026

Approach	Posture checks	CloudTrail analysis	Threat intelligence enrichment	Compliance mapping	Unified local workflow
AWS Config	Yes	Limited	No	Yes	No
AWS Security Hub	Yes	Partial	Limited	Yes	No
Amazon GuardDuty	No	Yes	Yes	No	No
Prowler / ScoutSuite	Yes	Limited or no	No	Yes	Partial
Cloudsplaining	IAM-focused	No	No	Limited	Partial

Cloud-CTI-Engine	Yes	Yes	Yes	Yes	Yes

III. BACKGROUND

Cloud computing delivers computing resources as on-demand services over the internet, removing the need to manage physical infrastructure [5]. Regulatory compliance is more challenging in cloud environments, particularly when cross-border data transfers and differing international regulations are involved [6]. The shared responsibility model divides security duties between the cloud service provider and the customer [7]. Effective monitoring requires native logging such as AWS CloudTrail, centralized log correlation, and anomaly detection [8]. Threat intelligence provides continuous streams of indicators of compromise, such as malicious domains and IP addresses [9]. Mapping detected threats to frameworks such as the NIST Cybersecurity Framework and CIS Controls supports compliance verification [10]. AI-based approaches on cloud log sources detect behavioral anomalies with higher accuracy than signature-based methods [11]. Combining threat intelligence with machine learning is effective for volumetric attacks such as DDoS [12].

IV. SYSTEM ARCHITECTURE

Cloud-CTI-Engine follows a modular architecture composed of three main components: a command-line interface (CLI), a backend API server, and a web-based frontend. The CLI performs the main security analysis tasks, the backend orchestrates communication between the CLI and the graphical interface, and the frontend provides visualization and user interaction. The Python-based CLI implements the core analysis engine. It performs cloud security posture checks for selected AWS services, including S3, IAM, and EC2, processes CloudTrail logs, and enriches indicators such as IP addresses, domains, and file hashes. It interacts with AWS services through the boto3 SDK, uses Typer for command orchestration and parameter handling, and applies Pydantic to validate structured data and normalize results into a consistent schema. The backend API server, implemented in Node.js with Express, serves as a lightweight orchestration layer. It does not perform security analysis directly; instead, it invokes the CLI as a subprocess with the required parameters and returns the results to the frontend. This design centralizes the analysis logic in the CLI while allowing the API to manage configuration, execution workflows, and result retrieval. The web frontend allows users to initiate scans, visualize analysis results, and review detected findings. The platform supports direct CLI execution and web platform mode. In platform mode, the frontend sends HTTP requests to the API, which launches the CLI, performs the analysis, and returns the results. All processing is performed locally on the user's machine. The platform does not require a centralized backend service or external credential storage, ensuring that AWS credentials and analysis data remain under the user's control.

1. Cloud Posture Check

Cloud posture assessment uses deterministic security controls for Amazon S3, Identity and Access Management (IAM), and Elastic Compute Cloud (EC2), representing data storage, identity management, and network security. Each modular control receives an authenticated AWS session, queries the relevant configuration via AWS APIs, and evaluates it against predefined rules informed by recommended security practices and industry frameworks. Detected issues are normalized into a unified finding structure containing the service name, resource identifier, issue type, severity, and supporting evidence. An AWS scan runner initializes the session, resolves the target services and regions, executes the service-specific checks, and aggregates the findings into a consolidated posture report.

- S3 Security Checks

The S3 module performs four configuration checks for each bucket: public access detection, default encryption validation, versioning status verification, and server access logging configuration.

Public access detection evaluates three configuration components: Block Public Access (BPA) settings, bucket policies, and access control lists (ACL). A high-severity finding is generated when BPA protections are not fully enabled, and either the bucket policy or ACL configuration allows public access. The default encryption check verifies that buckets use approved encryption mechanisms, such as AES-256 or AWS Key Management Service (AWS KMS). Buckets that do not have encryption enabled or use unsupported encryption algorithms generate a medium-severity finding. Versioning and server access logging checks are configurable controls that can be enabled or disabled through the platform configuration. When enabled, buckets without versioning or logging configured generate low-severity findings.

- IAM Security Checks

The IAM module evaluates identity and access configurations within the AWS account. It performs five security checks: multi-factor authentication (MFA) for IAM users, root account MFA configuration, access key rotation policies, detection of unused access keys, and policy analysis for administrative or risky permissions. For each IAM user, the platform verifies whether an MFA device is configured. Users without MFA are reported as high-severity findings due to the increased risk of credential compromise. Access keys are evaluated against configurable thresholds that define the maximum allowed key age and maximum unused period. Keys that exceed the configured age limit are flagged for rotation, while keys that have never been used or have not been used within the defined threshold are classified as unused. Root account MFA is evaluated once at the account level. If MFA is not enabled for the root account, the system generates a finding indicating a critical security risk. Policy analysis consists of two separate checks. The first identifies administrative wildcard permissions, which occur when policies grant unrestricted access using Action: "*" and Resource: "*". The second check identifies risky policy constructs, such as NotAction and NotResource used in Allow statements, as well as configurable privilege-escalation actions, such as iam: CreateAccessKey and iam: AttachUserPolicy.

- EC2 Security Checks

The EC2 module analyzes security groups across AWS regions using two checks: public exposure and unused security groups. Inbound rules are evaluated to determine whether sensitive ports are accessible from unrestricted ranges such as 0.0.0.0/0 or::/0. Exposure of all ports is classified as critical, while exposure of specific sensitive ports generates high-severity findings. The module also identifies security groups that are not attached to any network interface. These resources may represent residual or improperly cleaned-up infrastructure. Security groups are enumerated across all available regions, and their inbound rules are inspected for disallowed CIDR ranges and exposed ports.

2. CloudTrail Analysis

CloudTrail logs are analyzed to identify suspicious activity and extract indicators of compromise (IOCs). The analysis engine parses CloudTrail event records and extracts relevant attributes, including sourceIPAddress, eventName, eventSource, and userIdentity. These attributes provide visibility into who performed an action,

which service was accessed, and from which network location the request originated. The platform supports two complementary analysis modes: deterministic baseline analysis and optional AI-assisted log interpretation.

- Baseline IOC Extraction

Baseline analysis performs deterministic extraction of indicators using structured parsing and pattern-matching techniques. The system processes each CloudTrail event and extracts attributes that may indicate security relevance.

- AI-Assisted Log Analysis

In addition to deterministic parsing, the platform optionally performs AI-assisted analysis of CloudTrail activity. CloudTrail events are normalized and passed to a language model that generates structured summaries describing key actors, suspicious actions, and chronological activity patterns.

3. Threat Intelligence

The threat intelligence module evaluates the reputation of indicators extracted from CloudTrail logs or provided manually by the user. The system supports three indicator types: IP addresses, domain names, and file hashes. IP addresses are analyzed using external intelligence services such as AbuseIPDB and IPInfo, which provide metadata including abuse confidence scores, autonomous system numbers (ASN), and hosting provider information. Domain lookups return organizational and geographic metadata, while file hash analysis uses VirusTotal to retrieve malware detection statistics and threat classification results. IP lookups use the AbuseIPDB API v2, while domain lookups resolve the hostname to an IPv4 address and query IPInfo for organizational and geographic metadata. File hash analysis relies on the VirusTotal API v3 and supports common hash algorithms, including MD5, SHA-1, and SHA-256. An optional cloud attribution mechanism re-enriches IP indicators and domains by resolving their IP addresses using IPInfo data. The system compares ASN, organization, and hostname attributes against configurable cloud provider profiles (e.g., AWS, Azure, and GCP) to determine whether an indicator is likely associated with cloud infrastructure. All intelligence queries use a configurable timeout and retry policy with exponential backoff for server-side errors (5xx). The results are normalized into the same ScanResult structure used by the cloud posture checks, ensuring consistent correlation, visualization, and reporting across the platform.

V. COMPLIANCE MAPPING

Compliance evaluation is derived from the findings produced by the cloud posture checks. Each finding is mapped to security controls defined by established frameworks, including the CIS AWS Foundations Benchmark, NIST Cybersecurity Framework, ISO/IEC 27001, and SOC 2. The platform maintains a mapping between finding identifiers and framework control identifiers. When a finding corresponds to a control rule, the associated control is marked as failed. Compliance results are aggregated per framework (passed count, failed count, and percentage of controls passed), providing a high-level overview of how well the evaluated cloud environment aligns with each framework. The UI allows you to expand a framework to see which controls passed or failed and which findings contributed to failures.

VI. EVALUATION

Cloud-CTI-Engine was evaluated using multiple controlled AWS test cases with different security posture conditions. The goal was to verify whether the platform could distinguish between better-configured and more misconfigured environments, generate posture scores, summarize findings by severity, and map results to compliance frameworks. The test cases included AWS accounts with relatively secure configurations and accounts containing intentionally introduced misconfigurations across S3, IAM, and EC2. Table 2 summarizes some of the evaluation results.

Table 2. Scenario-based evaluation results of Cloud-CTI-Engine

Test case	**Evaluation focus**	**Main input**	**Main result**	**Compliance result**
Case 1	Better-configured AWS account	S3, IAM, EC2 scan	80 / 100 posture score; 0 critical, 1 high, 1 medium, 0 low findings	23 passed / 7 failed
Case 2	Misconfigured AWS account	S3, IAM, EC2 scan	52 / 100 posture score; 2 critical, 5 high, 4 medium, 2 low findings	14 passed / 16 failed
Case 3	CloudTrail and threat intelligence analysis	45 CloudTrail events and 8 indicators	8 indicators extracted; 6 enriched; 2 marked suspicious or malicious	Not applicable
Case 4	Extended misconfiguration (10 known weaknesses)	S3, IAM, EC2 scan	44/100; 3 critical, 7 high, 5 medium, 3 low	11/19

Each test case was prepared with a documented baseline before scanning. Cases 2 and 4 included deliberately introduced misconfigurations: Case 2 contained seven weaknesses (a public S3 bucket, missing encryption, two users without MFA, a stale access key, a wildcard IAM policy, and two exposed EC2 security groups); Case 4 extended this with three further weaknesses (a second public bucket, an unused access key, and an RDP-exposed security group), totalling ten. Case 3 used a fixed set of 45 CloudTrail events, each containing eight pre-identified indicator values (IP addresses, domains, and file hashes), two of which were sourced from known malicious entries in the enrichment services. For Cases 2 and 4, all 13 introduced misconfigurations were detected (zero false negatives). Case 1 produced two additional findings (one high, one medium) not part of any introduced weakness; manual review confirmed both as genuine residual issues in the account baseline, not false positives. For Case 3, all eight indicators were correctly extracted, and both pre-identified malicious entries were flagged as suspicious or malicious by the enrichment services, with no benign indicators misclassified. Posture scores in Cases 2 and 4 are lower than the count of introduced weaknesses alone would suggest, because the scoring algorithm also accounts for passing controls, causing the score to drop nonlinearly.

Figure 1 shows the summary dashboard generated during the evaluation for Case 1. It presents the main posture and compliance results, while the platform also provides detailed views for individual findings, compliance controls, CloudTrail analysis, AI-assisted insights, and threat intelligence enrichment.

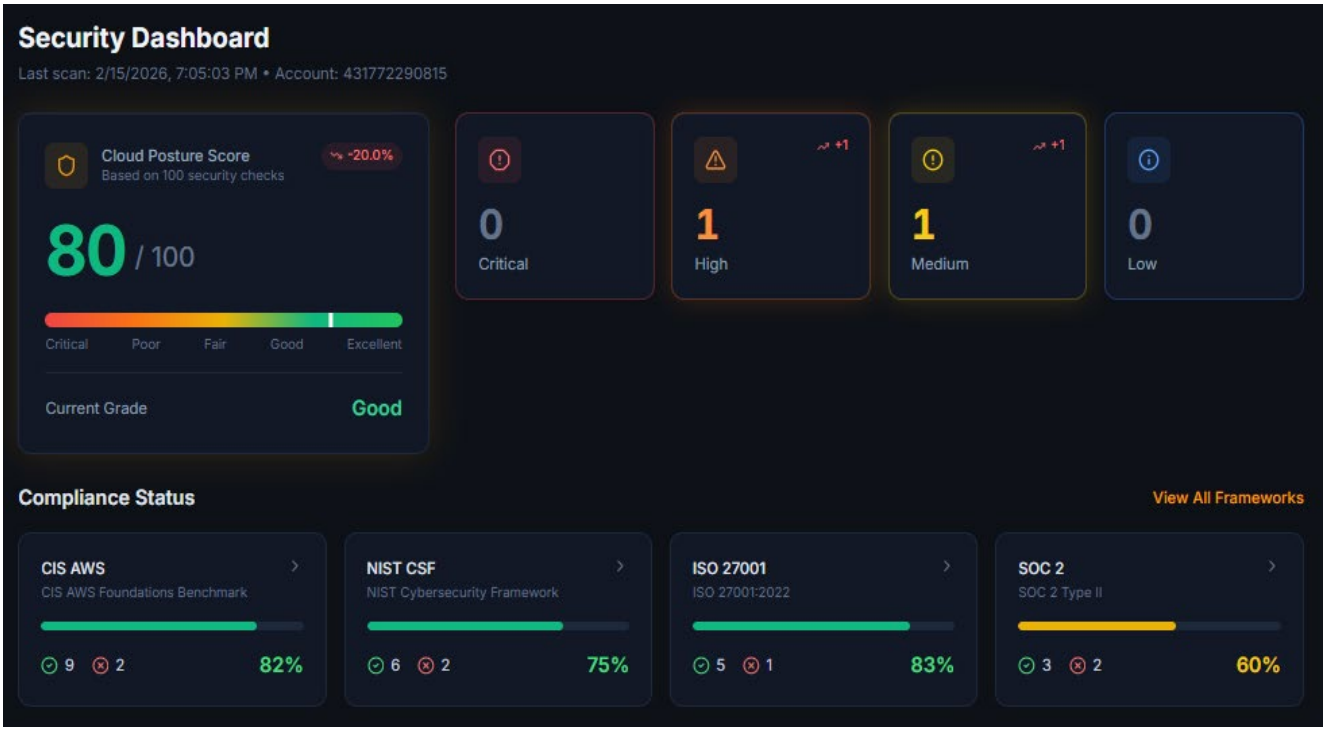

Figure 1. Summary dashboard of Cloud-CTI-Engine showing posture scoring, severity distribution, and compliance mapping results.

The results show that Cloud-CTI-Engine produces different posture scores and distribution of findings based on the security state of the evaluated AWS account. The better-configured account achieved a score of 80 out of 100, with no critical findings and few high and medium findings, while the more misconfigured account produced more findings. The CloudTrail and threat intelligence test also showed that the platform can extract indicators from activity data and enrich them using external intelligence sources.

VII. LIMITATIONS

The evaluation presented in this paper is scenario-based and demonstrative rather than statistical. It uses a small number of controlled AWS accounts, and the number of misconfigurations deliberately introduced in each account is not established as ground truth. Detection coverage, false-positive rates, and runtime overhead are therefore not quantified, and the reported posture scores should be read as indicative of relative configuration quality rather than as validated measurements. Posture coverage is also limited to selected controls for Amazon S3, IAM, and EC2 within a single cloud provider. Hence, the compliance mapping reflects only those controls that the implemented checks can evaluate. Threat intelligence enrichment depends on external services, including AbuseIPDB, IPInfo, and VirusTotal. Each service enforces rate limits: AbuseIPDB limits requests to 1,000 per day on the free tier, IPInfo provides 50,000 requests per month, and VirusTotal enforces 4 requests per minute and 500 per day on the free public API. The platform applies configurable per-request timeouts and exponential backoff for 5xx errors, but does not implement token-bucket rate limiting or graceful degradation when a service is unavailable.

The comparison presented in Table 1 is derived from published product and project documentation. The tools were not executed against the same test accounts, so the table reflects advertised functional coverage rather than measured performance.

The AI-assisted log interpretation mode is an optional, preliminary feature that is not evaluated in this work and should not be relied upon for production security analysis. Assessing the faithfulness of generated summaries, the risk of hallucinated content in a security analysis context, and the impact of prompt design on output quality are left to future work. Deterministic baseline extraction remains the primary and only evaluated indicator source and does not depend on this component.

VIII. CONCLUSION

This paper presented Cloud-CTI-Engine, a locally executable platform that integrates cloud posture analysis, CloudTrail inspection, threat intelligence enrichment, and compliance mapping. The evaluation showed that it can detect AWS misconfigurations, extract and enrich indicators, and map findings to security frameworks. Its CLI-first design supports local security workflows, while the web interface improves accessibility and visualization.

IX. FUTURE WORK

Future work will extend the platform to Microsoft Azure and Google Cloud Platform, expand posture checks, and improve AI-assisted analysis automation. Further improvements will include refined cloud activity detection, stronger indicator correlation across data sources, and enhanced reporting for operational and compliance use cases.

ACKNOWLEDGEMENT

The authors express their sincere appreciation to the Kosovo Cyber Team for supporting this research.

Abstract
Regular expressions reliably match fixed formats, but they produce many false positives when used to find sensitive data in noisy corpora such as source code, logs, tickets, and configuration files. We make context a mandatory part of the matching condition: a candidate value is reported only when a keyword, field label, or linguistic cue for its data type, such as card, api key, authorization, or IBAN, occurs within a bounded window of the value. We describe the rule model, pattern families, and implementation choices, and then evaluate the method through paired ablation on two public benchmarks. On CredData, requiring a context anchor raised the precision of generic credential rules from 0.003 to 0.475 and reduced the reviewed volume from 5.6 million lines to 7,235, while recall fell from 0.956 to 0.356. On ai4privacy, precision more than doubled for categories whose value formats collide and was unchanged for self-distinctive formats such as IBANs. Anchoring, therefore, buys precision at a measured cost to recall, so anchored rules are best deployed as a high-confidence alerting layer alongside a high-recall sweep rather than as a replacement for one.

Keywords: regular expressions, context-aware matching, secret scanner, PII scanner

I. INTRODUCTION

Detecting sensitive and personally identifiable data is a recurring requirement in application security, privacy engineering, and compliance tooling. Organizations routinely scan code repositories, CI/CD artifacts, logs, and documents for exposed secrets, personal data, and financial identifiers, and regular expressions remain the most widely deployed component of these scanners. Yet most deployed patterns match on format alone, which causes a persistent precision problem [1], [2]: a format-only expression can capture the lexical structure of a credit card number or an API key perfectly and still not tell whether the matched text denotes that entity or a benign identifier, a synthetic example, a hash, or test data. For operational teams, the consequence is noisy findings, wasted triage effort, and reduced trust in the scanner [3]. For many sensitive-data categories, the value format alone is not sufficient to determine what a matched string represents. We therefore require the candidate secret or identifier to appear near a keyword, label, or field name associated with the target category, and refer to such rules as context-aware regular expressions. The objective of this study is to quantify the precision gained by making semantic context a mandatory part of the matching condition and the resulting cost in recall. We make three contributions: (1) a deterministic anchor-constrained rule model compatible with production regex catalogs, (2) paired ablation on CredData [4] and ai4privacy [5] that isolates the anchor's contribution, and (3) an empirical characterization of when anchoring helps—principally for ambiguous value formats—and when it does not.

II. RELATED WORK

Prior work shows both the scale of secret leakage and the limits of format-only detection. Meli et al. [1] and Sinha et al. [6] focused on credentials with distinctive structures, whereas SecretBench and subsequent tool

evaluations report substantial false-positive rates in broader secret detection [7], [2]. In industry, such noise contributes to warning fatigue and detector bypass [3].

False-positive reduction has also been approached with learned or hybrid methods, including lexical and contextual classifiers [8], PassFinder [9], and LLM-based post-filtering [10]. In PII detection, Presidio adjusts confidence using nearby context [11], CASSED combines headers and sample values [12], and more recent work likewise exploits surrounding text [13], [14], [15]. These approaches confirm the value of context but typically apply it as a score or in a post-processing stage.

Our formulation differs in three ways. Context is a mandatory conjunct: a value without a nearby anchor is not reported. The constraint is encoded directly in the regex and can therefore be shipped in existing YAML rule catalogs [16] without model inference or a separate filtering stage. Finally, paired ablation holds the value pattern fixed and removes only the anchor, allowing its precision-recall effect to be measured directly. Industrial scanners such as Gitleaks and TruffleHog also use keyword hints [17], [18], providing a practical point of comparison.

III. CONTEXT-AWARE RULE MODEL

Consider card_id: 5555-5555-5555-4444 and user_id: 5555-5555-5555-4444: a format-only card regex can match both, although only the first label supplies card semantics. We therefore model a rule as a value pattern constrained by a nearby context anchor, and report a value only when that anchor occurs within a bounded vicinity.

More precisely, a rule can be written as a tuple r = (V, δ_{pre}, δ_{post}), where A is a finite anchor vocabulary for the semantic category, V is the value pattern, and δ_{pre} and δ_{post} bound the distance, measured in characters or in lines, at which an anchor may precede or follow the value. A candidate string matching V is reported if and only if some anchor in A occurs within δ_{pre} units before it or within δ_{post} units after it. Prefix-anchored rules are the special case δ_{post} = 0; suffix anchors, as in a trailing comment such as "# customer card number" written after the value, correspond to δ_{pre} = 0; bidirectional windows are obtained by setting both bounds. The unit delta is fixed per rule: single-line rules, such as the canonical form above, bound characters, whereas the neighboring-line window analysis of Section VI bounds it in lines.

The following expression represents the prefix-anchored rule form:

(?i)(?:keyword_1|keyword_2|keyword_3) (?:[\s:=_-]{0,10}) (value_pattern)

The prefix form matches one of several labels, a bounded separator, and the value. The separator absorbs common assignment syntax while preventing the anchor from binding to an unrelated value farther along the line; suffix and bidirectional forms are obtained by reversing or alternating the order.

A card rule, for example, can require credit or card near a 13–19 digit candidate: (?i)\b(?: credit[\s_-]?)?card\w*[\s:=_-]{0,10}((?:\d[-]?){13,19}). Generic secrets benefit even more because their value patterns overlap heavily with those of ordinary random strings; anchors such as api_key, secret, client_secret, or authorization supply the missing semantic cue.

Accordingly, anchoring is expected to help most with ambiguous credentials and financial identifiers, less with personal data, and little with formats that are already intrinsically distinctive. Section VI tests this prediction.

IV. DESIGN AND IMPLEMENTATION

We keep ambiguous value patterns narrow and recover recall by expanding anchor vocabularies. Anchors are stored separately so that a value rule can be reused across languages; corpus-dependent validation, such as Luhn or mod-97, is applied outside the regex. The resulting catalog is optimized for triage quality rather than maximum detection volume.

We evaluate two implementations: a single regex that embeds anchor, separator, and value, and a two-stage variant that first locates anchors and then scans a bounded window for the value. The single-regex form is directly portable to production YAML catalogs, whereas the two-stage form permits a more expensive second pass. Runtime is compared in Section VI.

V. EMPIRICAL EVALUATION

1. Dataset and Setup

CredData [4] provides labeled suspicious lines for hard-coded credentials. We use 40 repositories selected by labeled-line count, yielding 48,856 labeled lines across 4,539 files and 8,668 targeted true findings. The paired ablation compares each context-aware rule with the same value pattern after removing the anchor; precision is measured at the line level and recall at the finding level. Format-intrinsic rules, for which anchor removal is not meaningful, serve as controls.

Anchor vocabularies were derived from field experience and common configuration-naming conventions, and were fixed before measurement; no English term was changed in response to CredData scores. Turkish password aliases produced no detections on this English corpus and were dropped, so the multilingual claim is evaluated on ai4privacy. Scripts, rules, and raw outputs are released in the replication package.

2. Results

Table 1. Context-aware vs format-only (anchor-ablated) rules on the CredData subset.

Metric	Context-aware	Format-only
Detected lines	7,235	5,649,099
True-positive lines	3,105	17,325
Overall precision	0.475	0.003
Recall (true findings)	0.356	0.956
Lines per true positive	2.3	326.1

Table 2. Per-category paired results: context-aware (CA) rule vs the same value pattern with the anchor removed (FO).

Category	CA det.	CA prec.	FO det.	FO prec.	Gain

Category	CA det.	CA prec.	FO det.	FO prec.	Gain
API key	48	0.432	1,527,044	0.0013	330×
Auth/access token	361	0.208	1,527,044	0.0013	159×
Token	364	0.202	1,527,044	0.0013	155×
Secret	279	0.542	1,527,044	0.0013	415×
Password	3,489	0.310	3,989,034	0.0007	453×
AWS secret key	0	—	9,980	0.0209	—
GitHub credential	41	0.244	64,212	0.0006	423×
Bearer/basic	1,277	0.563	3,185,996	0.0049	115×

Table 1 shows the main effect: anchoring raises overall precision from 0.003 to 0.475 while reducing candidate volume from 5.65 million to 7,235 lines. Table 2 shows large gains for every generic category with nonzero anchored matches (115×–453×); the AWS secret rule produced no anchored matches because benchmark obfuscation suppresses its exact assignment form. In contrast, intrinsically structured controls are already precise without anchors (PEM: 0.942, AWS key identifiers: 0.855, JWT: 0.769).

To account for repository-level dependence, we resampled the 40 repositories with replacement (B=5000). The 95% percentile interval is [0.282, 0.641] for anchored precision and [10, 631] for overall gain; despite the wide intervals, the per-category lower bounds for password and secret remain well above one.

3. Anchor Proximity and Window Size

Table 3. Relaxing the proximity constraint. Upper block: anchor window in lines over the generic categories. Lower block (italic): structured separator versus a pure character-distance bound on the assignment-shaped subset, which has its own baseline and is not comparable with the rows above.

Variant	Detections	Precision	Recall
Anchor adjacent (canonical)	7,235	0.475	0.356
Same line (w=0)	7,143	0.202	0.154
Within ±2 lines	42,605	0.036	0.165
Within ±5 lines	60,692	0.028	0.173
No anchor (ablated)	5,649,099	0.003	0.956
Structured separator	5,783	0.367	0.491
Pure distance δ=3	14,068	0.100	0.350
Pure distance δ=10	26,259	0.065	0.420
Pure distance δ=40	58,159	0.030	0.437

Table 3 shows that wider proximity windows quickly sacrifice precision while recovering little recall. Same-line matching falls to 0.202 precision, and extending the window to ±5 lines reaches only 0.173 recall at 0.028 precision. This suggests that expanding anchor vocabulary is a more promising recall lever than relaxing proximity.

4. Separator Model Ablation

The same table also tests whether the structured assignment separator contributes beyond what raw character distance alone provides. Replacing it with a pure distance bound reduces precision from 0.367 to at most 0.100 and does not recover the baseline recall. The separator, therefore, captures a syntactic anchor-value relationship rather than distance alone; this ablation applies only to assignment-shaped rules.

5. Generalization to Personal and Financial Data

To test generalization beyond credentials, we repeat the paired ablation on ai4privacy pii-masking-200k [5], 209,261 synthetic records in English, French, German, and Italian with span labels. The target categories deliberately include format collisions: the anchored variant requires a category keyword within 40 characters of the value, while the format-only variant uses the same value pattern.

Table 4. Context-aware vs format-only rules on the ai4privacy personal and financial corpus.

Category	FO prec.	CA prec.	Gain	FO rec.	CA rec.
Credit card	0.340	0.814	2.4×	1.000	0.303
Account number	0.270	0.738	2.7×	1.000	0.706
Phone	0.113	0.173	1.5×	0.946	0.093
SSN	1.000	1.000	1.0×	0.251	0.108
IBAN	0.982	1.000	1.0×	1.000	0.286

Table 4 reproduces the main pattern: anchoring more than doubles precision for the format-colliding credit-card and account-number categories. At the same time, SSN and IBAN gain no precision because their formats are already distinctive. The gains are consistent across all four languages, supporting the multilingual-anchor design.

Figure 1 explains the card result: 98% of format-only false positives are other PII with the same shape, mainly masked numbers, IMEIs, and IBANs. Format alone, therefore, cannot resolve the semantic category. Check-digit validation was not used because the synthetic corpus does not consistently preserve it; for example, only 10.3% of synthetic cards are Luhn-valid.

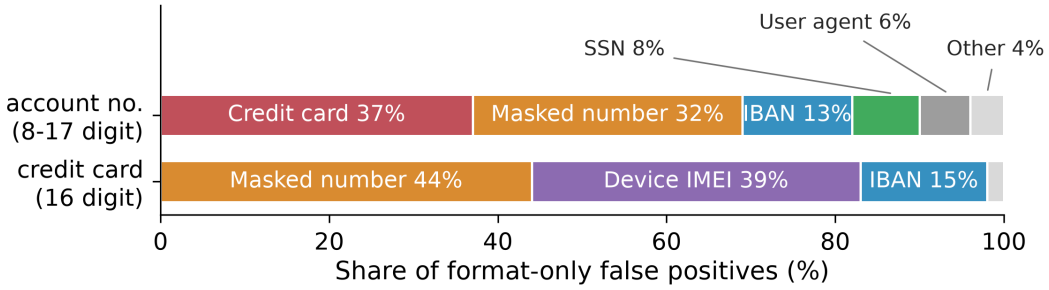

Figure 1. Composition of the format-only false positives for the credit-card and account-number rules on ai4privacy. Slices below 10% are labeled directly.

6. Comparison with Production Scanners

Existing scanners also use contextual keywords, so gitleaks 8.18.4, TruffleHog 3.82.6, detect-secrets 1.5.0, and Microsoft Presidio were run over the same CredData subset with their default rulesets and scored against the same ground truth. Results are reported at the line level and, where applicable, at the file level; file-level scoring is the fair unit for TruffleHog, whose filesystem mode reports no line numbers.

Table 5. Context-aware rules versus production scanners on the CredData subset.

Method	Det.	Line P	Line R	File P	File R
Context-aware (ours)	7,235	0.475	0.356	0.561	0.618
gitleaks	6,621	0.748	0.568	0.904	0.336
detect-secrets	8,591	0.261	0.174	0.526	0.594
TruffleHog	179	0.335	0.004	0.554	0.044
Format-only (ablated)	5,649,099	0.003	0.956	0.345	0.987

Without tuning thresholds or allowlists, our rules outperform detect-secrets and TruffleHog in line precision, while gitleaks is more precise (0.748 vs. 0.475). Most gitleaks findings come from its generic-api-key rule, an anchor-and-proximity construction augmented by entropy and a curated allowlist; the bare regex reaches 0.314 precision, entropy 0.443, and the allowlist 0.739. These post-filters are complementary to our rule model but were excluded because they would confound the anchor ablation.

7. Discussion and Limitations

Runtime was not a limiting factor: the six anchored assignment rules scan the 860 MB subset in 3.5 s (about 247 MB/s) on a commodity laptop. The two-stage implementation is slower (8.6 s) because the scanner already extracts literal keywords and efficiently skips non-matching lines; a separate prefilter is useful only when the second stage is genuinely expensive.

The central trade-off is recall. Anchored rules recover 35.6% of true findings, versus 95.6% for the ablated variants, so we recommend using the two modes at different operating points: anchored rules for high-confidence real-time alerts or blocking, and format-only rules for lower-priority exhaustive sweeps.

The evaluation has four main limitations. First, format-only variants are ablations of our rules rather than native production-scanner rules, so the paired comparison isolates the anchor contribution rather than tool superiority. Second, the repository subset is non-random, although bootstrap intervals quantify repository dependence. Third, CredData labels only examined lines; manual inspection of 100 detections on unlabeled lines found no plausible missed secret, limiting the possible precision shift to 0.475–0.479. Finally, the method assumes a nearby semantic label and therefore misses bare secrets, free-form cases, and unforeseen

anchor vocabulary. The canonical expressions avoid nested quantifiers and showed no pathological backtracking in our tests, but deployments on other regex engines should still validate rules and enforce per-match timeouts.

VI. CONCLUSION AND FUTURE WORK

Context-aware regular expressions provide a simple, deterministic way to trade recall for substantially higher precision when value formats are ambiguous. Across two public benchmarks, the benefit is strongest for generic credentials and colliding personal or financial identifiers, while intrinsically distinctive formats gain little. The method is therefore best used as a high-confidence layer alongside, not instead of, a high-recall sweep.

Future work will extend evaluation to the full CredData benchmark and additional country-specific identifiers, expand or learn anchor vocabularies automatically, and combine anchoring with orthogonal filters such as entropy and allowlists.

ACKNOWLEDGEMENT

The authors thank Trendyol and the Security Development Hub team for their support, and the maintainers of CredData and ai4privacy for releasing the benchmarks that made this evaluation possible.

Abstract
Systems increasingly need to determine whether a given secret has been seen before without storing that secret in plaintext. This is the problem underlying breached-password detection, credential-stuffing defense, and duplicate-secret prevention. Individual protocols have been analyzed in isolation, but their comparative behavior under identical experimental conditions is not well documented. We empirically compare three families: probabilistic membership filters (Bloom and Cuckoo), k-anonymity hash-prefix lookups, and Private Set Intersection and Oblivious Pseudorandom Function protocols, benchmarking both a classic Diffie-Hellman OPRF and a modern Ristretto255 OPRF. Under a threat model that separates stored-set privacy, query privacy, and offline brute-force resistance, and using a directly measured dataset of 100,000 secrets, we evaluate build cost, memory, latency, communication, error rate, and privacy. Filters answer in one to two microseconds with a 117–160KB footprint but leak membership to an offline attacker; k-anonymity adds query privacy for a thirty-fold larger stored set and 35 bytes of online communication at identical latency; the DH-OPRF removes offline brute-force leakage at 514 bytes online and about 104ms per query, while the Ristretto255 OPRF achieves the same guarantees with 32-byte storage and millisecond-scale queries. We distill these trade-offs into a decision guide and release our implementations and benchmark harness as open source.

Keywords: privacy, bloom filter, cuckoo filter, k-anonymity, private set intersection, oblivious pseudorandom function, breached credentials, membership testing

I. INTRODUCTION

A growing number of systems must check whether a user-supplied secret, such as a password, API token, recovery code, or cryptographic key, appears in some reference set, without learning or storing the secret itself. Use cases include breached-credential detection, secret scanning in committed files or logs, and duplicate or weak-secret prevention. Have I Been Pwned (HIBP) and Google Password Checkup are production deployments of the first case. The naive solution, storing the secrets and comparing, violates the very property these systems exist to protect. A range of techniques sidestep plaintext storage, but they are frequently conflated under the banner of "privacy-preserving" despite offering materially different guarantees: a Bloom filter and a Private Set Intersection protocol both avoid storing plaintext, yet only one resists an attacker who steals the server state and brute-forces, low-entropy candidates. Our contributions are:

- A threat model (Section III) decomposing privacy into stored-set privacy, query privacy, and offline brute-force resistance.
- Open implementations (Section V) of Bloom and Cuckoo filters, k-anonymity hash-prefix lookup, and a DH-based PSI/OPRF protocol.

- An empirical comparison (Section VI) on a shared 100K-secret dataset across build cost, memory, latency, communication, and false-positive rate.
- A decision guide (Table 4) mapping deployment requirements to a recommended method.

II. BACKGROUND AND RELATED WORK

1. Probabilistic membership filters

A Bloom filter [1] stores a set in a bit array of m bits using k hash functions; membership tests have no false negatives but a tunable false-positive rate. Bonomi et al. [2] extended this model with Counting Bloom Filters that support item deletion. Fan et al. [3] introduced Cuckoo filters, which store short fingerprints in a cuckoo-hashed table, offering deletion support and a better space–error trade-off at low target rates. Graf and Lemire [4] further optimized space and retrieval speed with XOR and Binary Fuse filters. Naor and Yogev [5] showed that standard filters can leak set members when queried adaptively by an adversary. All of these filters are compact and local: a query touches only the structure, with no network communication.

2. K-anonymity hash-prefix lookup

Hunt [6] popularized the k-anonymity prefix lookup with the Have I Been Pwned Pwned Passwords API: the client hashes its secret, sends only a short prefix of the digest, and receives every stored digest sharing that prefix. The client completes the comparison locally, so the server never sees the secret itself, only a prefix that is shared by an anonymity set of many candidate digests. Li et al. [7], [8] rigorously analyzed the security and privacy bounds of various bucketization techniques for this protocol. Golla et al. [9] showed in a large-scale field study that speed of validation is critical to real-world adoption.

3. Private Set Intersection and Oblivious PRF

Private Set Intersection (PSI) lets two parties learn the intersection of their sets without revealing the remainder, dating back to Meadows [10] and scaled via oblivious transfer extensions by Pinkas et al. [11]. Modern systems reduce per-query cost with Oblivious Pseudo-Random Functions (OPRFs), introduced by Kolesnikov et al. [12] and standardized for prime-order groups in RFC 9497 by Davidson et al. [13]. Google Password Checkup [14] provides the first massive-scale deployment: the client blinds its secret, the server applies a secret key, and the client unblinds to obtain a pseudorandom value comparable against a bucketed encrypted set. The server never sees the secret, and the stored pseudorandom group elements are not offline brute-forceable without the key. Angelou et al. [15] extended OPRF-based membership tests with asymmetric protocols that resist malicious servers, and Bellare et al. [16] and Krawczyk et al. [17] showed how HMAC-style keyed hashing prevents offline dictionary attacks against keyed checks.

4. Comparative Studies

Archer et al. [18] survey real-world deployments of secure computation, with private membership checks as one application, and Ateniese et al. [19] analyze proofs of storage with public verifiability. Yet, both focus on a single protocol family. The works surveyed above each propose, optimize, or deploy an individual primitive; none conducts a side-by-side empirical comparison of probabilistic filters, k-anonymity, and PSI/OPRF under a shared threat model, dataset, and benchmarking environment. This paper aims to fill that gap.

III. THREAT MODEL AND PRIVACY DEFINITIONS

We consider a client holding a secret x *and a server holding* a set büyük harf S.We evaluate each method against three independent adversarial goals. A method may satisfy any subset.

(P1) Stored-set privacy. An attacker who obtains the server's persisted state (filter bits, digest list, or encrypted set) should not be able to recover the secrets in S. We further distinguish offline brute-force resistance: even given the state and a dictionary of candidate secrets, can the attacker confirm which ccandidates arein S.?
(P2) Query privacy. The server, or a network observer, should not learn the queried secret x, beyond an explicitly bounded leakage such as a hash prefix defining an anonymity set of size k.
(P3) Correctness and no false negatives. A member must never be reported absent. False positives are tolerated at a tunable rate for filters and must be accounted for in the threat analysis: a false positive can cause an unnecessary rejection, but never a missed match.

Table 1. Qualitative privacy and communication placement of each method.

Method	P1 set	Offline BF	P2 query	Offline Setup/Dist.	Online Query Comm.
Bloom filter	partial	leaks	local only	High (Full index download)	0 B (local query)
Cuckoo filter	partial	leaks	local only	High (Full index download)	0 B (local query)
k-anonymity	digest list	leaks	k-anon set	0 B (hosted on server)	Small (35 B per query)
PSI / OPRF	pseudorandom	resists	blinded	0 B (hosted on server)	Moderate (514 B per query)

Table 1 encodes a central insight: *compactness is not privacy*. Filters and k-anonymity avoid plaintext storage yet leak set membership to an offline attacker; only PSI and OPRF close that gap, and Section VI measures the cost. The table also highlights an architectural trade-off in network overhead: filters require a large one-time offline download but query locally with zero bytes over the network, while k-anonymity and PSI host the reference set server-side but incur network overhead on every query.

IV. EXPERIMENTAL DESIGN

We evaluate on two distinct corpora designed to capture the full spectrum of entropy conditions encountered in practice: Random high-entropy: one hundred thousand random alphanumeric strings of length 8–64 (Python's secrets; scripts/generate_secrets.py), representing API tokens, recovery codes, and salts with near-maximal entropy. RockYou low-entropy: one hundred thousand unique printable ASCII passwords of length 4–64 from the RockYou breach corpus (scripts/extract_rockyou.py), filtered to match the random dataset cardinality. These are human-chosen secrets with severe repetition, low entropy, and a heavy-tailed Zipfian distribution. The two datasets span opposite entropy extremes; Section VI re-runs the full benchmark on RockYou to expose how each method behaves under low-entropy, skewed distributions.

Probabilistic Filters (Bloom & Cuckoo):

Empirical result: The measured FP rate (over 100,000 never-seen items) is 0.99% vs 1.04% (Bloom) and 0.60% vs 0.60% (Cuckoo) for random vs RockYou, a difference well inside the 95% confidence interval. The probabilistic error bounds hold under both entropy conditions (Section VI).

Security Vulnerability: Despite stable FP rates, low-entropy filters are highly vulnerable to offline brute-force. An attacker with the filter can test a local RockYou dictionary in microseconds to reveal membership in the set.

k-Anonymity Prefix Lookup:

Empirical result: Both datasets yield a median anonymity set of 1 and a maximum bucket size of 4 at a 20-bit pre10, son taban, üssü altıncı, bucket sparsity dominates regardless of the entropy distribution (see anonymity-set caveat).

Scale Mitigation: IHIBP ($N \approx 10^9$), the density parameter $\lambda = \frac{N}{B} \approx$ 954 guguarantees anonymity , underweightedistributions.

Cryptographic PSI and OPRF:

Empirical result: PSI build time is 45.8 min vs 45.8 min and query latency 103.6 ms vs 105.0 ms (about 1.3% difference) on the full 100K dataset. The two corpora are functionally identical, confirming that query cost is independent of secret entropy.

V. IMPLEMENTATION

Bloom. The bit count m and hash count kk follow the standard optimal formula in (1), with MurmurHash3 and incrementing seeds over a bit-packed array:

$$m = -\frac{nln\varepsilon}{(ln2)^2}, \qquad k = \frac{m}{n} ln2. \tag{1}$$

Luck. Four-slot buckets, fingerprint size $f = \lceil \log_2(2b/\varepsilon) \rceil$or bucket size b, a power-of-two table for XOR-based alternate indexing, and up to five hundred eviction kicks.

k-anonymity. SHA-1 digests bucketed by a five-hex-character (twenty-bit) prefix, matching HIBP. The client sends the prefix and compares the returned suffix digests locally.

PSI and OPRF. Our baseline uses a Decisional Diffie-Hellman (DH) construction over the RFC 3526 2048-bit MODP group, modeling the corof Google Password Checkup [14]: with server key k the stored value is $F_k(y) = g^{H(y)\cdot k}$; the client blinds with random r, the server raises to k, and the client unblinds with r^{-1}. The encrypted set is bucketed by a sixteen-bit prefix for k-anonymity-style scaling (256 bytes/item stored; 514 bytes online per query, see Section VI). A modern baseline uses the same OPRF structure over the Ristretto255 group (RFC 9496 [20]) following RFC 9497 [13], with 32-byte elements and no dependence on the legacy 2048-bit group. Both variants are pure Python with no external cryptographic dependencies, relying only on a hash function and modular exponentiation; mature open-source Ristretto implementations exist [21], so our pure-Python EC-OPRF latency bound is conservative.

VI. RESULTS

Table 2 reports all metrics for 100,000 secrets; every method, including the DH-based PSI's 45-minute public-key build, was measured directly on the complete dataset, so no values are extrapolated. False-positive rates are estimated over 100,000 never-seen items rather than the 2,000 used for latency, giving a narrow 95% confidence interval.

Table 2. Benchmark results (100K random secrets).

Metric	Bloom	Cuckoo	k-anon	PSI/OPRF	EC-OPRF
Build time (100k)	0.17 s	0.09 s	0.12 s	45.8 min	4.4 min
Stored size (100k)	117 KB	160 KB	3.4 MB	25.6 MB	3.2 MB
Stored size (per item)	1.2 B	1.6 B	35 B	256 B	32 B
Latency present (μs)	1.58	0.88	1.33	103,632	5,416
Latency absent (μs)	0.58	0.96	1.04	103,550	5,321
Offline distribution cost	117 KB	160 KB	0 B	0 B	0 B
Online query communication	0 B	0 B	35 B	514 B	96 B
False-positive rate	0.99%	0.60%	0%	0%	0%
Median anonymity set	—	—	1	1	2

Re-running the full benchmark on the RockYou corpus (Table 3) leaves every cross-method relative ranking unchanged: build times, stored sizes, and latencies move by at most a few percent, with Bloom's false-positive rate shifting from 0.99% to 1.04%. The privacy and cost ladder of Section III is thus structurally robust to data entropy.

Table 3. Low-entropy (RockYou) results.

Metric	Bloom	Cuckoo	k-anon	PSI/OPRF	EC-OPRF
Build time (100k)	0.16 s	0.08 s	0.12 s	45.8 min	4.5 min
Stored size (100k)	117 KB	160 KB	3.4 MB	25.6 MB	3.2 MB
Latency present (μs)	1.54	0.83	1.33	105,028	5,458
FP rate	1.04%	0.60%	0%	0%	0%
Median anon. set	—	—	1	1	2

Latency. As shown in Figure 1, probabilistic filters and k-anonymity all answer in one to two microseconds. The DH-based PSI answers in about one hundred milliseconds (103,632 μs), roughly sixty-six thousand times slower than a filter, because each query performs three 2048-bit modular exponentiations for blinding, evaluation, and unblinding; the EC-OPRF answers in 5,416 μs (pure Python), and a compiled curve25519/ristretto backend would place it in the 0.3–3 ms range. This is the price of cryptographic stored-set privacy.

Filter and k-anonymity latencies measure only local computation. A deployed k-anonymity or PSI/OPRF query additionally incurs a network round-trip: 0.47 ms median measured on loopback, 10–100 ms on a wide-area network. Adding one loopback RTT to the server-held methods collapses the k-anonymity-versus-DH-OPRF gap (Figure 1, solid markers); over a wide-area RTT, both sit within a constant factor because the

network leg dominates. Stored size. Filters are the most compact, under two bytes per item (117–160 KB at full scale), followed by k-anonymity (35 B/item, 3.4 MB), the EC-OPRF (32 B/item, 3.2 MB), and the DH-OPRF, whose 256-byte group elements total 25.6 MB, the price of brute-force-resistant pseudorandom storage. In all cases, per-item storage is smaller than the storage required for online query communication, which additionally carries the request element and the downloaded bucket. False positives. Both probabilistic filters track their one percent target: 0.99% (Bloom, 95% CI 0.93–1.05%) and 0.60% (Cuckoo, 95% CI 0.56–0.65%) over the 100,000-item never-seen sample. The hash-based methods are exact, with zero false positives, since they compare full digests or group elements rather than short probabilistic fingerprints. Communication. Probabilistic filters require a large one-time offline download (117–160 KB) but query locally with zero bytes online. k-anonymity and OPRFs host the reference set server-side (zero offline cost) but incur per-query costs: 35 bytes for k-anonymity, 514 bytes for the DH-OPRF, and 96 bytes for the EC-OPRF (Section V). Privacy versus cost. Figure 2 plots query latency against the privacy ladder of Section III: filters sit at the cheap, low-privacy corner; k-anonymity adds query privacy at near-zero extra latency; the DH-OPRF occupies the high-privacy corner roughly five orders of magnitude to the right; and the EC-OPRF shortens that gap to about 3.5 orders of magnitude.

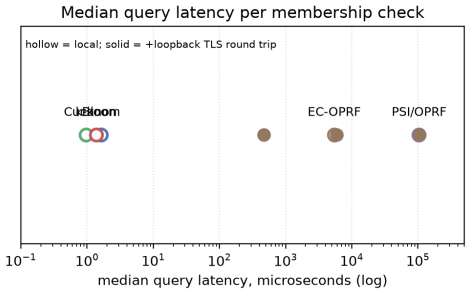

Figure 1. Median query latency per membership check, log scale.

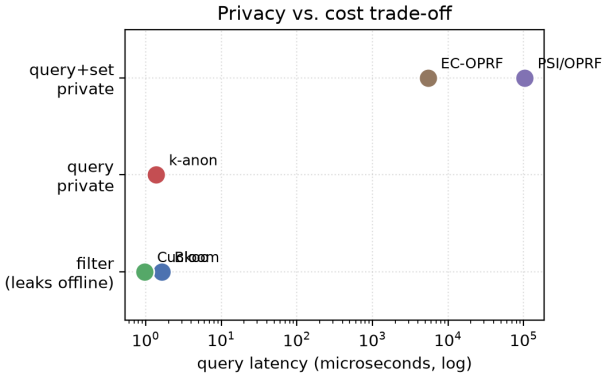

Figure 2. Privacy versus cost.

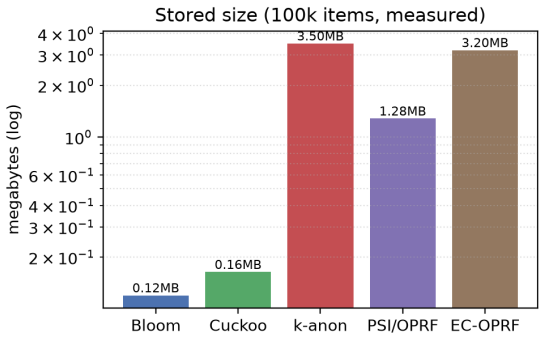

Figure 3. Stored size per method, measured (not extrapolated) on one hundred thousand items, log scale. EC-OPRF shows the 32-byte-element advantage over the DH group.

1. The anonymity-set caveat

Our high-entropy dataset yields a median bucket size of 1 for the hash-prefix method with a 20-bit prefix (and 2 for the OPRF variants, which use a shorter 16-bit prefix). In this corpus, a prefix often uniquely identifies the secret, providing little practical query privacy. Distributing N secrets across B independent prefix buckets, with SHA-1 behaving as a random oracle, gives a Poisson process with mean density per bucket:

$$\lambda = \frac{N}{B} \tag{2}$$

In our setup, $N = 100{,}000$ and a 5-hex-character (20-bit) prefix yields $B = 2^{20} = 1{,}048, buckets$, so the density parameter is:

$$\lambda = \frac{100{,}000}{1{,}048{,}576} \approx 0.0954 \tag{3}$$

The Poisson distribution gives the probability of exactly $ksecrets$ in a bucket and, from (3), the probability that a bucket is non-empty:

$$P(X = k) = \frac{\lambda^k e^{-\lambda}}{k!}, \qquad P(X \geq 1) = 1 - e^{-\lambda} \approx 0.0910. \tag{4}$$

Conditioned on a bucket being active, the probability that it contains exactly one secret is therefore

$$P(X = 1 \mid X \geq 1) = \frac{P(X = 1)}{1 - P(X = 0)} = \frac{\lambda e^{-\lambda}}{1 - e^{-\lambda}} \approx 0.953, \quad (5)$$

ov 95% of, a, activ, bucket, contai, extly, ne, sect,, which expinshyhenonymity set is one.

Now consider a massive dataset like Have I Been Pwned (HIBP), where N is approximately equal to 10^9; secrets are indexed using the same 5-hex prefix (B = 1,048,576) The density parameter rises to:

$$\lambda = \frac{10^9}{1{,}048{,}576} \approx 953.7 \quad (6)$$

Because λ is large, the Poisson distribution can be approxmated by a Gaussi an distribution $N(\mu = 953.7, \sigma^2 = 953.7)$, with a standard deviation of:

$$\sigma = \sqrt{953.7} \approx 30.9 \quad (7)$$

The central takeaway is that k-anonymity's query privacy is scale-dependent: it is a direct function of the density ratio, büy harf B $B.A$ small or sparse set degrades to near-plaintext prefixes; we report this artifact rather than tuning the dataset to flatter the method. Prefix-length sensitivity. The prefix length trades anonymity-set size against download cost. On the 100K dataset, the 20-bit prefix (five hex characters, HIBP's choice) yields the median bucket of one that was already reported. A 16-bit prefix ($B = 65{,}536$) raises the density to $\lambda \approx 1.53$ and the median bucket to two (maximum nine, the EC-OPRF configuration in Table 2), at the cost of roughly twice the suffix data per query. Shortening to 12 bits ($(B = 4{,}096, lambda \approx 24)$ $restores\ a\ median\ bucket\ of\ around$ 20Still, it downloadsmost of the set for a single query, defeating the purpose. We therefore recommend adaptive prefix selection: choose B so that $\lambda = N/B$ exceeds the desired anonymity bound (subject to the response-size budget. Our PSI/OPRF implementations expose this as a configurable parameter.

Table 4. Decision guide: mapping deployment priorities.

Priority	Set	Use
Smallest footprint, fast local check	public or shippable	Bloom or Cuckoo
Same, plus deletions	public or shippable	Cuckoo
Hide the query from a server	large, server-held	k-anonymity
Hide query and stored set; offline resistance	sensitive, server-held	EC-OPRF preferred
Exact membership, modest privacy; low latency	server-held	k-anonymity
Match existing Checkup-style deployment	sensitive, server-held	DH-OPRF (legacy)

VII. CONCLUSION

Privacy-preserving secret validation is not one guarantee but a ladder of them. We decomposed it into stored-set privacy, query privacy, and offline brute-force resistance, and measured five method variants spanning the ladder on a common 100K-secret benchmark. The practical takeaway is that compactness and privacy are distinct properties with a steep exchange rate, and the right choice follows directly from which of the three guarantees a deployment actually needs.

Abstract
Machine-learning-based intrusion detection systems (ML-based IDSs) often achieve high performance under intra-dataset evaluation but exhibit substantial degradation when applied to unseen datasets due to class imbalance and distributional differences. This study is based on two benchmark intrusion detection datasets, CIC-IDS2017 and CIC-IDS2018, and investigates whether data augmentation can improve the cross-dataset generalization of binary and multiclass intrusion detection models. Before model development, both datasets were cleaned by removing duplicate records and samples containing missing values. Their feature spaces were then harmonized by retaining common features, and attack labels were mapped to a unified taxonomy. Models were subsequently trained on the CIC-IDS2017 dataset using five data augmentation techniques and their corresponding non-augmented baselines. Their performance was assessed through intra-dataset evaluation on CIC-IDS2017 and cross-dataset evaluation on CIC-IDS2018. Without augmentation, multiclass macro recall decreased from 0.99 to 0.48 across the two evaluation settings, while binary Attack recall declined from 0.95 to 0.45. Among the evaluated techniques, SMOTE achieved the strongest cross-dataset performance, increasing multiclass macro recall to 0.88 and binary Attack recall to 0.78, followed by random oversampling with 0.84 and 0.70, respectively. GAN-based augmentation and ADASYN yielded moderate improvements, whereas MixUp was less effective. These findings indicate that appropriate data augmentation can substantially enhance cross-dataset intrusion detection, although additional approaches are needed to address distributional differences across heterogeneous network datasets better.

Keywords: Intrusion Detection System; Cross-Dataset Generalization; Data Augmentation; Class Imbalance; Machine Learning.

I. INTRODUCTION

As enterprise networks grow in scale and complexity, ML-based IDSs have become important for automatically detecting malicious network activities [1]. However, their real-world effectiveness is often limited by class imbalance, as benign traffic dominates while relatively few samples represent many critical attacks. This imbalance can bias models toward majority classes, resulting in high overall accuracy but poor detection of rare and security-critical attacks [2],[3]. Several data augmentation techniques have been proposed to address this problem [4],[8]. Although these methods often improve detection performance, most studies evaluate them only within the same dataset. Therefore, it remains unclear whether these improvements generalize to unseen network environments or mainly reflect adaptation to dataset-specific traffic characteristics. This issue is important because distributional differences between datasets can substantially reduce IDS performance [9],[10], while the impact of augmentation on cross-dataset generalization remains insufficiently explored [11].

Accordingly, this study evaluates multiple data augmentation techniques to improve cross-dataset generalization of binary- and multiclass ML-based IDS models. Models are trained on CIC-IDS2017 and evaluated in both intra- and cross-dataset settings, with CIC-IDS2018 as the external dataset. The study aims to determine whether augmentation helps models learn more transferable attack representations and maintain effective detection on previously unseen network traffic. The findings can benefit cybersecurity researchers, IDS developers, and network security practitioners by guiding the selection of augmentation techniques to enhance intrusion detection robustness. The study also demonstrates the importance of cross-dataset evaluation when assessing IDS generalization and provides a basis for further research on domain adaptation, distribution alignment, and multi-dataset learning. The remainder of this paper is organized as follows. Section 2 reviews related work on ML-based IDSs, data augmentation, and cross-dataset generalization. Section 3 presents the datasets, preprocessing procedures, augmentation techniques, and evaluation methodology. Section 4 presents and discusses the experimental results, and Section 5 concludes the paper and outlines future research directions.

II. RELATED WORK

ML has become the dominant paradigm for Network Intrusion Detection Systems (NIDSs), progressively replacing traditional signature-based approaches with data-driven techniques. Over the past decade, extensive research has investigated the application of ML to intrusion detection, resulting in a wide variety of supervised, unsupervised, ensemble, and deep learning models. Recent comprehensive surveys [12-16] have highlighted the rapid evolution of ML-based IDSs, covering advances in learning algorithms, feature engineering, benchmark datasets, and evaluation methodologies. Despite these significant advances, the literature consistently identifies several unresolved challenges, including class imbalance, dataset bias, model robustness, explainability, and the limited ability of current models to generalize across heterogeneous network environments. Among these challenges, class imbalance is particularly important because minority attack classes are often underrepresented, which may considerably reduce their detection rates. To address this problem, various data augmentation techniques have been proposed to generate additional minority-class samples without discarding majority-class traffic [17]. In network intrusion detection, these techniques must preserve the statistical and behavioral characteristics of high-dimensional tabular network data to avoid generating unrealistic traffic samples [18]. Existing approaches can be broadly classified into three categories. Distance-based oversampling methods, such as SMOTE and ADASYN, generate new samples by interpolating between neighboring minority instances, but they may introduce noisy or ambiguous samples in sparse feature spaces [19], [20]. Deep generative models, including GANs, VAEs, and CTGANs, learn the underlying data distribution to generate more realistic synthetic traffic, although they often suffer from training instability and high computational complexity [18],[21],[22]. Feature-interpolation methods, such as MixUp, improve model regularization through convex combinations of training samples. Nevertheless, their effectiveness in tabular network traffic remains insufficiently explored, as feature interpolation may alter the semantic relationships among flow characteristics [23]. Although data augmentation is widely used to address class imbalance, its practical value also depends on whether it helps models learn patterns that generalize beyond the training dataset. Strong intra-dataset performance does not necessarily translate to robustness under different network conditions. Cross-dataset validation, where models are trained on one dataset and evaluated on another, provides a more realistic assessment of generalization [24],[25]. However, despite growing interest in both data augmentation and cross-dataset evaluation, the effectiveness of augmentation in improving cross-dataset generalization remains underexplored. Therefore, this study systematically evaluates five representative data-augmentation techniques—SMOTE, ADASYN, GANs, MixUp, and random oversampling (RO)—within a harmonized experimental framework based on the CIC-IDS2017 and CSE-CIC-IDS2018 datasets. Unlike most previous studies that focus primarily on intra-dataset performance, this work examines whether augmentation can improve the transferability of learned attack patterns across heterogeneous network environments. The

models are evaluated in both binary and multiclass settings, in intra- and cross-dataset scenarios, enabling a direct comparison of augmentation effectiveness under distribution shift. This analysis aims to clarify the extent to which data augmentation can mitigate the generalization limitations of ML-based IDSs.

III. METHODOLOGY & EXPERIMENTAL SETUP

This section presents the experimental framework adopted to assess the impact of data augmentation on cross-dataset intrusion detection. As illustrated in the figure. 1, the proposed methodology comprises five main steps: (1) dataset cleaning and feature harmonization; (2) dataset splitting; (3) training-set preparation, including categorical encoding, normalization, feature selection, and the application of the selected data augmentation techniques; (4) model training; and (5) performance evaluation under both intra-dataset and cross-dataset settings.

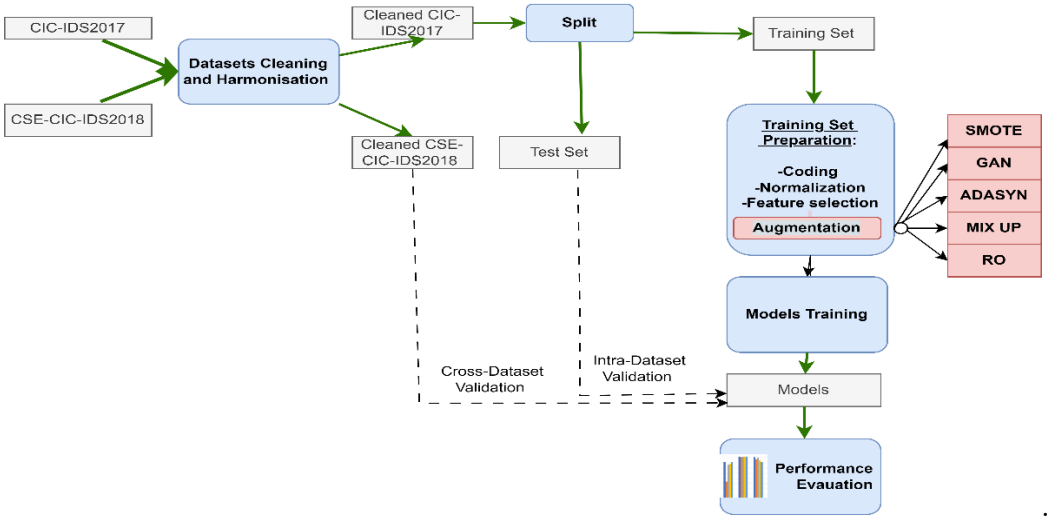

Figure 1. Overview of the proposed experimental framework.

1. Datasets

This study employs two publicly available benchmark intrusion detection datasets: CIC-IDS2017 and CSE-CIC-IDS2018 [26],[27]. CIC-IDS2017 was developed by the Canadian Institute for Cybersecurity (CIC) at the University of New Brunswick [26], while CSE-CIC-IDS2018 was developed through a collaboration between CIC and the Communications Security Establishment (CSE) [27]. Both datasets contain labeled benign and malicious network traffic and are available in PCAP and CSV formats. Their flow-based features were extracted using CICFlowMeter, providing more than 80 network traffic features suitable for ML analysis. In this study, the CSV versions were used and harmonized to obtain a common feature representation for cross-dataset evaluation. Despite their related feature spaces, the datasets differ in traffic distributions, attack scenarios, and network environments, making them suitable for evaluating the generalization capability of ML-IDSs.

2. Datasets Cleaning and Harmonization

To ensure a consistent and reliable experimental framework, both CIC-IDS2017 and CSE-CIC-IDS2018 datasets underwent a comprehensive cleaning and harmonization process before model development. First, duplicate network flows were removed to eliminate redundant observations. Subsequently, samples containing missing, infinite, or invalid feature values were identified and discarded. After data cleaning, the feature schemas of both datasets were harmonized by retaining only features common to both, thereby establishing a unified feature space for cross-dataset evaluation. Finally, the original attack labels were reorganized into a common taxonomy by grouping semantically related attacks into seven unified categories: DoS**,** DDoS**,** Bot**,** Patator**,** Web Attack**,** PortScan**,** and DoS Hulk.

3. Dataset Splitting Strategy

To ensure a reliable and unbiased evaluation, the CIC-IDS2017 dataset was partitioned using a stratified splitting strategy that preserved the original class distribution. Specifically, 70% of the data were allocated to model training, 10% to validation, and the remaining 20% to final testing.

4. Training Set Preparation

- The training data were first encoded to transform categorical class labels into numerical representations suitable for ML. For the binary classification task, Label Encoding was applied by assigning 0 to benign traffic and 1 to attack traffic. For the multiclass classification task, One-Hot Encoding was employed to represent the different attack categories.
- Feature normalization was applied to reduce the effect of differences in feature scales and improve model stability. Two normalization techniques, Robust Scaler and Min-Max Scaling, were experimentally evaluated for both binary and multi-class classification.
- Feature selection was performed to reduce dimensionality and improve model performance. A Random Forest classifier was used to rank features by importance score. Multiple candidate subsets of the highest-ranked features were systematically evaluated, and the optimal subsets were selected based on the best validation performance, yielding 45 features for the multiclass task and 30 for the binary classification task.
- Training set is augmented using five distinct oversampling and synthetic sample generation techniques before classifier fitting: SMOTE, GAN, ADASYN, MIX UP, and RO**.**

IV. LEARNING MODEL SELECTION AND EVALUATION STRATEGY

XGBoost was selected as the classification model due to its high predictive performance and efficiency in handling high-dimensional tabular network data. Following data preparation and augmentation, a separate XGBoost model was trained for each augmentation technique as well as for the original non-augmented dataset. As illustrated in Figure 1, model performance was evaluated under two experimental settings: intra-dataset validation using the CIC-IDS2017 test set and cross-dataset validation using the unseen CSE-CIC-IDS2018 dataset to assess generalization. Performance was measured using Precision, Recall, F1-score, and macro-average values, providing a comprehensive evaluation of both overall classification performance and minority attack detection.

V. EXPERIMENTAL RESULTS AND DISCUSSION

This section presents the results obtained for both binary and multiclass classification.

1. Multi-Class Classification Results

Table 1 presents the multiclass classification results obtained without data augmentation. In the intra-dataset evaluation on CIC-IDS2017, the model achieved consistently high recall values, reaching 0.99 for most attack classes and 0.94 for Web Attack, with a macro recall of 0.98. This strong performance indicates that the model effectively learned the attack patterns represented in the training dataset. However, during cross-dataset evaluation on CIC-IDS2018, recall decreased substantially, with relatively strong performance only for Patator (0.85) and DDoS (0.71), suggesting that these attack patterns were more transferable across the two datasets. In contrast, DoS, Web Attack, and Bot achieved recalls of 0.54, 0.27, and 0.01, respectively, which may reflect differences in traffic characteristics and attack distributions between the datasets. The resulting macro recall of 0.48 highlights the model's limited ability to generalize under distribution shifts. These findings are further supported by the confusion matrices presented in Figures 2 and 3.

Table 1. Multi-Class Classification Performance: CIC-IDS2017 vs. CIC-IDS2018 (Before augmentation)

Traffic Type	CIC-IDS2017			CIC-IDS2018		
	Precision	**F1 score**	**Recall**	**Precision**	**F1 score**	**Recall**
DoS	0.99	0.99	0.99	0.95	0.69	0.54
DDoS	1.00	0.99	0.99	0.86	0.78	0.71
DoS Hulk	0.99	0.99	0.99	/	/	/
Bot	1.00	0.99	0.99	0.99	0.03	0.01
Web Attack	0.97	0.96	0.94	0.97	0.42	0.27
Patator	0.99	0.99	0.99	0.87	0.86	0.85
PortScan	0.99	0.99	0.99	/	/	/
Macro avg	**0.98**	**0.98**	**0.98**	**0.93**	**0.56**	**0.48**

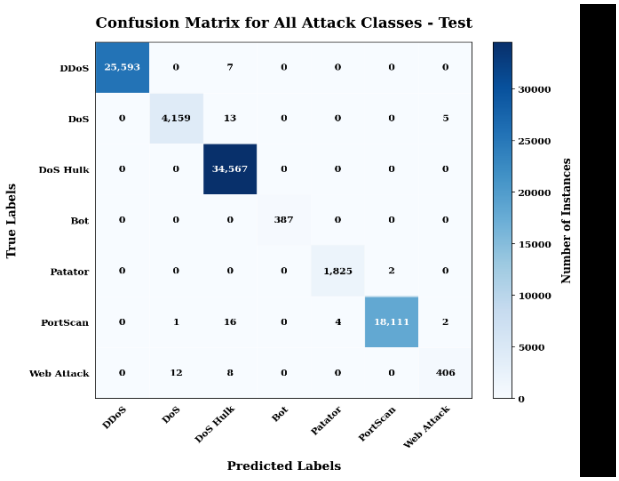

Figure 2. Multiclass confusion matrix of CIC-IDS2017 before augmentation.

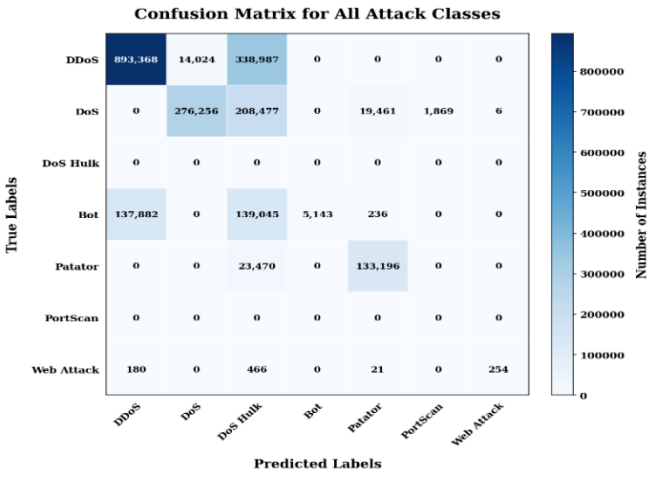

Figure 3. Multiclass confusion matrix of CIC-IDS2018 before augmentation.

Table 2 presents the multiclass classification results obtained after applying various data augmentation techniques. In the intra-dataset evaluation on CIC-IDS2017, all techniques maintained consistently high recall, with a macro recall of 0.99, indicating that augmentation did not degrade performance on the original data distribution. More importantly, augmentation substantially improved cross-dataset performance on CIC-IDS2018 compared with the non-augmented macro recall of 0.48. SMOTE achieved the best generalization performance, with a macro recall of 0.88, followed by RO at 0.84 and MixUp at 0.69, suggesting that balancing minority classes improved the learning of more transferable attack patterns. SMOTE also achieved strong recall for Bot (0.99), DDoS (0.97), Patator (1.00), and DoS (0.85). In contrast, GAN and ADASYN provided only moderate improvements, with macro recalls of 0.60 and 0.54, respectively, suggesting that the generated samples were less representative of the attack distributions in CIC-IDS2018. Overall, these results show that the effectiveness of augmentation varies considerably across techniques, with SMOTE and RO yielding the greatest improvements in cross-dataset generalization. The confusion matrices in Figures 4 and 5 further support these observations.

Table 2. Impact of Data Augmentation Strategies on Attack Detection Recall (CIC-IDS2017 vs. CSE-CIC-IDS2018)

Attack Type	CIC-IDS2017					CIC-IDS2018				
	SMOT	GAN	ADASYN	Mix Up	RO	SMOT	GAN	ADASYN	Mix Up	RO
DoS	0.99	0.99	0.99	0.99	0.99	0.85	0.72	0.69	0.70	0.68
DDoS	0.99	0.99	0.99	0.99	0.99	0.97	0.35	0.37	0.75	0.95
DoS	0.99	0.99	0.99	0.99	0.99	/	/	/	/	/

2. Binary Classification Results

Table 3 presents the binary classification results obtained without data augmentation. In the intra-dataset evaluation on CIC-IDS2017, the model achieved strong performance, with recalls of 0.97 for Benign traffic and 0.95 for Attack traffic, resulting in a macro recall of 0.96. This indicates that the model effectively distinguished malicious from benign traffic when both training and evaluation data originated from the same distribution. However, during cross-dataset evaluation on CIC-IDS2018, the Attack recall decreased substantially to 0.45, indicating that approximately 55% of malicious samples were misclassified as benign. This reduction suggests that the attack patterns learned from CIC-IDS2017 were not fully transferable to the different traffic distribution of CIC-IDS2018. In contrast, Benign recall remained high at 0.99, showing that normal traffic characteristics were more consistently recognized across the two datasets. Consequently, the macro recall decreased to 0.72, highlighting the model's limited ability to generalize attack detection across heterogeneous network environments. These observations are further reflected in the confusion matrix presented in the figure. 6.

Table 3. Comparative Evaluation of Binary Classification Performances: CIC-IDS2017 vs. CIC-IDS2018. (Before augmentation).

Traffic Type	**CIC-IDS2017**			**CIC-IDS2018**		
	Precision	**F1 score**	**Recall**	**Precision**	**F1 score**	**Recall**
Benign	0.99	0.98	0.97	0.81	0.89	0.99
Attack	1.00	0.97	0.95	0.98	0.61	0.45
Macro avg	**0.99**	**0.97**	**0.96**	**0.90**	**0.75**	**0.72**

Table 4 shows that all binary classification models maintained strong intra-dataset Attack recall on the CIC-IDS2017 dataset, with values ranging from 0.97 to 0.99. In contrast, performance decreased substantially on the unseen CSE-CIC-IDS2018 dataset. Nevertheless, most augmentation techniques improved the cross-dataset Attack recall compared with the non-augmented baseline of 0.45. SMOTE achieved the highest recall of 0.78, followed by random oversampling (RO) at 0.70, GAN at 0.60, ADASYN at 0.56, and MixUp at 0.45. The superior cross-dataset performance achieved with SMOTE is further illustrated by the confusion matrix shown in the Figure. 7.

Table 4. Impact of Data Augmentation Strategies on Binary Classification Recall (CIC-IDS2017 vs. CIC-IDS2018)

Traffic Type	CIC-IDS2017					CIC-IDS2018				
	SMOTE	GAN	ADASYN	Mix Up	RO	SMOTE	GAN	ADASYN	Mix Up	RO
Benign	0.99	0.99	0.99	0.99	0.99	0.99	0.98	0.95	0.94	0.97
Attack	0.98	0.97	0.99	0.98	0.97	0.78	0.60	0.56	0.45	0.70
Macro Recall	**0.98**	**0.98**	**0.99**	**0.98**	**0.98**	**0.87**	**0.79**	**0.75**	**0.69**	**0.83**

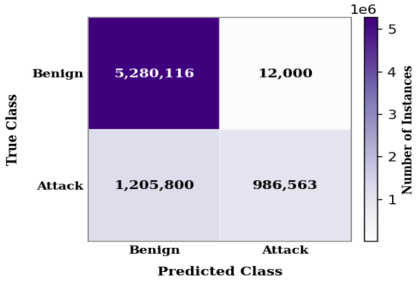

Figure 6. Binary classification confusion matrix of CIC-IDS2018 (Before Augmentation)

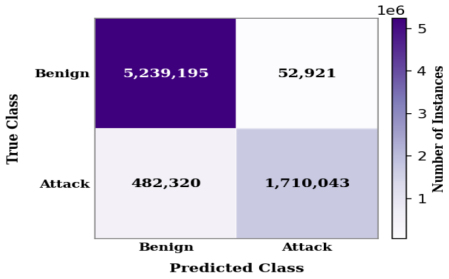

Figure 7. Binary classification confusion matrix of CIC-IDS2018 (using SMOTE)

The findings demonstrate a substantial difference between intra-dataset and cross-dataset performance. While all models achieved high Attack recall on the CIC-IDS2017 dataset, their effectiveness declined markedly when tested on the unseen CSE-CIC-IDS2018 dataset, indicating limited generalization across distinct network traffic distributions. Most augmentation techniques reduced this performance degradation, confirming their potential to improve cross-dataset robustness. SMOTE achieved the best results, followed by RO, suggesting that increasing minority-class representation helped the model learn more transferable attack patterns. In contrast, MixUp provided no improvement over the non-augmented baseline, indicating that interpolation-based augmentation may not preserve the complex characteristics of network attack traffic. Overall, the findings demonstrate that the effectiveness of data augmentation strongly depends on the selected technique.

VI. CONCLUSION

This study systematically investigated the effect of data augmentation on the intra-dataset and cross-dataset performance of ML-based IDS using CIC-IDS2017 for training and CSE-CIC-IDS2018 for external evaluation. The results showed that models achieving very high performance under intra-dataset evaluation can experience substantial degradation when applied to an unseen dataset, confirming that cross-dataset generalization remains a critical challenge for ML-based IDSs. This finding also highlights the limitations of relying solely on intra-dataset evaluation when assessing model robustness. The experimental results further demonstrated that data augmentation can substantially improve cross-dataset detection performance while preserving strong intra-dataset results. Among the five evaluated techniques, SMOTE and random oversampling consistently achieved the greatest improvements, whereas GAN-based augmentation, ADASYN, and MixUp showed more variable effectiveness across evaluation settings and attack classes. These differences indicate that the benefits of augmentation depend strongly on the technique used and the characteristics of the underlying attack

distributions. Moreover, the remaining performance gap across several attack classes suggests that class imbalance alone does not fully explain the generalization problem; distributional shifts and differences in traffic and attack characteristics between datasets also play important roles. Overall, the findings demonstrate that appropriately selected data augmentation techniques can enhance the robustness and transferability of ML-based IDSs across heterogeneous network environments. Still, augmentation alone is insufficient to overcome cross-dataset distribution shifts fully. The results, therefore, provide useful guidance for researchers and IDS developers when selecting augmentation strategies for models intended to operate beyond a single benchmark dataset. Future work will explore hybrid approaches that combine advanced data augmentation with domain adaptation, representation learning, distribution alignment, and multi-dataset training to further improve intrusion detection reliability under previously unseen network conditions.

Abstract
E-commerce product-matching models are affected by false-positive matches and category-dependent label inconsistencies. This paper presents a selective data-cleaning method to improve human-operator-labeled training data in a large industrial catalog setting. Instead of sending the full dataset to a large language model, a Turkish BERT-based matching model first identifies high-risk records in which the operator label and the model prediction strongly disagree. Only these records are reviewed by Qwen3-8B under category-specific matching rules. In an experiment with 1,559,716 labeled product pairs and 3456 categories, the BERT pre-filter reduced the review set to 13,373 candidates, reducing the large language model review volume by 99.14 percent. Based on the BERT and large language model agreement, 7,586 records were flagged, and 37,659 records were removed after including related negative examples. Retraining on the cleaned data increased F1 from 88.18 percent to 90.18 percent, accuracy from 95.30 percent to 96.09 percent, and AUC from 98.61 percent to 98.95 percent. An ablation against a BERT-only cleaning rule shows that the large language model review is what preserves recall: BERT-only filtering removes 1.72 times as much training data and reaches 89.48 percent F1, compared with 90.18 percent for the combined rule. The results show that large language models can serve as targeted, rule-guided, and cost-aware quality control layers for large-scale e-commerce data cleaning.

Keywords: e-commerce product matching; data cleaning; large language models; BERT; noisy labels.

I. INTRODUCTION

In product and price comparison platforms, the same product can be listed by different sellers with different titles, descriptions, prices, and images. This makes product matching a central data-quality problem, not just a search or classification task. Wrong matches can show different products as the same item, distort price comparisons, feed recommender systems with wrong signals, and reduce user trust. Therefore, model success depends not only on architecture, but also on accurate, consistent, and category-aware training data. In the industrial setting examined in this study, product and offer records are updated frequently. Product titles are often short, incomplete, marketing-oriented, or seller-specific. Different stores may use different names for the same product, while different products may look very similar because they share the same brand, model family, capacity, package content, or color. Past operator decisions are valuable training data, but they may also contain inconsistencies because category rules change and borderline cases are interpreted differently. In the current machine-learning-based matching infrastructure, model training primarily relies on manually labeled data from past operator decisions. If this data contains false positive matches, the model can learn incorrect patterns, especially for product pairs that are textually similar but refer to different product identities [1-5]. Large language models can interpret semantic similarity, follow category rules, and produce explainable decisions. However, reviewing millions of product-matching records using a large language model is impractical due to processing time and hardware costs. This study, therefore, uses the large language model as a selective quality-control layer for records that the existing matching model flags as suspicious. The main hypothesis is that high-confidence conflicts between the operator label and the model output can indicate error regions in the training data. A

Turkish BERT-based model first scans the large dataset; Qwen3-8B then rechecks only the risky candidates under category-specific rules. The paper makes four contributions. First, it presents a label-model disagreement flow to identify false-positive candidates in product-matching data. Second, it uses the large language model as a second-review layer for high-risk candidates, not as a full-data relabeling tool. Third, it applies cleaning with group consistency by removing related negative examples when needed. Fourth, it validates an integrated, cost-controlled industrial architecture that combines BERT-based matching, noisy-label checking, and large-language-model verification. Thus, the main contribution lies in scalable system design, domain rule transfer, and measurable impact on data quality, rather than in introducing a new base learning algorithm.

II. RELATED WORK

Product matching, also known as entity matching, decides whether records from different sources refer to the same real-world object. Classical methods rely on character similarity, field-level thresholds, and rules, whereas deep learning methods learn more flexible representations for short and noisy texts [2], [6]. In e-commerce, product titles are often not standardized and may mix identity information with missing attributes or marketing phrases. Pretrained language models help capture relations between fields such as brand, model, series, variant, and product family [1], [3]. BERT-based models can encode two product titles together and evaluate more than word overlap. However, this advantage depends on reliable labels. If the training data contains false positives, the model may associate semantic similarity with an incorrect matching signal. The noisy-label literature shows that wrong labels can have lasting effects on deep models [4], [5], [7]. Confident learning uses conflicts between model predictions and given labels to estimate possible label errors [4]. Weak supervision and data programming methods, such as Snorkel, combine expert rules, labeling functions, and data sources to create training data more quickly [8], [9]. The present study connects such label-error checking to a second review by a large language model within a high-volume product-matching pipeline. Large language models have also been studied as tools for data preprocessing, cleaning, annotation, and synthesis [10-15]. They can combine language knowledge with task instructions, but running them on all records is costly in high-volume e-commerce settings. The proposed approach is selective: the large language model is applied only to a small candidate subset first marked as risky by a faster base model. In this context, the study combines ideas from confident learning, weak supervision, and large language model-based data preparation in a category-sensitive product matching problem. BERT is used both as a classifier and as a scanning component that produces risky candidates; the large language model serves as a limited-scope, rule-based verification layer. The difference from full LLM relabeling is operational: the expensive semantic reviewer is called only after a fast model has narrowed the error region.

III. PROBLEM DEFINITION

Each sample represents a binary matching decision between an offer product title and a main product title. A positive label means that the titles refer to the same product identity; a negative label means that they do not. Some positive labels can be wrong, for example, when two products share the same brand but differ in capacity, weight, shade, package contents, or main-product vs. accessory status. This study focuses on false-positive matches because they can teach the model to treat different products as the same item. A false positive can also affect negative examples generated around the same offer. Therefore, cleaning is designed as a product-group-level intervention rather than a simple row-level correction. The research question has two parts. First, can operator-based false positives be detected at scale by combining high-confidence BERT disagreements with category-rule-guided large language model review? Second, does this cleaning improve the product matching model when it is retrained under the same evaluation conditions? The problem is formulated as a binary classification problem with label checking. For each record, the title pair is xi, the operator label is yi, and the BERT non-match probability is pi. A record becomes a cleaning candidate only if yi = 1 and pi >= 0.90. This

rule focuses the method on the subset with the highest false-positive risk and keeps the large-language-model review volume low.

IV. DATASET AND DOMAIN CONSTRAINTS

The experiment used an industrial dataset comprising 1,559,716 operator-labeled product-matching samples and 3,456 categories. The samples cover 314,869 distinct offers. Each offer contributes exactly one positive pair and about 4 linked negative pairs derived from variant product titles, yielding a mean group size of 4.95 rows. Each record contains an offer product title and a main product title. Titles are mainly Turkish but may include brand names, model codes, foreign technical terms, units, package counts, and seller-specific abbreviations, which makes simple text similarity insufficient. Category structure is a main source of uncertainty. In electronics, model code or capacity may determine the decision; in cosmetics, shade, volume, and package content may be critical; in fashion, color and size may be variants in some cases and identity separators in others. For this reason, the large language model prompts include category-specific rules rather than asking only a general, same-product question. Positive matches and related negative examples appear together. For one offer, the correct main product can be accompanied by similar but non-matching products. When a positive match is found to be incorrect, related negatives may also lose their meaning, so the cleaning process considers linked records. During preprocessing, product titles were standardized while preserving meaningful fields. Extra spaces, repeated separators, promotional expressions, and differences in formal writing were reduced. Still, model code, capacity, series, package count, volume, and measurement units were kept because these details may define product identity. To ensure evaluation reliability, cleaning was applied only to the training data, and the evaluation split was held fixed. Thus, observed changes could be linked to a more consistent training signal rather than to a changed test set. The dataset is industrial and cannot be shared publicly; therefore, the paper reports the observable scale, category coverage, cleaning counts, and performance deltas, while treating detailed category distributions and some internal annotation details as reproducibility limitations. One structural property of the splits should be noted. Offers are cleanly partitioned: none of the 314,869 offers appears in more than one split. Products are not: 32,356 of 84,621 distinct products appear in more than one split, because different offers matched to the same product can fall on different sides of the partition. Re-splitting the data on product identity would remove this overlap but would also invalidate the comparison with the existing production model, so it is left as future work.

Table 1. Example matching rules that differ by category.

Category example	Critical fields	Effect on the decision
Electronics	Model code, capacity, series	Strong veto if different
Cosmetics	Shade, volume, package content	Variant and amount check
Pet products	Animal type, weight, count, age group	Correct type and package required
Fashion	Size, color, gender, and collection	Category-dependent flexibility
Accessories	Main product vs. compatible part	Wrong product type veto

V. METHOD

The selective data cleaning method has three layers. First, a Turkish BERT-based product-matching model is trained on the initial operator-labeled dataset and then re-run on the same data. Records labeled as positive by the operator but predicted as non-matches with high confidence are accepted as risky candidates.

A 90 percent non-match probability threshold was used for candidate selection. This conservative point sends only strong BERT-operator disagreements for large-language-model review, thereby limiting costs and reducing the risk of deleting true matches. Keeping the threshold high narrows the candidate pool. Lower thresholds may find more errors but increase review volume and deletion risk; higher thresholds reduce cost but leave more false positives. This study keeps the threshold fixed at 0.90. Two observations support the choice. First, the large language model rejection rate increases monotonically with BERT confidence, from 49.5 percent in the 0.90-0.925 band to 69.5 percent above 0.99, indicating that the pre-filter score carries meaningful information rather than serving as an arbitrary cutoff. Second, raising the threshold to 0.95 reduces the candidate pool from 13,373 to 8,848 while raising the rejection rate only from 57.7 to 60.9 percent, so the extra strictness mostly discards true errors. A full sensitivity analysis, with a separate retraining run for each threshold, is left for future work.

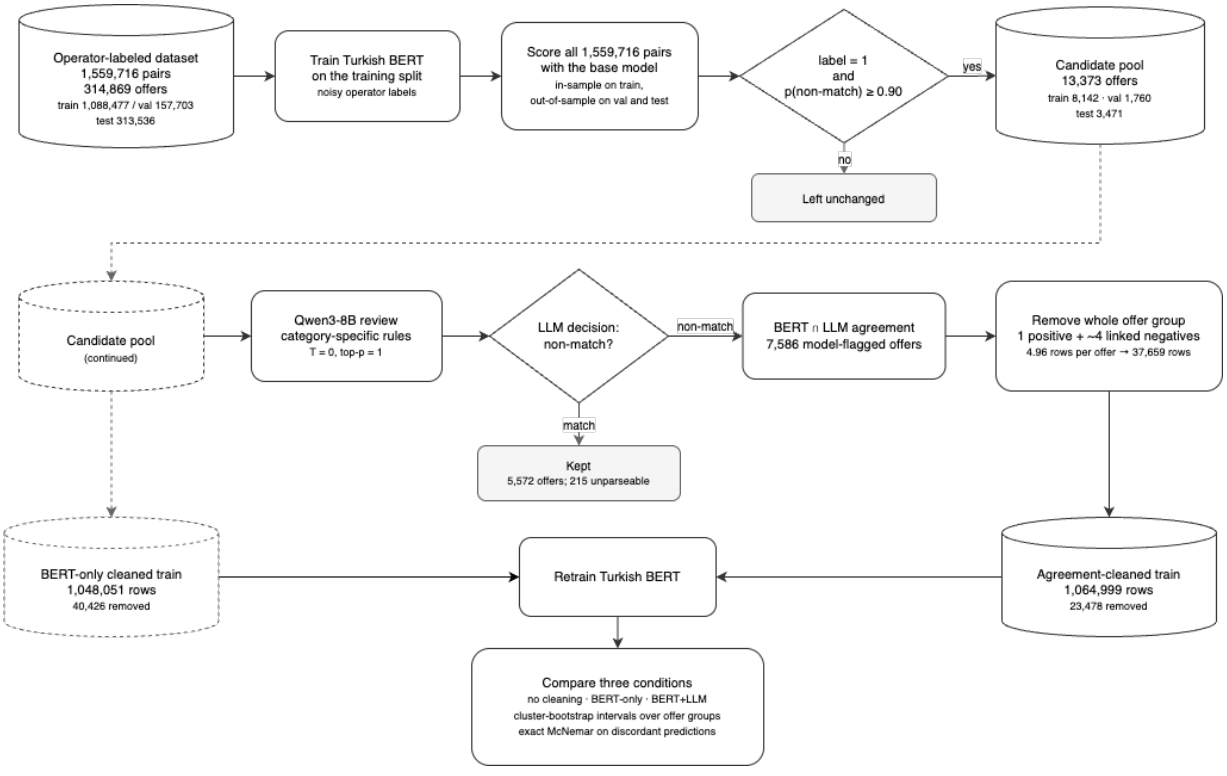

Figure 1. The selective data cleaning pipeline was executed. A single Turkish BERT model is trained on the noisy training split and then scored on the whole dataset. High-confidence disagreements with the operator label become candidates, which are reviewed by Qwen3-8B under category-specific rules. Removal occurs at the offer group level. All conditions are then retrained and compared on the same evaluation split. The dashed path is the BERT-only ablation, which skips the review step.

Second, Qwen3-8B is guided by category-specific rules. The prompt defines which fields break a match, which differences can be accepted as variants, and which cases must be marked as non-matches. This prevents the model from relying only on surface text similarity. Third, BERT and large-language-model outputs are evaluated

together. A record is removed only if both layers mark it as a non-match. BERT serves as a fast suspicion generator, while the large language model serves as a slower but more detailed, rule-based reviewer. When a cleaning decision is made, group consistency is preserved. The false positives and their linked negatives are removed together so that the model does not learn inconsistent signals around the same offer.

VI. LARGE LANGUAGE MODEL REVIEW

The large language model review is not a final production decision module. It is a semi-automatic offline review layer for improving training data. This keeps production matching fast while limiting the more expensive large-language-model step to the most useful subset of candidates. The prompt design has two steps. First, the category context is identified. Second, category rules are used to decide whether the titles describe the same product, an acceptable variant, or different products. The decision checks the brand, model, technical fields, measurement units, package content, category-specific meanings of color or size, and main product/accessory differences. The prompt asks for three outputs: a match or non-match decision, a short list of critical fields, and a veto reason if a critical difference invalidates the match. In compact form, the prompt contains the offer title, the main product title, the detected category, category-specific critical fields, allowed variant differences, veto rules, and the requested structured output. This creates auditable decision traces instead of long free-form explanations. The review explicitly avoids depending only on textual closeness. Sellers may list the same product family under different campaign words or with missing fields. At the same time, small differences, such as 128 GB versus 256 GB or single versus multi-pack content, can change the product identity. Therefore, category-specific tolerance and veto rules are used, and uncertain cases are cleaned only when BERT and large language models agree. The large language model output is treated as structured decision logic. The expected answer is the decision, the critical conflict, and the related category rule. This helps operators verify the result and refine category prompts as needed. This setup adds category knowledge to the data cleaning loop. BERT may treat similar brand-and-series phrases as positive evidence. At the same time, the large language model can reject the match when capacity, model code, or package content violates the category rule.

VII. EXPERIMENTAL SETUP

The baseline is a Turkish BERT-based matching model that takes offer-main product title pairs as binary classification input. It was trained on 1,088,477 operator-labeled samples and then applied back to the data to find positive labels it strongly disagreed with. In the BERT model, the offer title and the main product title are processed as a pair of inputs separated by special tokens. The classification head produces a match or non-match decision from the pair representation. The model is fine-tuned on the task data rather than used solely as a frozen feature extractor, and evaluation is performed on a fixed split separate from the cleaning process. The same architecture and evaluation split are used before and after cleaning. All runs fine-tune dbmdz/bert-base-turkish-uncased for two epochs with a per-device batch size of 64, gradient accumulation of 4, a learning rate of 5e-5, 500 warmup steps, a maximum sequence length of 512, and mixed precision. The checkpoint with the best validation precision is kept. The reviewer model is Qwen3-8B in GGUF format served through llama.cpp, decoded with temperature 0.0, top-p 1.0, and a 1024-token limit. No random seed was fixed in any run, so exact reproduction of a single run is not possible, and run-to-run variance was not measured. Multiple seeds and cross-validation are not included in this version.

Table 2. Candidate filtering and cleaned records in the data cleaning flow.

Measure	Value	Explanation
Labeled samples	1,559,716	Operator-labeled product pairs

Measure	Value	Explanation
Positive labels	314,869	Only positive labels can become candidates
Number of categories	3456	Broad category coverage
BERT risky candidate pool	13,373	0.86 percent of the dataset, 4.25 percent of positive labels
Records flagged by the BERT and LLM agreement	7,586	BERT and LLM agreement (56.7 percent of the candidate pool)
Records removed with related negatives	37,659	Records removed while preserving group consistency
LLM review volume reduction	99.14 percent	Selective review instead of full-data review

The BERT scan reached about 6577 sequences per second on RTX 5090 hardware, so a full pass over the 1,559,716-sample dataset takes about four minutes. With a 90 percent non-match threshold, 13,373 records were selected, so the large language model reviewed only about 0.86 percent of the dataset, or 4.25 percent of the positive labels. Because the pre-filter itself is inexpensive, almost all of the method's processing cost is due to the large language model review time, which is controlled by the selectivity ratio. Qwen3-8B was used for the large-language-model review. With llama.cpp on a single GPU, the observed speed was about 45 tokens per second. Since the model reviewed only BERT-selected candidates, the candidate pool size became the main driver of processing cost. The evaluation used three measurement groups: reduction in large language model review volume, model performance after retraining under each cleaning condition, and practical processing time. Processing time is reported from measured throughput rather than estimated. Three conditions are compared quantitatively in Table 3: no cleaning, cleaning using the BERT pre-filter alone, and cleaning using BERT and large-language-model agreement. A full large language model pass over every record was not run because, at the observed review speed, it would require several weeks of processing for this dataset.

VIII. RESULTS

Of the 13,373 candidates sent for review, the large language model rejected 7,586, accepted 5,572, and returned 215 responses that could not be parsed. The two layers, therefore, agree on 56.7 percent of the candidate pool. This is an agreement rate between two automated layers, not a detection rate. No human-validated reference set was built for this study, so the number of mislabeled positives outside the flagged region is unknown, and no claim about recall can be made. For the same reason, the 7,586 records are described throughout this paper as model-flagged rather than as confirmed errors.

As summarized in Table 2, from 1,559,716 samples, 13,373 records were identified as risky by BERT.

After a large language model review, 7,586 records were flagged by BERT and the large language model agreement. With related negatives included, 37,659 records were removed, reducing the review volume by 99.14 percent compared with the full-data review.

Table 3. Performance of the Turkish BERT matching model under three cleaning conditions. All conditions are scored on the same evaluation split of 304,101 pairs from 61,377 offers. Removal counts are training rows.

Condition	Train rows	Removed	Precision	Recall	F1	Accuracy	AUC
No cleaning	1,088,477	0	89.45	86.94	88.18	95.30	98.61
BERT-only, threshold 0.90	1,048,051	40,426	91.69	87.37	89.48	95.85	98.74
BERT and LLM agreement	1,064,999	23,478	91.47	88.93	90.18	96.09	98.95

The Turkish BERT model was retrained under three cleaning conditions and compared on the same evaluation set. Under the BERT and large language model agreement, precision increased from 89.45 percent to 91.47 percent, recall from 86.94 percent to 88.93 percent, F1 from 88.18 percent to 90.18 percent, accuracy from 95.30 percent to 96.09 percent, and AUC from 98.61 percent to 98.95 percent. The joint increase in precision and recall suggests that cleaning did not simply make the model more conservative. Removing false positives and related negatives helped the model reduce wrong matches while keeping correct matches more consistent. The 2.27 percent relative F1 increase indicates a measurable improvement. The BERT-only condition isolates the contribution of the large language model layer. Removing every high-confidence BERT disagreement without a second review yields the highest precision among the three conditions: 91.69 percent, slightly above the combined rule. It recovers almost none of the recall, however: 87.37 percent against 88.93 percent, and it ends 0.70 points behind in F1. The reason is visible in the removal counts. BERT-only deletes 40,426 training rows against 23,478, and the additional 16,948 rows cover 3,415 offers, 42 percent of everything the pre-filter flagged, that the large language model examined and judged to be genuine matches. Those offers carry the borderline-but-correct patterns the model needs to maintain recall. Skipping the review, therefore, removes 1.72 times as much training data and produces a more conservative model that misses more true matches. The AUC gain is smaller because the starting AUC was already high. For the BERT-only condition, per-record predictions were retained, so the comparison against the uncleaned baseline can be tested directly. Confidence intervals were computed using a cluster bootstrap with 2000 replicates that resamples entire offer groups rather than individual rows, because the roughly 5 rows belonging to one offer are not independent. All five metric gains exclude zero: precision +2.24 points, 95 percent interval [+2.06, +2.43]; recall +0.42 [+0.22, +0.63]; F1 +1.30 [+1.16, +1.44]; accuracy +0.56 [+0.50, +0.61]; and AUC +0.13 [+0.10, +0.16]. An exact McNemar test over discordant predictions yields 3,167 records correct only under the baseline, compared with 4,861 correct only under BERT-only cleaning, with a two-sided p-value below 1e-70. Per-record predictions were not available for the agreement condition in this analysis, so the same intervals could not be computed for it. Because no random seed was fixed, run-to-run variance was not measured, and multiple-seed replication remains necessary to assess the stability of the reported gains.

IX. DISCUSSION

The results show that a large language model can be useful as a targeted review layer to improve training data, but not as a direct production decision model. BERT provides speed and scalability, while the large language model provides semantic reasoning and rule-following ability. A key advantage is that the cost of the large language model does not grow directly with the full data volume. Only 13,373 of 1,559,716 records were reviewed by the large language model. This is more sustainable than full-dataset relabeling and shows that large language models can create value by giving a second opinion only where existing models struggle. Operationally, the selective flow creates about a 116.6-fold reduction in review volume compared with running the large language model on all data. This reduces compute time, output checking, decision logging, error analysis, and possible human approval effort. Thus, even a limited gain in accuracy can be meaningful when

combined with higher precision, higher recall, and lower review volume. The group-consistency cleaning strategy is also important in practice. In product matching data, positive and negative samples often gain meaning together around the same offer. If a false-positive match is removed but related negatives are retained, the model may still receive inconsistent signals in the same context. For this reason, the proposed method treats the cleaning decision at the level of the training example group, not only at the row level. This leads to a more consistent data improvement process. The approach also has limitations. First, the quality of large language model decisions depends on how complete, clear, and up to date the category rules are. If the rules are missing or unclear, the model may rely too much on surface similarity. Second, the study primarily focuses on cleaning up false-positive matches. Finding false negatives may require different sampling strategies. A third limitation concerns candidate generation. The pre-filter is trained on the training split and then scored back on it, so its predictions on training records are in-sample and prone to memorization. The size of this effect can be measured directly because the validation and test splits were never used for training. At the 0.90 threshold, the model flags 3.70 percent of training positives, 5.53 percent of validation positives, and 5.49 percent of test positives. Validation and test agree within 0.04 points, indicating memorization rather than a distributional difference, and implying that in-sample scoring suppresses the flag rate by a factor of 1.48. The direction of this bias is conservative: it under-detects rather than over-detects, so the candidate pool used here is smaller than that produced by an out-of-fold pipeline. It is also worth noting that 5,231 of the 13,373 candidates, 39.1 percent, come from the validation and test splits and were therefore already scored out-of-sample. Grouped out-of-fold candidate generation, with folds formed by product identity, is the natural next step and would be expected to surface roughly 12,100 training candidates rather than 8,142. There is also a risk of deleting correct examples by mistake, especially in unclear product variants. For example, if capacity or package amount is missing from the title in the same product family, the model may interpret two records as different products. Similarly, the main product versus accessory distinction, the category-dependent meaning of color and size, or missing product codes in seller titles may lead to wrong cleaning decisions. Therefore, the proposed system uses an automatic but conservative agreement rule. Borderline cases should be sent back to operators or experts and used to improve the rule pool. In addition, the method does not directly target false negative matches. In future work, it can be extended into a two-sided cleaning strategy. For example, records that the operator labeled as non-match but that BERT predicts as match with very high confidence could be sent to a separate active learning queue. However, this extension requires more careful human validation than false-positive cleaning does, because adding a record as a positive match may create incorrect merges in the catalog. The most important operational output of the method is that data quality improvement can be linked to measurable improvements in model performance. A data cleaning study should not be evaluated solely by the number of records removed. It should also show how the cleaned data affects model learning. In this study, retraining under the same evaluation conditions made the effect of data cleaning on model decision quality directly visible. For sustainable use in production-like settings, the decision flow should not depend only on model scores. In the proposed architecture, each cleaning decision can be stored with the source record, BERT score, large language model decision, category rule, removed related negatives, and timestamp. This audit trail can help recover incorrectly cleaned examples, improve category rule sets, and analyze potential changes in data distribution over time. From an ablation and comparison perspective, each component of the proposed architecture has a different role. Cleaning with BERT alone is fast and inexpensive, and Table 3 shows that it already improves the model over no cleaning. It over-deletes, however: it discards 42 percent more offers than the combined rule, including many that a rule-guided review recognizes as correct, and the resulting model gives up 1.56 points of recall and 0.70 points of F1. Reviewing the full dataset solely with the large language model may yield strong semantic decisions, but at the observed review speed, it would require several weeks of processing. The BERT and LLM agreement strategy, therefore, combines the speed of BERT with the decision quality of the large language model, and the ablation indicates that the second review earns its cost by preventing the removal of informative true positives. The 90 percent threshold was selected as a conservative operating point to reduce the risk of deleting correct examples by mistake. Bootstrap confidence intervals and a significance test are reported for the BERT-only comparison, and candidate volumes are reported

for thresholds ranging from 0.80 to 0.95. Threshold sensitivity, separate retraining runs per threshold, multiple-seed experiments, and cross-validation are not reported in this version. In terms of failure analysis, missing capacity information, unclear variants, package content, main product versus accessory distinction, and missing product codes can increase the risk of deleting a correct example. For such borderline cases, human approval, rule updates, and active learning queues are recommended.

X. CONCLUSION

This study presented a selective data-cleaning approach that combines BERT pre-filtering and large-language-model review to clean operator-based false positives in e-commerce product-matching training data. Experiments with 1,559,716 samples and 3456 categories showed that the large language model review volume could be reduced by 99.14 percent. The agreement between BERT and the large language model flagged 7,586 records, and 37,659 records were removed when related negatives were included. After retraining the Turkish BERT model with the cleaned data, all main metrics improved: precision, recall, F1, accuracy, and AUC. The increase in F1 from 88.18 percent to 90.18 percent shows that the proposed method does more than make the data more consistent. An ablation against a BERT-only cleaning rule shows that the large language model review is the component responsible for preserving recall. Filtering on the BERT score alone removes 1.72 times as much training data and reaches 89.48 percent F1, so the second review adds 0.70 points of F1 while deleting substantially less data. Cleaning, therefore, improves both data consistency and the final decision quality of the product matching model. The findings show that large language models can serve as cost-controlled, domain-rule-guided, and measurable quality-control layers for high-volume catalog data. Future work can extend the method with grouped out-of-fold candidate generation, an independently human-annotated validation set, a random-removal control, multimodal product images, active learning-based operator feedback, category-level threshold learning, automatic rule discovery, student model distillation, multiple-seed experiments, and threshold sensitivity analysis. Because the BERT pre-filter already narrows the candidate pool, replacing Qwen3-8B with a smaller Qwen-based student model trained through knowledge distillation may further reduce processing time and hardware cost. The method can also be supported by automatic category-based threshold adjustment, rule updates from operator feedback, and periodic retraining cycles. In such an architecture, the large language model becomes not a one-time data-cleaning tool but a periodic, auditable, and cost-controlled component of catalog quality monitoring.

Abstract
Centralized laboratory-based detection methods for Aflatoxins, such as ELISA and HPLC, are expensive and time-consuming and are also constrained by limited laboratory capacity and sample transportation challenges in developing countries. This bottleneck prevents timely detection and intervention, leaving producers and consumers exposed to the health risks of Aflatoxins. Therefore, the lack of rapid, low-cost, and field-deployable aflatoxin detection tools represents a critical gap. A novel handheld, low-cost sensor for analyzing aflatoxin-related compounds on surfaces in open air, based on an IoT and AI architecture, has been developed and deployed, offering portability for in-field analysis. A sensor array comprising MQ3, MQ5, MQ131, MQ135, MP503, temperature, and humidity sensors, with a micropump to aid airflow across the sensors, was constructed and housed in a 3D-printed box. Custom-designed circuitry within the device was developed, and when powered on, the sensor readings can be sent to the cloud or a local repository via USB or Wi-Fi. Initial results have indicated that the portable AI powered sensor for aflatoxins is a green sensor for field applications, without the use of solvents or gases for the analysis of analyte(s) in neat solution near real-time analysis and quantification using assemble machine learning AI model that combines random forest, SVM and ANN with 85% accuracy and sensitivity obtained for the analysis of Aflatoxins in the open environment with little to no sample preparation in the open air.

Keywords: aflatoxins analysis; AI-powered IoT Sensor; field analysis, real-time analysis; food safety

I. INTRODUCTION

Food contamination is a persistent global challenge with far-reaching implications for human health, food security, and international trade. Among the most concerning contaminants are mycotoxins, particularly aflatoxins, produced by Aspergillus species (e.g., A. flavus and A. parasiticus) and frequently found in staple crops such as maize, peanuts, cereals, and spices [1]. The World Health Organization (WHO) recognizes aflatoxins as among the most poisonous mycotoxins and highlights their genotoxic and carcinogenic effects, including acute poisoning and long-term cancer risks [2]. Globally, about 25% of food crops are estimated to be affected by mycotoxins, with aflatoxins being the most prevalent [3]. In sub-Saharan Africa, environmental conditions, particularly warm and humid climates, foster fungal growth and mycotoxin production, while

constrained post-harvest infrastructure exacerbates the risk [4], [5]. The East African region has witnessed serious outbreaks of acute aflatoxicosis, notably in Kenya (2004) with 317 reported cases and a fatality rate of ~39%, and in Tanzania with 68 cases and a ~30% fatality rate [6].

Aflatoxin contamination in Uganda's food supply poses an urgent threat to public health, food safety, and economic development. A recent survey revealed that 41.8% of groundnut samples and 62.8% of maize products in eastern and northern regions exceeded the European Union limit of 20 ppb for total aflatoxins, a level deemed unsafe for food and feed [7]. Additionally, another study across Masindi and Soroti districts found that 45% of maize samples and 30% of groundnut samples were contaminated with aflatoxins above detection thresholds, highlighting widespread exposure across diverse agro-ecological zones [8].

Chronic exposure to aflatoxins is known to cause severe health issues, including liver cancer, stunting in children, and immune system suppression, amplifying its burden on vulnerable rural communities [9]. Furthermore, contaminated maize and groundnuts are frequently rejected in export markets, limiting trade opportunities and undermining the incomes of smallholder farmers [10]. Currently, Uganda relies on centralized laboratory-based detection methods such as ELISA and HPLC [11]. These methods are not only expensive and time-consuming but also constrained by limited laboratory capacity and challenges in sample transportation. This bottleneck prevents timely detection and intervention, leaving producers and consumers exposed. Therefore, the lack of rapid, low-cost, and field-deployable aflatoxin detection tools represents a critical gap [12]. Addressing this gap is essential for safeguarding public health, enhancing market access, and aligning with national goals such as Uganda Vision 2040, National Development Plan IV (NDP IV), and Sustainable Development Goals (SDGs 2, 3, and 9).

The growing challenge of aflatoxin contamination in food systems, particularly in tropical and subtropical regions, where maize, groundnuts/peanuts, spices, and cereals are highly susceptible [10]. Conventional lab-based analytical techniques, such as HPLC, ELISA, and LC-MS/MS [13], although accurate, are expensive, destructive, and unsuitable for rapid, large-scale monitoring [14]. Recently, artificial intelligence (AI), in its various forms (e.g., supervised, unsupervised, and reinforcement learning), has advanced aflatoxin detection and quantification [3]. By combining state-of-the-art Internet of Things (IoT) and deep learning, and integrating models with blockchain technology, high accuracy and specificity can be achieved in detecting aflatoxins [15]. Here, an AI-powered Internet of Things (IoT) sensor platform for rapid, portable, and integrated AI and machine learning (ML) is developed and applied to detect aflatoxin active compounds in open environments with little or no sample preparation. The developed platform can complement lab-based analytical systems by enabling rapid, non-destructive, and predictive in-field detection. Low-cost detection of food contaminants, focusing on aflatoxins, has been developed and applied to detect active, volatile aflatoxin compounds in the open air. The developed portable sensor is integrated with an AI ensemble model comprising a random forest, an SVM, and an ANN. The developed platform is significant in several ways: (1) Public Health Impact: By enabling real-time detection of aflatoxins at the point of production and storage, the project will contribute to reducing chronic exposure that is linked to liver cancer, child stunting, and immune suppression [9]. Early detection and intervention will directly improve food safety and protect consumers (2). Economic Contribution: Aflatoxin contamination has led to repeated rejections of Ugandan maize and groundnut consignments in international markets, undermining farmers' incomes and national trade competitiveness [9]. A reliable local detection solution will enhance compliance with global standards, open export opportunities, and strengthen the agricultural value chain [16].

II. EXPERIMENTAL SECTION

1. Chemicals and Reagents

All analytical aflatoxin volatile organic chemical standards of 1-Octen-3-ol ("Mushroom Alcohol"), a very common fungal VOC associated with moldy odors and emitted by Aspergillus species. It is used as a biomarker for mold contamination in grains, often with a low odor detection threshold (Inamdar, Arati A., et al.); 3-Methyl-1-butanol and 2-Methyl-1-propanol are alcohols frequently associated with both aflatoxigenic and non-aflatoxigenic A. flavus strains. They are identified as key volatiles in contaminated pistachios and corn [17]; 2-Pentylfuran is often found in the headspace of Aspergillus flavus-contaminated grain and is highly associated with A. flavus infection in samples such as maize/corn [18]. "An overview of fungal volatile organic compounds (VOCs)" Fungal associations; Dimethyl Disulfide is part of the VOC profile found in Aspergillus species-infected samples [19]. All VOC standards were dissolved in HPLC-grade methanol. All working solutions of the samples (1-100 µg/mL) were prepared in methanol to the target concentration by stepwise dilution.

2. Sample Preparation

In all experiments, the sample preparation step was reduced to diluting explosive stock solutions in methanol to the desired concentration. From each solution, 3 µg/mL was applied to cellulose filter paper (Whatman, Maidstone, UK, Grade 1) and analyzed immediately with a portable, AI-powered sensor, as shown in Figure 1.

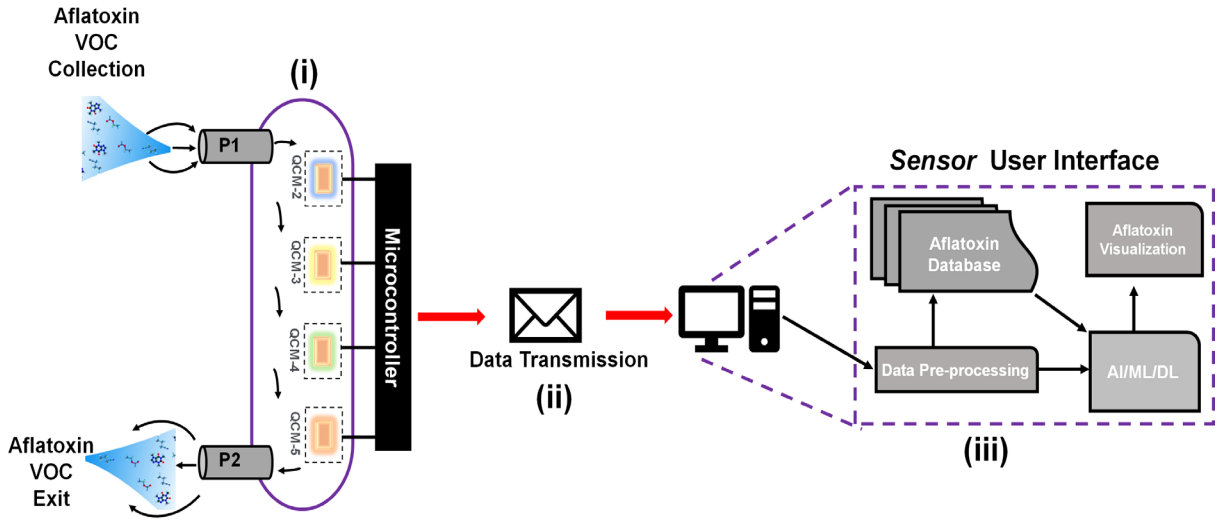

Figure 1. Experimental setup for the direct analysis of Aflatoxins at atmospheric pressure in open air. Schematic of the smart intelligent IoT sensor platform for food contaminants monitoring. The system consists of: (i) array of sensors, (ii) data transmission via Bluetooth, USB to a local PC, Wi-Fi or 4G network to the cloud for visualization and provide informative recommendations for users to take actions to safeguard health and reduce/prevent food contamination, (iii) the collected data can be aggregated securely and in line with data protection best practice and stored in a centralized database for future use to improve strategic understanding and response to poor food quality.

3. AI-powered portable Sensor for Aflatoxin analysis

A custom-designed, handheld, portable, AI-based IoT sensor (Figure 1) was developed. It consists of an array of sensors: MQ3, MQ5, MQ131, MQ135, MP503, temperature, and humidity sensors that were mounted in a 3D printed box (Figure 2 (B)). The sensor array is connected to the custom-designed circuitry module and the microcontroller. A small diaphragm pump (Schwarzer Precision, 12FC35A) with a maximum flow rate of 6 L/min was used to aid in drawing samples from the open environment to the sensing module across the sensor array for detection and to create an air flux within the portable sensor device platform.

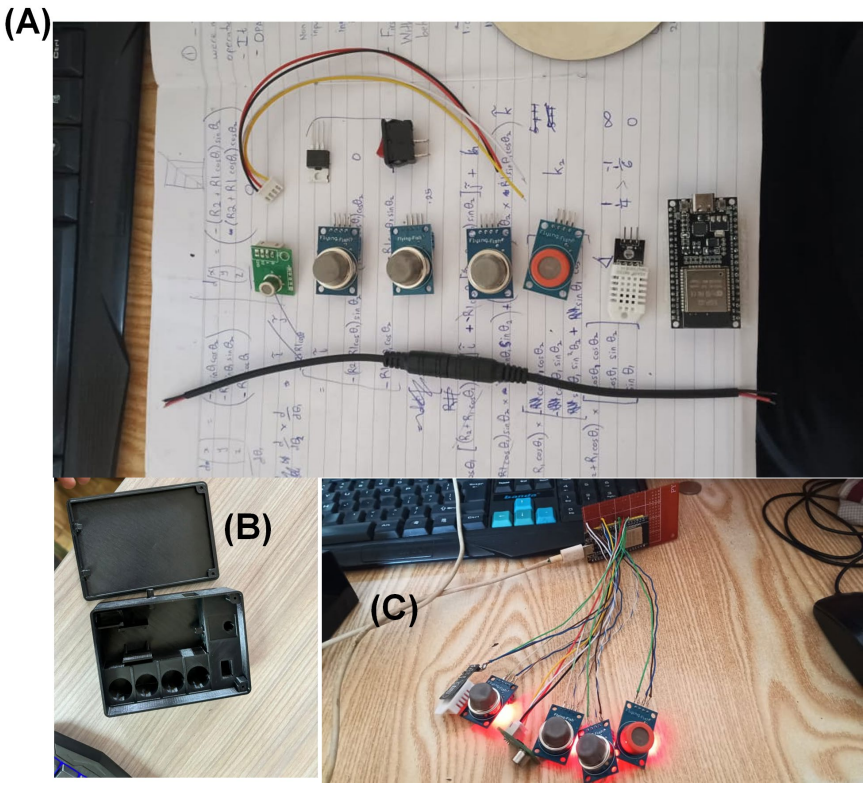

Figure 2. Shows the development of the IoT-based sensor before packaging: (A) list of the sensor components, (B) 3D-printed sensor housing, (C) testing of the individual sensors.

A custom-designed high-voltage control circuit is used to generate a high voltage in the range of 1-5 kV. Figure 2 shows a fully packed portable sensor in a 3D-printed plastic enclosure (MakerBot Replicator 2, Robo Savvy, UK). The circuitry of the portable sensor is powered by a 12 V, 4 Ah lithium Polymer battery with an in-built charging circuit and a power level indicator that indicates when recharging is necessary. From a fully charged state, the battery can power the device for up to 12 hours of continuous use and up to 3-4 days when used intermittently. The high voltage regulated DC-to-DC converter module (EMCO HIGH VOLTAGE, c50/c50N) and the diaphragm pump (Schwarzer Precision, 12FC35A) require a minimum 12V supply to operate correctly; therefore, due to the discharge curve of a battery, it is necessary to include a buck-boost DC-to-DC converter to ensure voltage regulation at the required level at all times. An ARM-based microcontroller board (Teensy 3.1, PJRC, US) handles all internal command communication and receives user input via a laptop. The high-voltage DC-to-DC converter is programmed via a precision voltage reference and a digital potentiometer whose wiper

position is set by commands from the microcontroller. The pump speed is controlled by digitally varying the duty cycle of the PWM (Pulse Width Modulated) signal that drives the diaphragm pump's MOSFET. Figure. Figure 3 shows the entire portable AI-powered sensor housed in a 3D-printed plastic enclosure (MakerBot Replicator 2, Robo Savvy, UK).

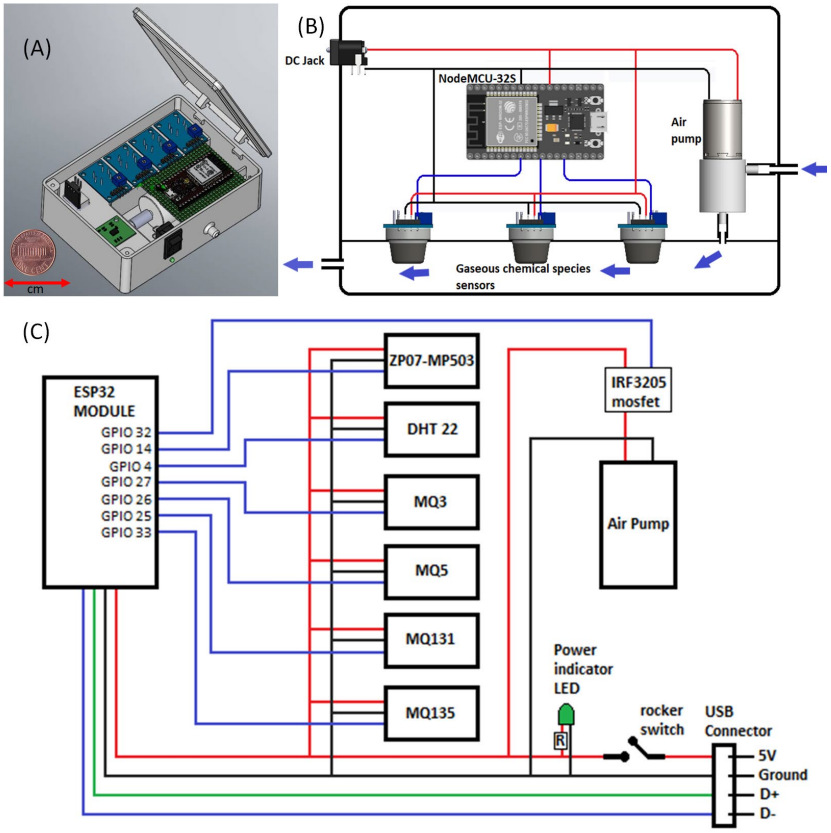

Figure 3. (A) 3D diagram of the packaged Smart Aflatoxin sensor device, (B) shows the layout of the major components of the developed sensor platform for aflatoxin analysis, (C) the electrical Circuit diagram for the developed sensor.

The device operates by sucking in the gases/air to be tested using a small air pump and blowing it over six sensor modules in a channel. It is made up of the following components; An ESP32 microcontroller which serves as the brains of the device, a small 5v DC air pump, an IRF3205 MOSFET that is used by the microcontroller to switch the air pump on or off, a ZP07-MP503 sensor, a DHT22 temperature and humidity sensor, an MQ3 sensor, an MQ5 sensor, an MQ131 ozone sensor, and an MQ135 sensor. The type of sensors is chosen based on their ability to detect a specific chemical class. The device has a rocker switch to turn it on or off and a power indicator LED with a 33ω current-limiting resistor. It connects to an external host computer via a USB cable to send the collected data for tallying and recording, and to receive commands from the host computer. The USB cable also supplies power to the device.

All the sensors are powered directly from the 5V of the host computer's USB port through the USB cable. The sensors all use a single wire to facilitate communication with the microcontroller. The DHT22 module uses a

proprietary single-wire communication protocol. All the other sensors provide a continuous voltage signal proportional to the concentration of the gas they sense. These sensors are connected to the ESP32 pins with Analog-to-Digital Converters (ADCs) that convert the continuous analog voltage signal into a digital signal. The pump is also powered from the same 5V source through an IRF3205 N-Channel MOSFET. The microcontroller switches the MOSFET to operate the air pump.

4. AI Integration with the potable aflatoxin sensor platform

Approximately 5 µL of the standard solution for each sample was spotted on Whatman grade 1 paper and analyzed immediately using a developed portable AI-powered sensor platform (as shown in Figure 4). Figure 4 shows the procedure followed for data collection from the portable IoT sensor developed for processing, and the workflow of the integration of the AI machine learning algorithms (SVM, Random forest, and ANN) with feature selection and parameter tuning was implemented.

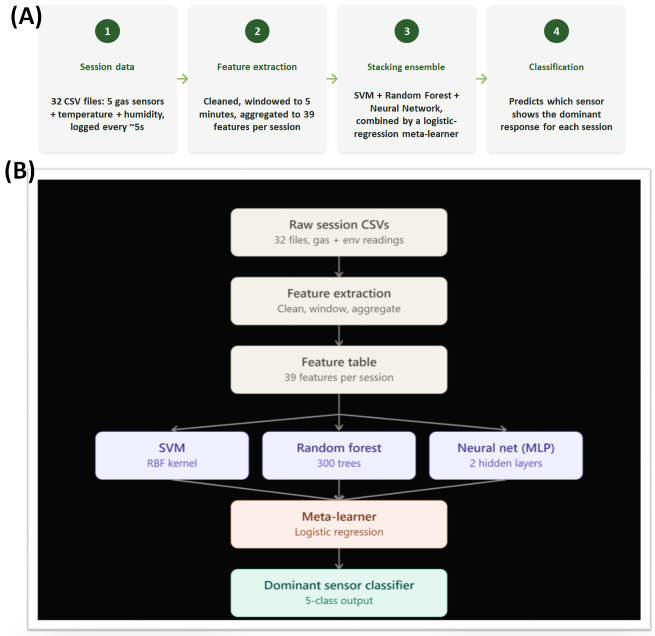

Figure 4. AI Integration with the portable aflatoxin sensor platform; (A) shows the data collection and processing pipeline of the IoT sensor platform for the Aflatoxin analysis in the open air; (B) shows the actual AI ML integration of the assembly ML algorithm developed for the Aflatoxin analysis.

III. RESULTS AND DISCUSSION

To assess the potential of the developed portable IoT sensor to analyze aflatoxin volatile compounds (VOCs) in the open air and to establish an analytical procedure, standard model VOCs were first analyzed. After establishing the analytical approach, 1-Octen-3-ol ("Mushroom Alcohol"): A very common fungal VOC associated with moldy odors and emitted by Aspergillus species [5]. It is used as a biomarker for mold contamination in grains, often with a low odor detection threshold; 3-Methyl-1-butanol and 2-Methyl-1-propanol: These are alcohols frequently associated with both aflatoxigenic and non-aflatoxigenic A. flavus strains. They are identified as key volatiles in contaminated pistachios and corn. 2-Pentylfuran: This

compound is often found in the headspace of Aspergillus flavus-contaminated grain and is highly associated with A. flavus infection in samples such as corn. Dimethyl Disulfide: Along with dimethyl sulfide, this compound is part of the VOC profile found in Aspergillus species-infected samples [19].

Direct Aflatoxin analysis using the developed smart IoT-based sensor. Figure 4 shows the recorded s spectra of 1-Octen-3-ol (MQ 3), 3-Methyl-1-butanol (MQ 5), 2-Pentylfuran (MQ 31), 2-Methyl-1-propanol (MQ 35), and Dimethyl Disulfide (MP 503) model compounds dissolved in [MeOH] v/v, at 1000 ppm as the standard solvent. Approx. 5 µL were spotted on Whatman chromatographic paper 1 and analyzed for 5 minutes using the developed portable IoT sensor in open air. In Figure 5(A), a stable signal is observed for all target VOCs of the Aflatoxins, with no background subtraction. Figure B shows the stable mean signal response for the Aflatoxin model VOCs detected by the developed sensor. It is very important to note that the developed device is capable of measuring both the temperature and the humidity of the environment, as shown in both Figure 5 (A and B). These results are in good agreement with results obtained previously [20]. The recordings with different timestamps were stored as a CSV file, ready for AI machine learning modeling and visualization.

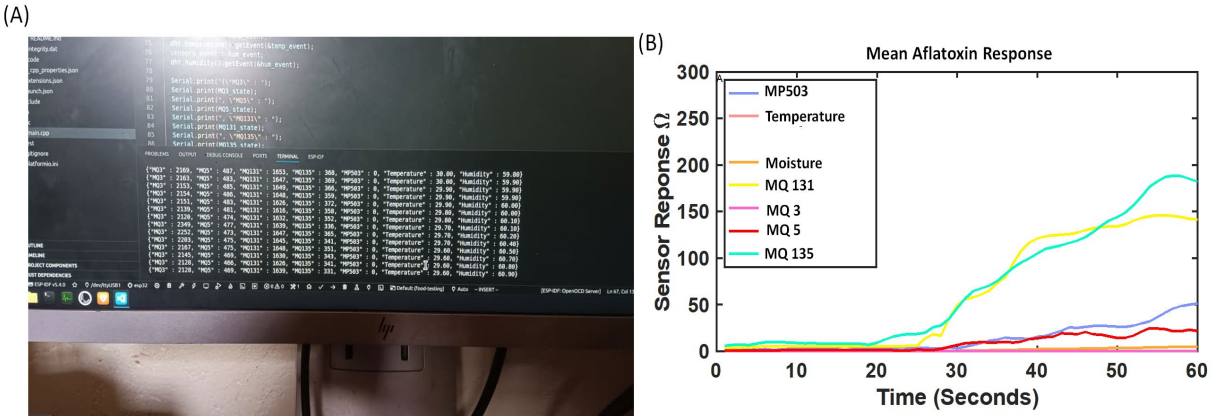

Figure 5. Analysis of Aflatoxins model VOCs using the developed IoT Sensor for 1-Octen-3-ol (MQ 3), 3-Methyl-1-butanol (MQ 5), 2-Pentylfuran (MQ 31), 2-Methyl-1-propanol (MQ 35), and Dimethyl Disulfide (MP 503) model compounds dissolved in [MeOH] v/v, at 1000 ppm. Approx. 5 µL were spotted on Whatman chromatographic paper 1 and analyzed for 5 minutes using the developed portable IoT sensor in open air. (A) and (B) show the recorded data and the mean Aflatoxin response, respectively.

AI Integration with the portable aflatoxin sensor platform. The developed IoT smart sensor was used to record data for 6 minutes and stored as CSV for the AI modelling as shown in Figure 3 Figure 6 (A to D), shows the capability of the developed sensor to detect individual a Aflatoxins VOCs; (A) shows which sensor is more dominant, (B) shows the confusion matrix obtained, while (C) and (D) shows the stacking classifier evaluated on a held out 20% validation split of the recorded data and the per class precision, recall and F1 score respectively. Figure 6(A) shows the dominant sensor; the reading that deviates most from its own baseline (z-score) per session. For the 31 labeled sessions, 85.7% accuracy and Cohen's kappa of 0.78 were obtained on real sensor data. The system performance was validated using the Stacking classifier on a held-out 20% validation split. Figure 6(B) shows the model's confusion matrix, with one error: the MQ135 session was predicted as MQ5-dominant.

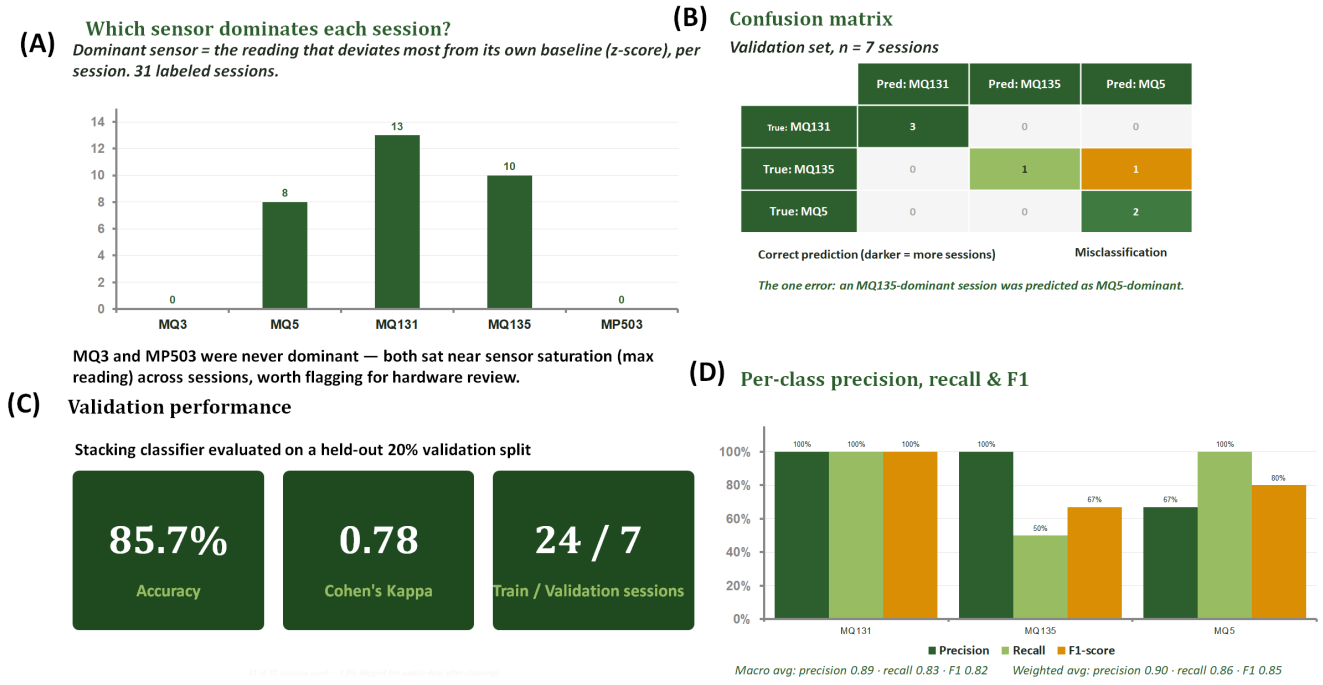

Figure 6. AI model for the detection of Aflatoxins detected using the developed IoT smart sensor; (A to D), shows the capability of the developed sensor to detect individual a Aflatoxins VOCs; (A) shows which sensor is more dominant, (B) shows the confusion matrix obtained, while (C) and (D) shows the stacking classifier evaluated on a held out 20% validation split of the recorded data and the per class precision, recall and F1 score respectively.

In this study, an AI-powered IoT smart sensor platform for rapid, portable, and low-cost detection of aflatoxin using VOCs specific to the aflatoxin species is demonstrated. The developed platform integrates an array of sensors within an IoT architecture and an ensemble machine learning framework that combines Random Forest (RF), Support Vector Machine (SVM), and Artificial Neural Network (ANN) classifiers. Unlike conventional laboratory-based techniques, the proposed system can allow rapid in-field detection with minimal sample preparation while maintaining high analytical performance. The main contributions of this work are summarized as follows: (i) design and development of an AI-enabled portable IoT sensor platform for rapid detection of aflatoxin in the open environment with minimal sample preparation; (ii) development of an ensemble machine learning model integrating RF, SVM, and ANN classifiers to improve detection accuracy, robustness, and generalization with high accuracy and precision; (iii) implementation of real-time edge intelligence on an IoT platform for low-latency field deployment without dependence on cloud computing; (iv) comprehensive experimental validation using VOCs aflatoxin makers; (vi) demonstrated a scalable intelligent sensing framework capable of supporting food safety surveillance, precision agriculture, and early warning systems in resource-limited environments.

The developed platform contributes toward achieving Sustainable Development Goals (SDGs) 2 (Zero Hunger), 3 (Good Health and Well-being), and 9 (Industry, Innovation and Infrastructure), while supporting Uganda's Vision 2040 and National Development Plan IV through the development of affordable intelligent food safety technologies. It's very important to note that the experiments were conducted using VOC standards deposited on filter paper rather than naturally contaminated maize, peanuts, or grain samples. Real agricultural samples

contain moisture, dust, a mix of VOCs, fungi, and environmental interference. Therefore, laboratory performance may not reflect real-world performance, which is the main focus of future work.

IV. CONCLUSION

Centralized laboratory-based detection methods for Aflatoxins, such as ELISA and HPLC, are expensive and time-consuming and are also constrained by limited laboratory capacity and sample transportation challenges in developing countries. This bottleneck prevents timely detection and intervention, leaving producers and consumers exposed to the health risks of Aflatoxins. In this study, the ability to detect and characterize Aflatoxins has been demonstrated by detecting the active, species-specific volatile compounds using a portable, smart, IoT-based sensor. The use of the sensor array to detect VoCs specific to a class of Aflatoxins is novel and shows promise; however, the stability of the sensors used must be investigated further with different VOCs and validated using a laboratory-based instrument such as a GC-MS or HPLC with tandem mass spectrometry. Further studies could address this limitation and/or investigate the possibility of Aflatoxin analysis using a high-resolution mass spectrometer. With high accuracy and precision of 85% achieved using AI machine learning, the method demonstrated in this study shows great promise for the holistic monitoring of food products, with little or no sample preparation. The results obtained indicate that the portable AI powered sensor for aflatoxins is a green sensor for field applications, without the use of solvents or gases for the analysis of analyte(s) in neat solution near real-time analysis and quantification using assemble machine learning AI model that combines random forest, SVM and ANN with 85% to 100% accuracy and sensitivity obtained for the analysis of Aflatoxins in the open environment with little to no sample preparation.

Abstract
The correction of Kazakh word forms is complicated by agglutinative structure, morphological ambiguity, and affix allomorphy governed by phonological rules. This paper reports the design and an initial implementation of a neuro-symbolic architecture that combines formal morphological analysis, morphology-constrained candidate generation, and a three-way decision rule that may abstain rather than correct. The prototype performs script normalization, reverse-trie analysis constrained by vowel harmony and allomorph selection, edit-based candidate generation with stem recombination, and confidence-gated routing of each token to KEEP, CORRECT, or REVIEW. We evaluate it on the UD Kazakh-KTB treebank and on a controlled error corpus generated inside each cross-validation fold. The analyzer covers 99.7% of content tokens, and 62.7% admit more than one parse. Candidate generation achieves Recall@1 of 26.2%, with the gold form retrieved; it ranks first in 78.3% of cases, so generation, rather than ranking, is the limiting stage. The three-way rule raises correction precision to 49.7% against 14.2% for a binary corrector, a difference significant under paired testing, and issues no automatic corrections on unmodified normative text, against a false-correction rate of 1.9% for the binary corrector. It does not improve aggregate correction quality: recall is 2.5%, and F0.5 is indistinguishable from the binary baseline. Two methodological findings are reported. Excluding wrongly replaced tokens from the recall denominator inflates the recall of systems that intervene frequently. A frequency dictionary built without fold isolation inflated F0.5 by 7.3 points and reversed the sign of the baseline comparison.

Keywords: automatic text correction, Kazakh language, neuro-symbolic model, morphological analysis, selective abstention, false-correction rate

I. INTRODUCTION

Automatic text correction in Kazakh faces difficulties due to agglutination and vowel harmony: a single lemma can yield many grammatically correct forms, and an identical character sequence can correspond to different morphological structures. The surface appearance of a word form is therefore not a sufficient criterion for error detection; the acceptability of its morphological structure and its fit to the context must both be checked.

Early correction systems relied on dictionaries, noisy-channel models, and the Damerau–Levenshtein distance [1], [2], and handled simple typographical errors when the correct form was present in the lexicon. Corpus and frequency models extended coverage through automatically extracted word forms and typical substitutions [3]. Still, frequency does not guarantee normativity: a common error may outrank a rare term or a correctly formed derivative. Character-level comparison also fails to separate candidates that are equidistant from the input but differ in grammatical function. A hybrid architecture for Kazakh morphological processing that combines formal, statistical, and transformative components is presented in [4]. Formal morphological analyzers [5], [6] prune structurally impossible variants by checking the admissibility of transitions between morphological states under phonological constraints, but they do not always yield an unambiguous analysis. Neural models built on symbolic, morphemic, and contextual representations [7–11] capture such dependencies better, yet with limited labeled data, they may learn spurious statistical correlations rather than productive rules, and propose contextually plausible but morphologically unacceptable substitutions. The research gap lies not in the absence of individual components but in the insufficient elaboration of their coordinated interaction: morphology should constrain the candidate space, competing interpretations should survive until contextual processing, and the decision should remain transparent. The risk of falsely correcting an already valid word from a name, a term, or a rare derivative is often underestimated. However, its practical cost may exceed that of retaining a doubtful token. The contribution of this report is fourfold. First, we describe and evaluate an implemented correction pipeline in which morphological structure constrains candidate generation rather than filtering neural output after the fact. Second, we treat the false correction of a valid word form as an independent evaluation target and measure it directly; to our knowledge, no prior work on Kazakh correction reports this quantity. Third, we identify two evaluation pitfalls that materially alter conclusions for corpora of this size: an underspecified recall denominator and frequency-dictionary leakage across cross-validation folds, and quantify both. Fourth, we specify the components of the full architecture that remain unimplemented, together with the measurements that motivate them, so that the extended system can be compared against the present baseline.

II. RELATED RESEARCH

1. Correction in morphologically rich languages

Correction systems for morphologically rich languages have combined edit-based candidate generation with morphological validation and contextual ranking. Oflazer and Guzey [12] demonstrated the value of morphological processing for agglutinative languages; Sorokin [13] showed that character-level similarity must be complemented by morphological and contextual evidence; Rozovskaya and Roth [14] showed that large normative corpora partly compensate for limited error-annotated data. For Turkish, Kara et al. [15] built a rule-driven synthetic generation pipeline that covers more than twenty expert-curated writing rules and released parallel data along with detection and correction baselines, confirming that controlled corruption is a viable substitute for scarce annotated error data in agglutinative languages. Across these studies, candidate generation and linguistic verification generally remain separate stages.

2. Morphological synthesis with limited data

Reflection studies show that formal constraints, neural generation, transfer learning, and synthetic data support word-form generation in low-resource settings [16–18]. These methods assume that the lemma and grammatical features are known. In correction, they must first be recovered from the erroneous token and its context, after which the generated form must be verified by reverse analysis.

3. Contextual morphological disambiguation for the Kazakh

Disambiguation models for Kazakh and related languages encode alternative analyses together with sentence context and select the most compatible interpretation [19], [20]. Hybrid architectures have demonstrated the complementarity of formal analyzers and contextual language models in Kazakh morphological processing [4]. These approaches improve the selection of an analysis but do not themselves construct and verify a corrected surface form.

4. Selective prediction and correction safety

Systems that may abstain rather than decide are studied under selective prediction, where performance is characterized by a risk–coverage curve rather than a single accuracy figure. Traub et al. [21] analyze the evaluation of such systems and show that conclusions drawn at a single operating point can be misleading, thereby motivating the reporting of the full curve. We adopt this framing: the REVIEW decision is an abstention, and the false-correction rate is the risk quantity it is designed to control.

5. Selective prediction and correction safety

The proposed method connects correction-candidate generation, morphological verification, and thresholded decision-making. The formal analyzer constrains admissible morphological paths, the decision rule separates confident corrections from uncertain cases, and uncertain cases are retained for review rather than corrected automatically.

III. MATERIALS AND METHODS

1. Notation and hyperparameter values

Table 1. Notation and calibrated values.

Symbol	Value	Meaning
δ	2	maximum Damerau–Levenshtein distance
κ_min	0.40	morphological compatibility floor
τ_e	0.05	error-probability gate
τ_c	0.10	top-1 probability floor for CORRECT
τ_m	0.02	top-1 vs top-2 margin floor (not binding)
λ_ed	1.0	edit-distance energy weight
λ_morph	0.5	residual morphological uncertainty weight

λ_freq	0.3	corpus-frequency weight
λ_ctx	0.0	contextual weight (no trained ranker)
ρ_stem	0.15	energy penalty for stem-recombined candidates
K	1, 5, 10	Recall@K cutoffs

Thresholds τ_e, τ_c, and τ_m were calibrated on fold 0 and fixed before folds 1–4 were evaluated. Fold 0 does not appear in any reported result.

2. Processing pipeline

The system takes a token sequence and returns a sequence of the same length, with each token either retained or replaced; ambiguous cases are marked for manual review rather than replaced automatically. The processing order is: orthographic and script normalization, morphological analysis, error estimation, candidate generation, candidate ranking, and one of three final decisions: KEEP, CORRECT, or REVIEW.

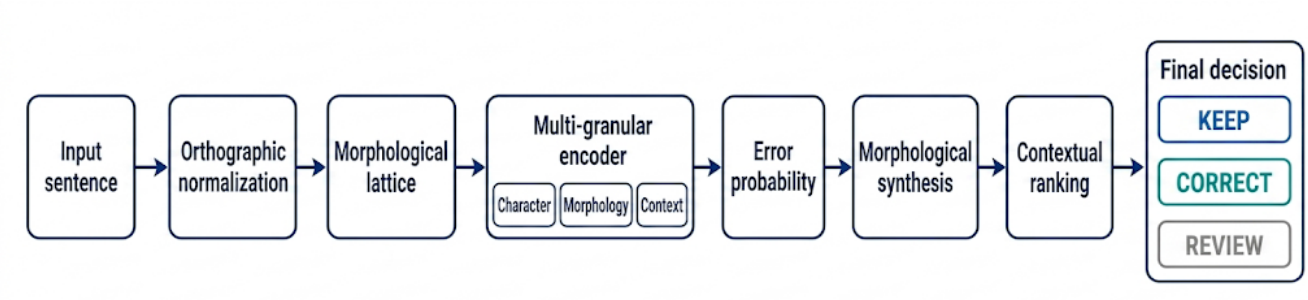

Figure 1. Overall architecture of the neuro-symbolic correction pipeline.

3. Language resources

Table 2. Data resources and their function.

Resource	Size	Role
UD Kazakh-KTB [22]	1,078 sentences; 10,536 tokens	analysis evaluation, corruption source, correction evaluation
Apertium-kaz lemma inventory	≈22,000 lemmas	candidate index (SymSpell, radius δ = 2)
Controlled error set	862 pairs/fold-set (folds 1–4), regenerated × 3 seeds (≈65% corrupted, ≈35% identity); E = 1,683 injected-error tokens per evaluation point	error detection, candidate generation, correction

All texts were converted to a uniform Unicode representation; spaces, quotation marks, hyphens, and apostrophes were normalized. Kazakh–Russian grapheme substitutions were not silently corrected during preprocessing, since mixed-script forms constitute a separate error category.

The lexical representation of a word form w is

$$\mathrm{Lex}(w) = \{(\ell, m, p, f, \nu)\} \quad (1)$$

where ℓ is the lemma, m the morpheme sequence, p the universal part of speech, f the feature bundle, and ν the frequency estimated from the training partition. Frequency is used only as a secondary ranking signal and never as evidence of grammatical validity.

The corpus frequency dictionary is rebuilt independently for each fold from training sentences only. An earlier version of the pipeline was built once over the whole treebank; the effect of that overlap is quantified in Section IV-F.

4. Controlled error generation

Synthetic distortions are introduced only after document-level splitting. For a normative sentence Y, the corruption operator generates an input sentence

$$X = q_{\phi}(Y, t, k) \quad (2)$$

where t is the error type, k the token position, and φ the operation-specific parameters. Each corrupted–clean pair is stored with the token position, original form, corrupted form, error category, and the morphological analysis of the normative token. Error-free identity examples are retained to estimate the false-correction rate and to prevent the model from learning that every sentence contains a replacement.

Table 3. Controlled corruption operators.

Error category	**Corruption operation**	**Status**
Character deletion	remove one grapheme	implemented
Character insertion	insert a keyboard-neighbor or sampled grapheme	implemented
Character substitution	Replace a grapheme with a visually or keyboard-related one	implemented
Adjacent transposition	exchange two neighboring graphemes	implemented
Mixed-script substitution	Replace a Kazakh grapheme with a visually similar Russian Cyrillic one	implemented
Vowel-harmony violation	replace an affix with an incompatible allomorph	implemented
Affix-vowel deletion	remove a vowel from an affix	implemented

Grammatical-affix substitution	replace case, possessive, person, or agreement marking	implemented
Identity example	preserve the normative sentence unmodified	implemented

Each operation is applied only when its linguistic preconditions are satisfied. Examples producing another contextually valid word form are excluded or assigned to a separate ambiguity category.

5. Morphological analysis

For each token the analyzer produces a set of admissible interpretations

$$\mathcal{A}_i = \{a_{ij}\}, \quad j = 1 \dots M_i, \quad a_{ij} = \left(\ell_{ij}, m_{ij}, p_{ij}, f_{ij}\right) \tag{3}$$

retaining paths that satisfy stem compatibility, morphotactic order, vowel harmony, and allomorph selection. The implementation is a reverse-trie suffix matcher over 67 affix classes with 64 harmony and allomorph-selection rules, following the finite-state principle used in previous Kazakh analyzers [5], [6].

Specified but not implemented. The full architecture preserves M_i > 1 competing paths in a lattice until contextual disambiguation. The present implementation returns a single analysis per token. The measured proportion of tokens admitting more than one path (Section IV-C) quantifies what this simplification discards.

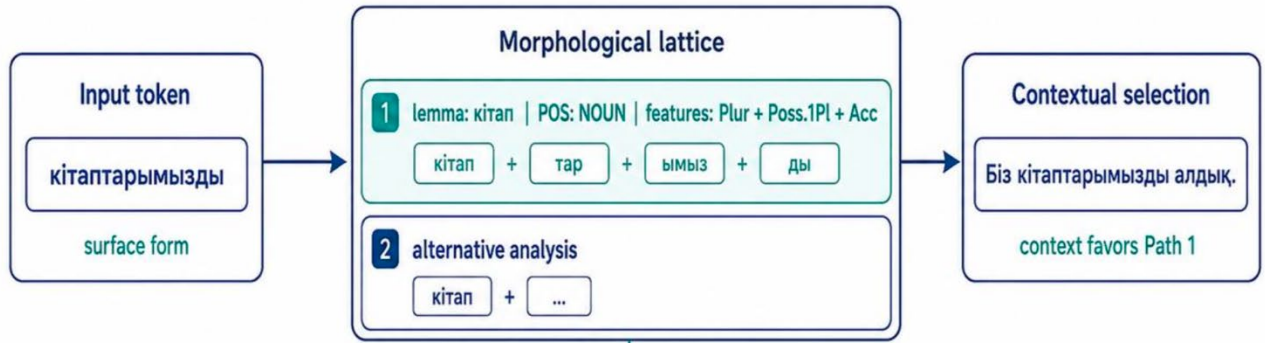

Figure 2. Morphological analysis of a Kazakh word form.

6. Candidate generation

The specified candidate set requires a morphological synthesizer:

$$\mathcal{C}_i^{\text{spec}} = \{\, c : c = \text{Synth}(\ell', f'),\ d(x_i, c) \le \delta,\ \text{Analyze}(c) \supseteq (\ell', f') \,\} \tag{4}$$

This condition specifies the intended verification step. The present implementation approximates it on the analysis side:

$$\mathcal{C}_i = \{\, c : d(x_i, c) \le \delta,\ \text{Analyze}(c) = (\ell', m'),\ \text{Reattach}(\ell', m') = c,\ \kappa(c) \ge \kappa_{\min} \,\} \qquad (5)$$

A candidate is retained if its stem is recovered by the analyzer, if re-attaching the recovered suffix sequence reproduces the candidate surface form, and if the re-parsed candidate attains compatibility κ ≥ κ_min. Candidates are additionally produced by recombining a recovered stem with admissible affix chains, at an energy penalty ρ_stem.

Specified but not implemented. A morphological synthesizer generating a surface form from a lemma and feature bundle, as in [6], is not implemented. The per-category results in Section IV-D show the consequence directly.

7. Ranking and the three-way decision rule

Each candidate receives an energy score $Büyük E(c \mid X, i) = -\lambda_{\text{ctx}} \log P_{\text{ctx}}(c \mid X, i) + \lambda_{\text{ed}}\, \tilde{d}(x_i, c) + \lambda_{\text{morph}}\, \Omega(c) - \lambda_{\text{freq}} \log(1 + \nu_c)$ (6)

where $\tilde{d}$ is the edit distance normalized by the length of the input token, Ω(c) is the residual morphological uncertainty of the candidate, and ν_c its training-partition frequency. Morphologically invalid candidates are removed before this score is computed. Normalised candidate probabilities are $P(c \mid X, i) = \frac{\exp[-E(c|X,i)]}{\sum_{c' \in \mathcal{C}_i \cup \{x_i\}} \exp[-E(c'|X,i)]}$ (7)

Sağriginal token is included in the same decision set as the candidates, making preservation a first-class decision rather than a fallback. c, son taban, alt 2, the two highest-ranked alternatives, the confidence margin is büyük harf delta alt i. EşittirWith c_1 and , c_2 the two highest-ranked alternatives, the confidence margin is $\Delta_i = P(c_1 \mid X, i) - P(c_2 \mid X, i)$, and the decision rule is

$$D_i = \begin{cases} \text{KEEP}, & p_i^{\text{err}} < \tau_e \ \text{ or } \ c_1 = x_i, \\ \text{CORRECT}, & p_i^{\text{err}} \ge \tau_e,\ P(c_1 \mid X, i) \ge \tau_c,\ \Delta_i \ge \tau_m, \\ \text{REVIEW}, & \text{otherwise.} \end{cases} \qquad (8)$$

All three conditions are active at the calibrated operating point. Proper names, abbreviations, and unknown stems are assigned a stricter automatic-correction threshold. REVIEW preserves the original token and returns an ordered set of candidates with morphological analyses.

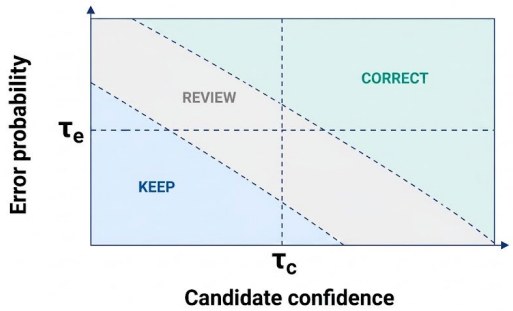

Figure 3. Three-way decision regions in the (error probability, candidate confidence) plane.

8. Specified neural components

Three components of the full architecture are specified but not implemented, and no equations for them are provided here, as none were trained.

A multi-granular representation would combine character-level, morphology-level, and sentence-context encodings through a learned gate, following the character-aware and multi-granularity modeling principles established for agglutinative languages [7], [8], [10], [11]. A joint training objective would optimize error detection, analysis selection, lemmatization, tagging, feature prediction, candidate ranking, and confidence calibration. The calibration term in that objective is intended to align model confidence with observed correctness and to support a defensible REVIEW threshold; Section IV-H shows the behavior that results when it is absent.

In the reported system, λ_ctx = 0: no contextual ranker is trained, and candidate scoring reduces to edit distance, morphological compatibility, and corpus frequency. KazBERT contributes part-of-speech confidence to the error-probability estimate but not to candidate scoring.

9. Baselines and ablations

Three systems are evaluated under identical partitions, preprocessing, and thresholds: frequency-ranked top-1 correction, a binary corrector without REVIEW routing, and the proposed three-way system. A no-op configuration, in which the input is returned unchanged, is included as a floor for the character- and word-error rates. Character-only and context-only neural baselines are specified in the comparison design but were not evaluated in this report, since they require the multi-granular encoder described in Section III-H. Ablations remove stem recombination, morphological filtering, and REVIEW routing. The ablation of lattice encoding is not reported as a measured row because the component is not implemented.

10. Evaluation metrics and protocol

Candidate-generation recall at cutoff K is

$$\text{Recall@}K = \frac{1}{N}\sum_{i=1}^{N} \mathbb{1}\left[\, y_i \in \text{Top}K(\mathcal{C}_i) \,\right] \tag{9}$$

Final correction is evaluated with precision, recall, and

$$F_{0.5} = \frac{(1+0.5^2)\,P\,R}{0.5^2 P + R} \tag{10}$$

which weights precision more heavily than recall, because an unjustified change to a correct word form is more costly than retaining an uncertain token. Recall is computed against the fixed number of injected errors in the fold, so that a token replaced with an incorrect form counts as both a missed correction and a false positive; denominators are therefore identical across systems. The false-correction rate is

$$\text{FCR} = \frac{N(\text{changed correct tokens})}{N(\text{correct tokens})} \tag{11}$$

For the selective-correction regime, risk and coverage at threshold τ are

$$R(\tau) = \frac{N(\text{incorrect automatic decisions at } \tau)}{N(\text{automatic decisions at } \tau)}, \quad C(\tau) = \frac{N(\text{automatic decisions at } \tau)}{N(\text{all evaluated cases})} \tag{12}$$

Quality is assessed in four areas: candidate generation (Recall@1/5/10, MRR), final correction (precision, recall, $F_{0.5}$, CER, WER), safety (false-correction rate), and selective behavior (the risk–coverage curve for the KEEP/CORRECT/REVIEW regime).

Protocol. Evaluation uses 5-fold stratified cross-validation on UD Kazakh-KTB. Fold 0 is held out for threshold calibration and excluded from all reported results; folds 1–4 are used for testing. Three corruption seeds (13, 42, 123) are applied, yielding 12-fold × seed evaluation points. Synthetic errors are generated independently inside each fold after splitting, preventing a normative sentence from appearing in training while its corrupted derivative appears in testing. Token-level traces — original form, generated candidates, morphological analyses, scores, final decision, and grounds for rejecting each option — are retained, permitting failures to be attributed to candidate generation, morphological analysis, ranking, or decision calibration.

Determinism. All reported numbers require full seeding of the Python, NumPy, and PyTorch random number generators, along with a fixed PYTHONHASHSEED set before interpreter startup. Without the latter, the dictionary iteration order during model and tokenizer loading varies across processes, which changes the classification of borderline tokens and shifts the reported precision by more than 10 percentage points. This sensitivity is a consequence of the low intervention rate reported in Section IV-E, with fewer than 100 automatic corrections per evaluation point; each borderline decision reduces precision by roughly 1 percentage point. Under full seeding, the pipeline produces bit-identical results across processes and across CPU and GPU backends.

Implementation details. The contextual encoder is KazBERT (Eraly-ml/KazBERT), a monolingual Kazakh BERT. Part-of-speech and lemma checkpoints were restored from a companion morphological-tagging project and are used for inference only; no network is trained in this report. Evaluation was conducted on an Apple MacBook Pro 2023 M3 Pro (MRX33) using the seeding procedure described above.

IV. RESULTS

1. Implemented and specified components

Table 4. Status of architecture components.

Component	Status
Script normalization; reverse-trie analyzer (67 affix classes); harmony and allomorph rules (64); error taxonomy	implemented
Edit-based candidate generation (SymSpell, $\delta \leq 2$)	implemented
Stem recombination with κ-gated re-parsing, eq. (5)	implemented (analysis-side approximation of eq. (4))
KEEP / CORRECT / REVIEW decision rule, eq. (8)	implemented
Morphological lattice preserving competing analyses	specified

Morphological synthesizer and analysis–synthesis–reanalysis cycle, eq. (4)	specified
Multi-granular encoder with learned gating	specified
Joint training objective with calibration term	specified

One element of the specified scoring function is inactive: the contextual energy weight λ_ctx is zero because no contextual ranker is trained; thus, candidate ranking uses only edit distance, morphological compatibility, and corpus frequency. The margin threshold τ_m is calibrated to 0.02 and is binding (a candidate must lead by ≥0.02 probability to be auto-applied). This is reported as a measured configuration setting and is revisited in the Limitations.

2. Experimental setup

UD Kazakh-KTB, 1,078 sentences and 10,536 tokens; 5-fold stratified cross-validation with fold 0 held out for calibration; three corruption seeds; corruption applied inside each fold after splitting; frequency dictionary rebuilt per fold from training sentences only.

3. Analyzer coverage

The analyzer produces an admissible analysis for 99.7% of the 8,437 content tokens (8,415 tokens, excluding punctuation and symbols) and recovers the correct lemma for 96.4% of tokens (8,131 tokens). Coverage is uniform across parts of speech, ranging from 93.9% (PART, n = 33) to 100.0%; the next lowest values are PROPN (98.6%, n = 562) and AUX (98.6%, n = 361).

62.7% of content tokens (5,290) admit two or more admissible suffix paths. This is the empirical justification for the lattice representation specified in Section III-E. For the majority of content tokens, more than one morphological parse is admissible, and collapsing to a single analysis before contextual disambiguation discards viable interpretations.

4. Candidate generation

Table 5. Candidate generation on the controlled error set (5 folds × 3 seeds, leakage-free protocol).

Configuration	**R@1**	**R@5**	**R@10**	**MRR**
DL, $\delta \leq 2$	19.6 ± 4.0	26.2 ± 4.6	28.0 ± 4.9	22.4 ± 4.1
DL + freq	22.2 ± 3.8	27.4 ± 4.6	28.6 ± 4.2	24.5 ± 4.1
DL + morph filter	19.8 ± 4.1	26.4 ± 4.6	28.1 ± 4.8	22.6 ± 4.1
Proposed	26.2 ± 4.0	32.1 ± 4.5	33.4 ± 4.1	28.8 ± 4.2

The Recall@1/Recall@10 ratio is 78.3% for the proposed generator: once the gold form is retrieved, it almost always ranks first. Retrieval rather than ranking is therefore the limiting stage — 20.9% of corrupted tokens yield no candidate at all, and Recall@10 saturates at 33.4%

Table 6. Recall@K by corruption category (proposed generator, fold-averaged, seed 0).

Category	N	R@1	R@5	R@10
Character insertion	134	50.7	51.5	51.5
Mixed-script substitution	79	35.4	38.0	38.0
Character substitution	112	33.9	38.4	38.4
Character deletion	141	27.7	40.4	41.1
Adjacent transposition	127	18.1	31.5	33.9
Vowel-harmony violation	44	11.4	13.6	13.6
Affix-vowel deletion	60	1.7	3.3	5.0
Grammatical-affix substitution	23	0.0	0.0	0.0

The breakdown localizes the failure. Character-level corruptions are recovered at 18%–51% Recall@1, whereas affix-vowel deletion (1.7%) and grammatical-affix substitution (0.0%) are essentially unreachable. These are precisely the categories that require generation from a lemma and feature bundle rather than edit-based retrieval, and they constitute the empirical case for the morphological synthesizer specified in Section III-F.

5. Correction quality

Table 7. Final correction on the controlled error set (folds 1–4 × 3 seeds; thresholds calibrated on fold 0: τ_e = 0.05, τ_c = 0.10, τ_m = 0.2). Number of injected errors E = 1,683 for all systems.

System	P	R	$F_{0.5}$	FCR↓	CER↓	WER↓
No-op	—	—	—	—	2.7 ± 0.3	9.7 ± 0.8
DL + freq top-1	10.7 ± 3.6	16.7 ± 4.2	11.5 ± 3.6	8.6 ± 3.7	5.5 ± 1.1	16.1 ± 3.2
Binary	14.2 ± 4.5	7.7 ± 2.0	11.9 ± 3.2	2.0 ± 1.5	3.7 ± 0.6	11.1 ± 1.5
Proposed	49.7 ± 18.9	2.5 ± 1.1	10.1 ± 4.3	0.2 ± 0.1	2.8 ± 0.4	9.7 ± 0.9

Confusion counts pooled over the twelve evaluation points: top-1 baseline TP = 283, FP = 2,500, FN = 1,400; binary corrector TP = 129, FP = 830, FN = 1,554; proposed system TP = 41, FP = 44, FN = 1,642.

The three systems occupy different points on the precision–recall trade-off. The top-1 baseline intervenes on 2,783 tokens and recovers 283 errors; the binary corrector intervenes on 959 and recovers 129; the three-way

rule intervenes on 85 and recovers 41. Precision therefore rises from 10.7% to 14.2% to 49.7%, while recall falls from 16.7% to 7.7% to 2.5%. Because λ_ctx = 0, candidate probability mass is spread thinly and the CORRECT branch fires rarely; the low recall is a consequence of the untrained ranker rather than of the decision rule itself.

Significance. Paired tests over the twelve-fold × seed points compare the proposed system with the binary corrector. On precision, the difference is significant: Δ = +0.355, 95% bootstrap interval [+0.248, +0.460], bootstrap *p* < 0.0001, Wilcoxon *p* = 0.0022. On $F_{0.5}$, the proposed system is not ahead: Δ = −0.018, 95% bootstrap interval [−0.046, +0.012], bootstrap *p* = 0.235, Wilcoxon *p* = 0.209. We therefore claim an improvement in correction precision and in correction safety, and explicitly do not claim an improvement in aggregate correction quality. The twelve points comprise four folds × three seeds and are not fully independent, so the *p*-values should be read as indicative. The large standard deviation in precision (±18.9) reflects the small number of automatic corrections per evaluation point — between three and eleven — although no evaluation point produced zero corrections, so the paired test is well-defined throughout.

Character and word error rates. Both quantities for the proposed system are at the no-op floor. This follows directly from the intervention rate: 41 errors repaired against 44 introduced, a net change of three errors in 1,683. We report CER and WER for completeness and do not present them as an advantage of the three-way rule. The binary corrector, by contrast, raises both rates well above the floor (3.7% and 11.1% against 2.7% and 9.7%), confirming that unconstrained intervention degrades text quality on this corpus.

6. Leakage-controlled comparison

An earlier version of the evaluation built the corpus frequency dictionary once over the entire treebank, so gold forms from the test folds were visible to the frequency-ranking modes.

Table 8. Effect of frequency-dictionary leakage (identical recall denominator; folds 1–4 × 3 seeds).

System	$F_{0.5}$ leaky	$F_{0.5}$ leakage-free	Inflation
DL + frequency, top-1	12.4 ± 4.1	11.5 ± 3.6	+1.0 pp
Binary corrector	11.9 ± 3.2	11.9 ± 3.2	0.0 pp
Three-way (proposed)	17.4 ± 6.5	10.1 ± 4.3	+7.3 pp

Protocol	Δ $F_{0.5}$	95% bootstrap CI	bootstrap *p*	Wilcoxon *p*
Leakage-free (reported)	-0.018	[−0.046, +0.012]	0.235	0.209
Leaky (original)	+0.055	[+0.027, +0.082]	< 0.0001	0.0012

Candidate Recall@1 for the proposed generator falls from 29.0% to 26.2% under fold isolation. Modes that do not consult the frequency dictionary are unaffected. The effect is not a matter of degree. Under the leaky protocol, the proposed system appears to outperform the binary baseline by a statistically significant margin; under fold isolation, the same comparison shows a small, non-significant deficit. The leakage therefore reversed the

conclusion's sign, not merely its magnitude. On a treebank of this size, a frequency resource built without fold isolation can yield spurious results, and corpus- and frequency-based correction methods for low-resource languages are commonly evaluated without this control. We report both protocols so that the comparison can be reproduced under either.

7. False correction on normative text

Table 9. False-correction rate on unmodified normative text (folds 1–4, 862 sentences, 8,270 tokens).

Configuration	FCR	KEEP	CORRECT	REVIEW
Binary corrector (− REVIEW)	1.9% (154/8,270)	8,116	154	0
Three-way (proposed)	**0.0%** (0/8,270)	7,996	0	274

On unmodified normative text, the three-way rule issued no automatic corrections at all: 7,996 tokens were kept, and 274 (3.3%) were routed to review, giving a false-correction rate of 0.0% across all four evaluation folds, compared with 1.9% for the binary corrector. This is not the trivial property of a system that never acts. On the controlled error set, the same rule, under the same thresholds, issued 85 corrections with 49.7% precision (Table 7). The rule, therefore, separates the two conditions: it intervenes when corruption is present and abstains when the input is already normative. What the clean-text measurement establishes is the absence of a failure mode, not the presence of a capability.

Per-fold false-correction rates for the binary corrector range from 0.90% to 4.38%, so the pooled figure conceals substantial variation.

Table 10. Stratified false-correction rate (binary corrector, pooled).

Partition	**N**	**FCR**
Not in the lexicon	5,870	2.5% (148)
Common	1,773	0.0% (0)
Proper name	440	1.4% (6)
Borrowing	187	0.0% (0)
Analyzer: known	8,249	1.9% (154)
Analyzer: unknown	21	0.0% (0)

The stratification must be read carefully. Tokens absent from the lemma lists account for 5,870 of 8,270 tokens and for 148 of the 154 false corrections; since this partition covers 71% of the corpus, the concentration is partly a property of the partition rather than of the errors. The analyzer-based partition is sharper: only 21 tokens are unparseable, and none received a false correction. The large lexicon-miss class, therefore, reflects a narrow frequency lexicon rather than words that the system cannot analyze.

To the authors' knowledge, no prior work on Kazakh correction reports a false-correction rate; the cited systems report only the accuracy of repairing injected errors.

8. Risk–coverage behavior

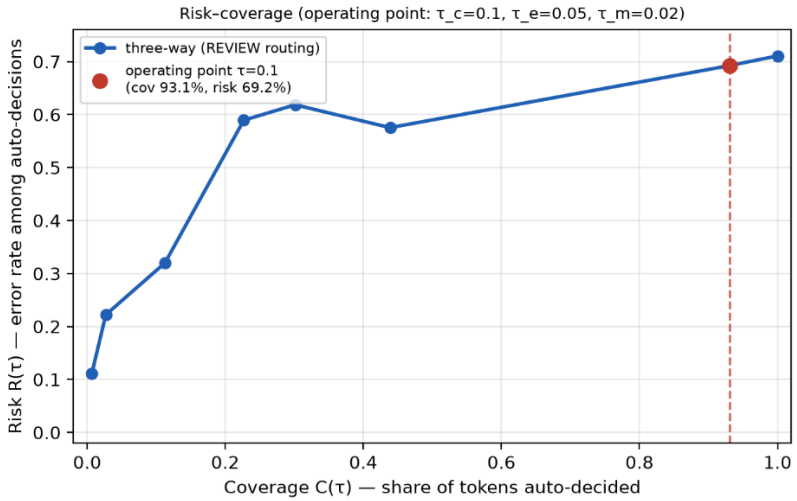

Figure 4. Risk R(τ) against coverage C(τ) for the three-way rule, with the calibrated operating point τ_c = 0.10 marked.

At the selected threshold τ_c = 0.10, the top-1 condition admits 93.1% of the 1,331 candidate-bearing tokens at 69.2% risk. Risk falls to 32.0% at 11.3% coverage, to 22.2% at 2.7% coverage, and to 11.1% at 0.7% coverage. The curve, therefore, exposes the trade-off and makes it selectable, but it does not offer a favorable operating region at any threshold that retains meaningful coverage. The curve exposes the trade-off and makes it selectable, but it does not yet offer a favorable operating region.

The curve is not monotone: risk rises from 57.5% at τ = 0.15 to 61.8% at τ = 0.20. Since λ_ctx = 0, the score entering the threshold is a normalized energy over edit distance, morphological compatibility, and frequency, and it is not calibrated against observed correctness. The calibration term specified in Section III-H is the component intended to remove this behavior, and its absence is the most direct explanation for the non-monotone region. As Traub et al. [21] note, conclusions drawn from a single working point of such a system can be misleading; we therefore report the full curve rather than the operating point alone.

9. Component ablation

Table 11. Ablation on candidate Recall@K (5 folds × 3 seeds). Each row removes one component from the proposed generator.

Configuration	R@1	R@5	R@10	MRR	Δ R@1
− stem recombination (analysis filter only)	19.8 ± 4.1	26.4 ± 4.6	28.1 ± 4.8	22.6 ± 4.1	−6.4 pp

− morphology (frequency ranking only)	22.2 ± 3.8	27.4 ± 4.6	28.6 ± 4.2	24.5 ± 4.1	−4.0 pp
Full proposed	26.2 ± 4.0	32.1 ± 4.5	33.4 ± 4.1	28.8 ± 4.2	—

The morphological re-analysis filter, applied on its own, is not effective (19.8% vs. 19.6% for plain edit-distance retrieval). The measured gain arises from stem recombination combined with frequency ranking, not from filtering out morphologically implausible candidates. The REVIEW-routing ablation is reported in Table 9 on clean text and in Table 7 on the controlled error set. The lattice-encoding ablation targets a component that is not implemented; rather than report a fabricated row, we report the quantity that motivates it — the 62.7% multi-path rate of Section IV-C.

V. DISCUSSION

The architecture treats correction as the reconstruction of a morphologically admissible word form rather than the selection of the nearest dictionary item. This distinction matters for Kazakh, where several valid forms may be equidistant from the input while expressing different grammatical functions. Morphological admissibility is enforced before ranking, so structurally impossible candidates are excluded rather than penalized probabilistically. The measurements support a narrow but specific claim. Abstention raises the precision of automatic correction 3.5-fold and removes false corrections on normative text entirely. It does not yet produce a better corrector: the system repairs 2.5% of injected errors, its aggregate $F_{0.5}$ is slightly below that of a binary corrector, and its net effect on corpus-level error rates is three additional errors in 1,683. The two components most responsible for this — a trained contextual ranker and a calibration term — are precisely the ones not yet implemented, and the risk–coverage curve directly reflects their absence. Two methodological findings are worth separating from the system itself. First, excluding incorrectly replaced tokens from the recall denominator inflates the recall of systems that intervene frequently, and the denominator must be fixed to the number of injected errors for cross-system comparison. Second, a frequency dictionary built without cross-validation fold isolation inflated the proposed system's $F_{0.5}$ by 7.3 percentage points and reversed the sign of its comparison against the binary baseline. Third, without a fixed process-level hash seed, the order of dictionary iteration during model loading altered the classification of borderline tokens and shifted measured precision by more than 10 percentage points between runs of identical code. Systems with very low intervention rates are structurally exposed to this. When a decision is taken on eighty-five tokens, each borderline case is worth more than a percentage point of precision.

VI. LIMITATIONS

Five limitations must be stated explicitly.

First, the morphological component returns a single analysis per token rather than the lattice specified in Section III-E. The measured 62.7% multi-path rate indicates the scale of what is discarded. Second, morphological synthesis and the corresponding analysis–synthesis–reanalysis verification are not implemented. The candidate generator approximates the cycle on the analysis side, and the per-category results show the consequence: affix-vowel deletion and grammatical-affix substitution are recovered at 1.7% and 0.0% Recall@1, respectively. Third, no contextual ranker is trained, so $\lambda_ctx = 0$. This is the direct cause of the low CORRECT recall and of the uncalibrated, non-monotone risk–coverage behavior. A trained contextual ranker with a calibration term is the highest-leverage next step. Fourth, the proposed system does not improve the aggregate quality of corrections. Its $F_{0.5}$ is below that of the binary corrector, though not significantly so, and its character and word

error rates are at the no-op floor. The results support claims only regarding precision and safety. Fifth, precision is estimated at between three and eleven automatic corrections per evaluation point, yielding a standard deviation of ±18.9 percentage points. The comparison against the binary corrector is significant because the gap is large, but the absolute value of 49.7% should be treated as an estimate with wide uncertainty. Sixth, evaluation uses five-fold cross-validation with three corruption seeds on a treebank of 1,078 sentences, with synthetic distortions rather than natural user errors. Synthetic errors do not reproduce the distribution of errors in natural writing, and a manually verified natural-error set is under construction.

VII. CONCLUSION

This paper reports the design and an initial implementation of a neuro-symbolic architecture for the correction of Kazakh word forms, combining formal morphological analysis, morphology-constrained candidate generation with stem recombination, and a three-way KEEP/CORRECT/REVIEW decision rule. On the UD Kazakh-KTB treebank, the analyzer covers 99.7% of content tokens, and 62.7% of these tokens admit more than one admissible parse. Candidate generation achieves Recall@1 of 26.2%, and when the gold form is retrieved, it ranks first in 78.3% of cases, identifying retrieval rather than ranking as the limiting stage. The three-way rule attains 49.7% correction precision against 14.2% for a binary corrector — a difference significant under paired testing — and issues no false corrections on unmodified normative text, at the cost of a 2.5% recall. It does not improve aggregate correction quality: recall is 2.5%, $F_{0.5}$ is slightly below the binary baseline, and character and word error rates are at the no-op floor. Two methodological findings accompany these results. Treating a wrongly replaced token as absent from the recall denominator inflates the recall of systems that intervene frequently. A frequency dictionary built without fold isolation inflated the proposed system's $F_{0.5}$ by 7.3 percentage points and reversed the sign of its comparison against the baseline. Process-level hash randomization shifted measured precision by more than 10 percentage points between runs of identical code. Both are reported so that the comparison can be reproduced under either protocol. Four components of the full architecture remain unimplemented: a morphological lattice, a synthesizer supporting analysis–synthesis–reanalysis verification, a multi-granular encoder with learned gating, and a joint training objective with a calibration term.

DATA AND CODE AVAILABILITY

All results in Section IV are reproducible from the accompanying repository *1*. Threshold calibration is performed on fold 0 and locked before folds 1–4 are evaluated; corruption is applied inside each fold after splitting; the frequency dictionary is rebuilt per fold from training sentences only. The KazBERT part-of-speech and lemma checkpoints are used for inference only. Both the leakage-free and leaky evaluation protocols are retained in the repository to enable Table 8 to be reproduced.

ACKNOWLEDGEMENT

The authors would like to acknowledge the use of large language models to assist in improving the manuscript's clarity, structure, and overall language quality. Additionally, the Grammarly tool was utilized for grammar checking and linguistic refinement. These tools were employed solely to enhance readability and presentation, while all scientific content, methodology, and results remain the authors' original work.

FUNDING STATEMENT

1 https://github.com/akhmedbike/IHCONCS_2026_paper

The authors declare that financial support was received for the research and/or publication of this article. This research was funded by the Science Committee of the Ministry of Science and Higher Education of the Republic of Kazakhstan (Grant No. IRN AP23487753) under the project titled “Innovative technologies for automated correction of Kazakh language texts: machine learning and morphological analysis”.

Abstract
Human Activity Recognition (HAR) enables automatic monitoring of human activities, with applications in intelligent healthcare, fall detection, and independent living for older people. Human activities occur in continuous sequences with seamless transitions; however, despite significant advances in radar-based HAR, continuous HAR remains underexplored, as many existing studies focus on single-activity windows rather than continuous activities. This paper addresses radar-based continuous HAR. We explored the efficiency of three time-series analysis strategies for continuous radar-based HAR, including 1) CNN-LSTM, 2) CNN-Transformer, and 3) CNN-Vision Transformer. We devised a fused ensemble learning approach that leverages the strengths of each pipeline by incorporating prior knowledge of per-class performance from each pipeline's evaluation. Our proposed ensemble method achieved the highest overall accuracy (84.81%) and better generalization, followed by the CNN-Vision Transformer and the CNN-LSTM. The natural imbalance condition of HAR data leads to prediction bias. In this paper, we address this problem and devise a data balancing and augmentation strategy based on averaging similar data windows.

Keywords: Human Activity Recognition (HAR), Doppler radar, continuous HAR, data balancing, Averaging, Ensemble, CNN-LSTM, CNN-Vision Transformer, CNN-Transformer

I. INTRODUCTION

The decline of cognitive and physical activity makes it difficult for some demographics, such as older people, to perform daily routine activities and increases their risk of accidents. According to the WHO, the population of people aged 60 and above will increase by nearly 50% [1]. Human activity recognition (HAR) provides a means to automatically explore, track, and categorize people's activities and actions. Both intrusive and non-intrusive methods can achieve HAR. Intrusive devices, such as digital cameras, invade users' privacy, while other devices, such as wearables, require users to wear them at all times. This makes them less than ideal devices to use, especially for elderly users with declining cognitive function who require independent living without compromising privacy. Therefore, the employment of non-intrusive devices is a far better idea. In recent years, digital sensors such as mm-wave Doppler radar have become a better alternative for continuous monitoring of

human activity while eliminating privacy invasion [2]. Another advantage of radar sensors is that they can operate under different lighting conditions without any loss of accuracy. For HAR, micro-doppler signatures comprising the movement of the head, torso, and limbs are extracted and analyzed [3]. One important, related challenge for HAR is that human activity data is inherently imbalanced. The huge imbalance in how human activities are naturally distributed might cause a model to be biased, favoring the most frequent activities and underperforming on rare ones. This can lead to very high overall accuracy despite failing to identify rare activities correctly. A fall is considered a rare activity, whereas standing or walking are very frequent. Missing a fall detection can come with dire and undesirable harm, especially for the elderly population. Furthermore, some activities might take longer, such as prolonged sitting or walking, while others might take less time, such as the transition from sitting to standing. Therefore, there is a need for balanced data to mitigate bias and improve recognition of underrepresented minority activities. Deep learning techniques such as convolutional neural networks (CNNs) have been used in HAR to extract features effectively from sensor data [4], and recurrent neural networks like Long Short-Term Memory (LSTM) are also promising for accuracy and performance on sequential data. This is due to their ability to learn and remember long-term dependencies in sequential data [5]. Other approaches combined CNNs and LSTMs, with the CNN layers extracting features for the LSTM layers. In wearable motion sensors [6], the hybrid CNN-LSTM approach achieved higher accuracy than using CNN or LSTM individually. In [7], a probabilistic neural network on single-subject activity data obtained from sensors was used to recognize activities. The limitation of these studies is that they utilized only single-activity recordings within a window. However, in real-life scenarios, activities occur continuously, one after another. Therefore, it would be valuable to extend these approaches to continuous HAR. Another promising approach for processing sequential data is vision transformers (ViTs), which modify the transformer architecture for image classification by treating image patches as sequential tokens [8]. This technique can be relevant to radar-based continuous HAR, where the data windows can be treated as sequences of image-like frames.

Most radar-based HAR studies utilized a single activity recording within a sample, e.g., sequences of frames, which are sometimes referred to as a window [3], [9]. On the other hand, some studies collect recordings from a series of various continuous activities. To investigate radar-based continuous HAR, the authors in [10] adopted two strategies for continuous activity recognition of radar data, using the Dynamic Time Warping (DTW) algorithm and LSTM. A hybrid CNN-LSTM approach was used by [11] for acoustic sensors, achieving good accuracy under non-noisy conditions. While some research has reported the adoption of some time-series analyses for continuous radar-based HAR, no clear comparison of such strategies has been conducted. Then, it is desirable to extend and perform a comparative study on these deep learning architectures that have demonstrated great potential.

Ensemble learning is the art of integrating multiple weak individual models to produce a model with improved performance and better generalization. Ensemble learning strategies such as unweighted averaging and majority voting are biased towards the stronger model's outcome [12]. Our proposed models have different strengths, with each model performing better on certain activity classes. This prior knowledge of per-class performance obtained during model evaluation is used to define class-specific experts among the models. Therefore, we perform ensemble learning based on how reliably each model predicts each class; we use class-specific performance as prior knowledge to guide the ensemble during inference.

This paper explores the efficiency of different time-series analysis strategies, including CNN-LSTM, CNN-Transformer, and CNN-Vision Transformer, for continuous radar-based HAR.

In this paper, we do: 1) highlight the natural imbalance condition in radar data and perform data augmentation by averaging, and data balancing with weighted cross-entropy loss during training to address the class-balance

challenge that drastically introduces prediction bias, 2) a comparison of several pipelines and devise a hybrid pipeline for Doppler radar-based continuous HAR for sequence to sequence modelling, and evaluate their overall performance and per class performance, 3) a fused ensemble learning approach to benefit from the strengths of each pipeline, by using prior knowledge of per-class performance obtained during each pipeline evaluation.

The dataset utilized for this research was collected at the Swansea University Living Lab. It contains radar recordings of different sequences of daily human activities.

II. METHODOLOGY

1. Data Description

The dataset used in this study is based on data collected using Doppler radar in the living lab at Swansea University, with 8 subjects aged 65 years and over; each subject conducted a series of activities 8 times. The data were then divided into overlapping windows (50% overlap), each with 15 timesteps and manually labeled per timestep. Some windows contain homogeneous activities, while others contain heterogeneous ones. A total of 1428 windows were generated. These were then divided into training (70%), validation (15%), and testing (15%) subsets. The split was based on random selection rather than a subject-wise basis. For this research, some activities from the experiment were omitted, and only five were used: sitting, standing, walking, falling, and bending. Figure 1 shows the sequence of activities.

2. Data Augmentation and Balancing

We utilized an averaging strategy for data augmentation to mitigate class imbalance and obtain more samples for the data-hungry pipeline (ViT). In the training dataset, for each class, a new window is created by averaging the features of every unique pair of homogeneous windows in that class. If the windows are similar, averaging occurs only when the pair has reached a 90% similarity threshold. Furthermore, generation is stopped when the total number of homogeneous windows for a particular class reaches 500. However, for class 3 (falling), the total number of homogeneous windows was set to 200. This is because the number of samples in that class is very limited, and repeatedly applying averaging can distort the class signals, causing much more severe confusion with other classes. Figure 2 shows the distribution of the training dataset before and after augmentation. Figure 3 shows a visualization of two windows and an averaged generated window.

3. Data Reshaping

The input data was originally shaped (15, 4096). Since all proposed pipelines require a CNN block, the input data was later reshaped to (15, 16, 256, 1) to make it compatible with conv2D layers in a convolutional neural network (CNN). Convolutional layers require a 2D input with channels to extract meaningful features.

4. Pipelines

The CNN-LSTM pipeline contains one CNN block applied at each timestep, followed by an LSTM layer that also outputs sequences of its hidden states at each timestep. The whole process is outlined in Figure 4.
CNN-Transformer The CNN-Transformer pipeline contains one CNN block applied per timestep, and the output is flattened into a 1D vector. This is followed by key components of the transformer: positional embedding, multihead attention, and a feed-forward network. The output features from the CNN block are linearly projected, and positional embeddings are added to capture temporal features. This is followed by two

transformer encoder layers applied sequentially. Each encoder contains the key elements of the transformer (multihead attention and feed-forward network).

CNN-Vision Transformer

This pipeline contains two CNN layers, applied per timestep, to extract features and reduce the spatial dimension, preparing the input for patch extraction. As required by vision transformers, features are converted into sequential tokens (patches), and positional embeddings are then applied. This is followed by four identical Vision Transformer encoder blocks, each containing multihead attention and a feed-forward network. Further, global average pooling is applied over the patch dimension at each timestep, and an output layer is applied to obtain sequence-to-sequence classification. The model architecture is shown in Figure 5. This model achieved the highest overall accuracy among the three pipelines.

The three pipelines above each have different strengths in prediction. To leverage all models, an ensemble approach is utilized. Since CNN-LSTM and CNN-vision transformer showed a better per-class accuracy, the two are chosen for ensemble learning. Each of the selected models has different strengths in predicting particular classes; therefore, a class-specific weighted fusion is used. This method outperforms the standard ensemble that assigns global weights regardless of the models' class accuracies. In our case, for example, CNN-LSTM achieves higher accuracy for the falling class, while CNN-Vision Transformer achieves higher accuracy for the standing, walking, and bending classes. Therefore, instead of assigning one weight per model, we first compute a performance matrix, which is the accuracy of each model for each class; we use this to obtain weights for each model per class. We define and compute class-specific w, c, m, son, alt, and simgeper models for each class (obtained by normalizing the performance matrix). The accuracy scores of all models are summed for each class, then each model's accuracy for that class is divided by this sum to ensure that the weights of a given class sum to 1 across all models.

Each model outputs a probability tensor, a $p_{i,t,c}^{(m)}$ is the probability assigned by model m for class c for each sample i at timestep t. We then generate a fused probability for each class, obtained by taking the weighted sum of the two models' predictions for that class. Since the weighted combination may not form a valid probability distribution, we further normalize the fused probability across all classes. The class with the highest probability is then considered the final prediction. Figure 6 shows the working mechanism of the ensemble learning model.

$$\text{fused}_{i,t,c} = \sum_{m=1}^{M} w_{c,m}\ p_{i,t,c}^{(m)} \tag{1}$$

normalise;

$$\hat{p}_{i,t,c} = \frac{\text{fused}_{i,t,c}}{\sum_{j=1}^{C} \text{fused}_{i,t,j}} \tag{2}$$

Finally,

$$y_{i,t} = \arg\max_{c} \hat{p}_{i,t,c} \tag{3}$$

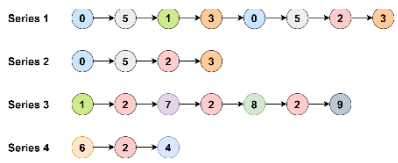

Figure 1. Example Original Series of activity sequences. The labels are as follows: 0-sitting, 1-standing, 2-walking, 3-falling, 4-bending, 5-sit to Stand, 6-standing and cooking, 7-standing and eating, 8-standing and opening/closing the microwave, 9-hitting the door.

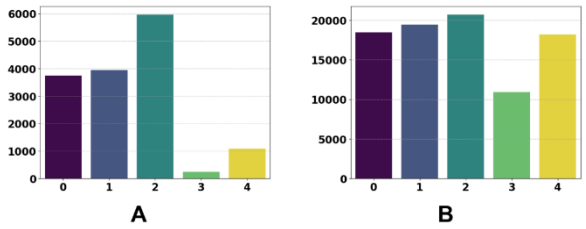

Figure 2. Distribution of the training dataset before and after augmentation. The X-axis represents the labels, and the Y-axis represents the number of occurrences. A represents the distribution of original data without augmentation, and B represents the distribution of data after augmentation. The labels are 0-sitting, 1-standing, 2-walking, 3-falling, 4-bending

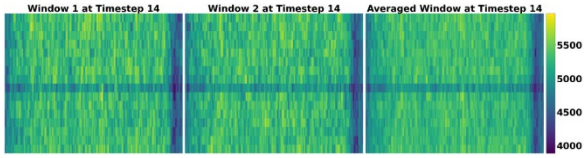

Figure 3. Comparison of two original windows with an averaged window. The averaged window is generated by averaging two similar windows of the same activity at each timestep.

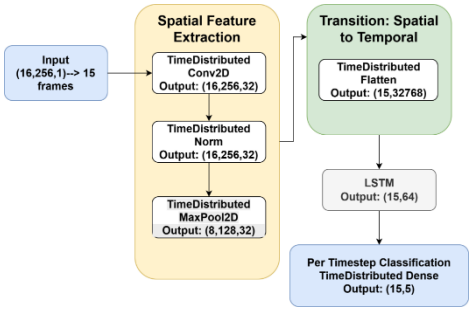

Figure 4. Processing workflow of CNN-LSTM Architecture. Convolutional block for feature extraction followed by an LSTM block and a per-timestep classification layer.

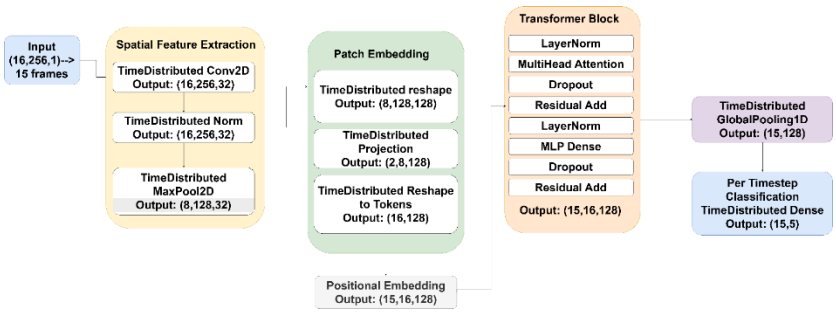

Figure 5. Processing Workflow of CNN-Vision Transformer architecture. Convolutional block for feature extraction followed by vision transformer blocks. The final block is a per-timestep classification layer.

III. RESULTS AND DISCUSSION

1. Results

In the first experiment, we evaluated the three pipelines on clean original data with no augmentation. To address class imbalance and improve the accuracy of the minority class, a weighted cross-entropy loss was used during training. In a preliminary experiment, we noticed that falling is consistently misclassified as walking. Since a fall activity usually follows a walk activity, confusion between the two classes persists. Hence, the weight of the minority fall class was manually set to 7, approximately 14 times that of the majority class (Walking). Falling cases are critical, and misclassifying them carries a higher risk than misclassifying other classes.

CNN-LSTM achieved an accuracy of 82.42%, CNN-Transformer achieved 49.22%, and CNN-Vision Transformer achieved an accuracy of 71.65%. The overall accuracy of the CNN-LSTM was higher under the unaugmented data condition. Moreover, CNN-Transformer had 0 detections of the minority falling class. The accuracy of CNN-Transformer and CNN-Vision Transformer is low because both require large amounts of data to perform at their full potential. The per-class accuracy results for this experiment are summarised in Table 1.

In the second experiment, we repeated the first experiment using the augmented train set defined in the methodology section. The number of data windows increased to 5845. Since the minority-falling class samples have now increased, we adjusted the class weights to approximately 9 times those of the majority class. CNN-LSTM achieved a slightly lower accuracy of 82.20%; CNN-Transformer increased by close to 35% to 83.68%, while CNN-Vision Transformer increased to 84.34%. However, despite the major increase in CNN-Transformer, its failure to accurately classify the minority class persists. The per-class accuracy results for this experiment are summarised in Table 2.

In the third experiment, we selected the two best models, specifically in terms of class accuracy (the non-augmented CNN-LSTM and the augmented CNN-Vision Transformer), for ensemble learning. We leveraged the best qualities of each model to guide ensemble predictions. This experiment achieved the highest overall accuracy, at 84.81%. The results of this experiment are summarised in Figure 7. Table 3 compares the performance of the two selected models and the ensemble model for minority-class detection (falling).

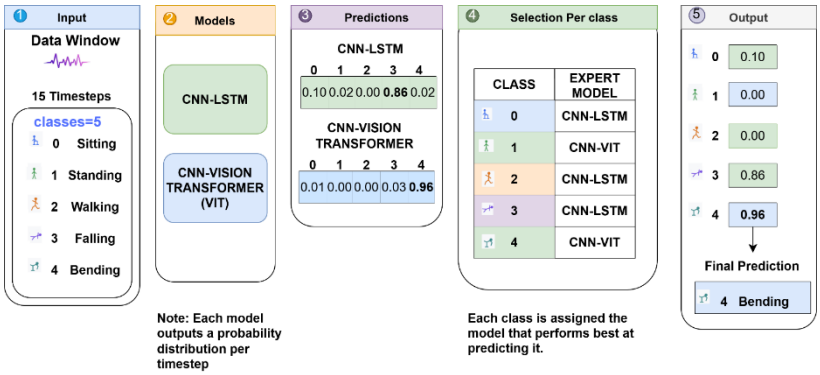

Figure 6. Ensemble model working mechanism: class probability vectors are obtained from candidate models for each timestep classification. An expert model for each class is assigned based on prior knowledge obtained from the performance matrix. The probability for each class is extracted from its assigned expert and combined into a new probability vector used for the final prediction. The class with the highest probability is the final prediction.

2. Discussion

The three different experiments reveal an interesting pattern. CNN-LSTM achieves the highest accuracy when only the weighted cross-entropy loss is used, and no augmentation is applied. This aligns with the findings in [11] for acoustic HAR. Although it achieved the highest accuracy for the falling class (our minority class), the excessive number of false alarms led to a precision of only 23%, resulting in the lowest F1-score at 0.38 and the lowest overall accuracy. The excessive number of false alarms could lead users to mistrust the model in real-life situations. In contrast, the performance of CNN-Vision Transformer increased after augmentation. This indicates that the proposed augmentation strategy is effective and that additional training data improved classification performance across all classes. Furthermore, the precision of the falling class increased to 49%, indicating fewer false-positive alarms, and the macro F1 score increased to 0.81, indicating balanced performance across all classes. A similar trend of performance improvement was also demonstrated in CNN-Transformer after augmentation. On the other hand, the ensemble model achieved the highest overall accuracy at 84.81% and had the strongest balance among all classes, with a macro F1 of 0.811, a slight increase over CNN-Vision Transformer, and a weighted F1 score of 0.85. Although CNN-LSTM achieves the highest fall-class detection, the ensemble model results indicate that a modest reduction in fall detection yields a middle ground with slightly lower accuracy but better generalization and a more balanced HAR.

Table 1. Per-class Accuracy on Unaugmented Data

Activity/Class	CNN-LSTM	CNN-Transformer	CNN-Vision Transformer
Sitting	**97.96**	25.61	79.49
Standing	**77.18**	54.87	93.86
Walking	**73.45**	48.46	47.09
Falling	**96.55**	0.00	77.78
Bending	**94.07**	81.36	95.34

Table 2. Per-class Accuracy on Augmented Data

Activity/Class	CNN-LSTM	CNN-Transformer	CNN-Vision Transformer
Sitting	**97.48**	96.39	93.87
Standing	87.28	93.27	**89.65**
Walking	70.14	69.31	**73.15**
Falling	34.48	17.24	**82.76**
Bending	84.75	85.17	**95.76**

Table 3. Comparison of Models in Terms of Minority Class Detection

Metric	CNN-LSTM	CNN-Transformer	CNN-Vision Transformer
Overall accuracy	82.42%	84.34%	**84.81%**
Weighted F1-Score	0.8300	0.8400	**0.8485**
Macro F1-score	0.7500	0.8100	**0.8107**
Precision	0.2300	0.4900	0.4545
Recall	**0.9655**	0.8276	0.8621
F1-score	0.3800	**0.6200**	0.5952

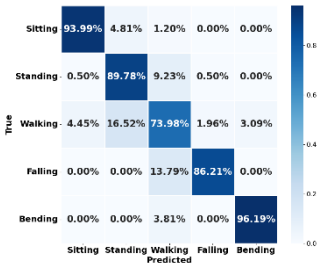

Figure 7. Confusion matrix for the Ensemble Model

IV. CONCLUSION

This study explored radar-based HAR in a continuous setting. 1) We addressed the natural imbalance condition of HAR data and devised a data balancing and augmentation strategy by averaging single activity windows that are at least 90% similar at every timestep, 2) We evaluated and compared three pipelines: CNN-LSTM, CNN-Transformer, and CNN-Vision Transformer, 3) We developed a fused ensemble learning strategy that leverages

the strengths of each pipeline by using prior knowledge of per-class performance obtained during each pipeline's evaluation. On non-augmented data, CNN-LSTM achieved remarkable accuracy using only a weighted cross-entropy loss. In the augmented data, we observed a significant increase in the accuracy of the CNN-Transformer and CNN-Vision Transformer models. This indicated that the augmentation and amount of data influence these architectures. The CNN-Vision Transformer achieves higher accuracy and better generalization across classes. In both augmented and non-augmented data, CNN-Transformer achieves lower accuracy, particularly due to its failure to detect and predict the minority class. Our proposed ensemble method achieved the highest overall accuracy, with a slight drop in accuracy for the fall class; however, this yields better generalization and a more trusted, reliable, and balanced HAR. For future work, we would like to extend this work to adapt it to a different radar environment with different subjects and different age groups.

Abstract

Automatic analysis of learner affect can support online learning by providing complementary information about behavioral and emotional states that are difficult for instructors to observe continuously. This study presents a reproducible, full-frame, sparse-temporal, multitask framework for student affective-state recognition using the DAiSEE dataset. The official Train, Validation, and Test partitions are preserved, and each usable clip is represented by 16 temporally distributed RGB frames, resized to 160 × 160 pixels, and associated with 4 clip-level targets: Engagement, Boredom, Confusion, and Frustration. The completed audit retained 5,357 training, 1,429 validation, and 1,784 test clips, yielding 8,570 sequences and 137,120 images. The proposed framework uses a shared MobileNetV2-GRU representation with four task-specific classification heads, while a single-frame baseline, temporal configurations, and imbalance-aware training are defined for controlled comparison. The dataset analysis reveals substantial, target-specific class imbalance, demonstrating that conventional accuracy alone can yield a misleading assessment of affective-state recognition. Therefore, the evaluation protocol emphasizes balanced and ordinal measures together with class-wise analysis. The reported quantitative results are limited to the verified majority-class validation baseline, which establishes a reference point for evaluating the trained models. The study provides an audited data pipeline, transparent experimental protocol, and reproducible foundation for subsequent temporal and multimodal student-state analysis.

Keywords: DAiSEE, student affective state, multitask learning, temporal modeling

I. INTRODUCTION

Automatic engagement estimation has become increasingly relevant as learning activities move between physical and digital environments. In a face-to-face classroom, instructors can combine eye contact, posture, note-taking, response timing, and interaction history when judging whether a learner is following the lesson. Most of these cues are difficult to monitor continuously in a large online class. A systematic review of automatic engagement estimation, therefore, identifies engagement recognition as a potential component of adaptive and personalized learning support, while emphasizing that engagement is multidimensional and must be interpreted through observable affective and behavioral cues [1]. DAiSEE was introduced as an in-the-wild multi-label video dataset containing 9,068 clips from 112 users. Each clip is annotated for Engagement, Boredom, Confusion, and Frustration at four intensity levels: very low, low, high, and very high [2]. This formulation is richer than binary engaged-versus-disengaged recognition because it represents several related learner states and preserves intensity. It is also more difficult: the labels are assigned at the clip level, visible expressions may be subtle, backgrounds and illumination vary, and neighboring ordinal levels can be visually similar. A central methodological challenge is the strong class imbalance in the official labels. Prior DAiSEE work has shown that dominant classes can obscure weak minority-class performance and motivate balancing

strategies [3]. A second challenge is ordinality: predicting level 2 rather than level 3 should not be treated as severely as predicting level 0 rather than level 3. Ordinal engagement research consequently supports reporting measures such as quadratic weighted kappa and mean absolute error in addition to exact classification accuracy [4]. These issues make a majority-class reference and macro-averaged metrics essential for credible evaluation. This paper develops a full-frame sparse temporal multitask pipeline and reports on the parts that generated files have already verified. The main contributions are fourfold: first, a validated preprocessing stage that links sixteen ordered full-frame images to the four original labels; second, a shared MobileNetV2-GRU design that provides a reproducible basis for static-versus-temporal and weighted-versus-unweighted comparisons; third, a transparent majority-class baseline showing how ordinary accuracy can hide minority-class failure; and fourth, a clearly defined multimodal journal extension based on calibrated facial, iris, head-motion, and posture cues. The learned-model protocol is specified without presenting numerical claims that the experiment pipeline has not yet produced.

II. RELATED WORK

1. Video-Based and Temporal Engagement Recognition

Engagement varies over time, so video-based recognition is often formulated as a spatiotemporal learning problem. Abedi and Khan combined ResNet frame features with a temporal convolutional network and showed that temporal variation across frames can improve four-level DAiSEE engagement recognition [5]. This design principle is relevant to the present work because a single image may capture a temporary expression or head position. In contrast, an ordered sequence can represent persistence, transitions, and small behavioral changes across the clip. Other studies have explored more computationally intensive combinations of spatial and temporal learning. Mehta et al. used three-dimensional DenseNet and self-attention to model engagement-related information and reported experiments for all four DAiSEE targets [6]. In contrast, Bag of States questioned whether the exact temporal order is always necessary and showed that non-sequential state occurrence can also be informative [7]. This disagreement motivates the static-versus-temporal comparison in the present protocol rather than assuming that a recurrent model must automatically be superior.

2. Multitask and Shared Representation Learning

The four DAiSEE targets describe the same video clip and may share visual evidence. For example, reduced engagement can co-occur with boredom, while confusion and frustration may appear together during a difficult task. Multitask engagement research has used auxiliary objectives to regularize representation learning and reduce overfitting [8]. DenseAttNet also examined the four DAiSEE labels within a common modeling context [6]. Click or tap here to enter text. These studies support investigating whether a shared feature extractor can learn information that is useful across related affective states. The multitask formulation used here is deliberately simple. It does not reproduce the triplet-loss design of [8]; instead, the same MobileNetV2-GRU representation feeds four independent categorical heads. This distinction is important because multitask learning is beneficial only when shared features transfer across tasks without causing negative transfer. For that reason, the framework saves per-target metrics as well as averages, so a high mean score cannot conceal degradation in one of the four outputs.

3. Imbalance-Aware and Ordinal Learning

Class imbalance is a major risk in DAiSEE. Santoni et al. explicitly examined imbalanced engagement labels and employed feature-level processing and resampling to reduce majority-class bias [3]. Synthetic

oversampling is not directly applied to the RGB images in the present pipeline because generated image samples could introduce unrealistic visual content. Instead, the training code supports class weighting at the loss level. The principal weighting option follows the effective-number concept proposed by Cui et al., in which the contribution of additional samples diminishes as the class size increases [9]. The resulting weights are less extreme than raw inverse-frequency weights and can therefore reduce unstable gradients. Because the labels are ordered, the evaluation combines balanced classification measures with QWK and MAE [4]. Together, these choices address two different problems: imbalance determines how strongly each class contributes during learning, whereas ordinal metrics determine how prediction distance is interpreted during evaluation.

III. DATASET AND PREPROCESSING

The project uses the official DAiSEE Train, Validation, and Test label files. The original clips are approximately ten seconds long [2]. Each raw video is matched to its ClipID, and its four labels are read from the corresponding CSV row. Although the physical image folders are organized by Engagement for storage convenience, the unified metadata file provides Engagement, Boredom, Confusion, and Frustration simultaneously. This avoids duplicating the same frame sequence into four separate label structures. Sixteen frame positions are distributed across each usable clip to form a sparse temporal representation. Every selected frame is converted to RGB, resized with aspect-ratio-preserving padding to 160 × 160 pixels, and stored as a JPEG image. The study uses only the full-frame webcam view; no upper-body crop, facial-only crop, or pose-landmark representation is included. Full-frame input retains the learner, visible body region, desk area, and environmental context, but it can also expose the model to background correlations. This trade-off is considered in the limitations.

Table 1. Audited full-frame sequence dataset

Split	Usable clips	Frames per clip	Image size
Train	5,357	16	160 × 160 × 3
Validation	1,429	16	160 × 160 × 3
Test	1,784	16	160 × 160 × 3
Total	8,570	16	160 × 160 × 3

Table 1 summarizes the completed audit. The extraction and integrity checks retained 5,357 Train, 1,429 Validation, and 1,784 Test sequences, for a total of 8,570 complete clips and 137,120 stored images. Figure 1 illustrates one ordered sequence. The learner remains the same throughout the sixteen frames, while small changes in head position, gaze direction, hand location, and posture provide the temporal information that a recurrent model may learn. The repeated appearance of the same person is therefore expected and does not indicate duplicate samples.

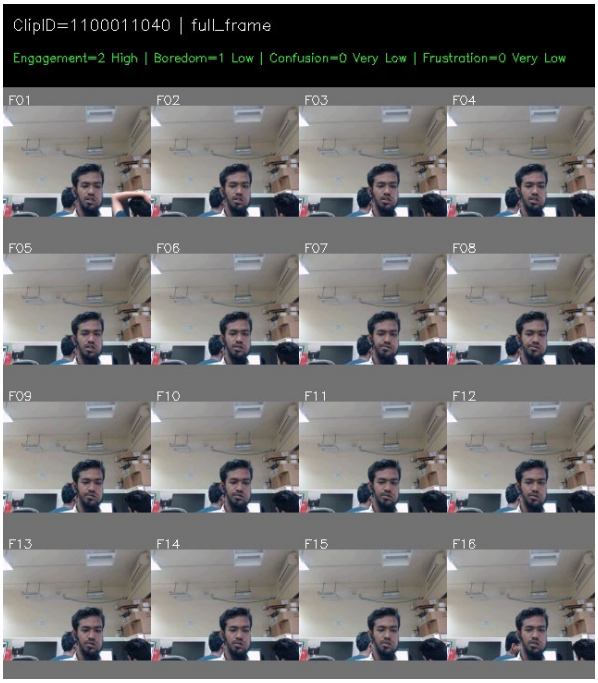

Figure 1. Example ordered sixteen-frame full-frame sequence extracted from one DAiSEE clip.

Table 2. Training-set class distribution for the four affective-state targets

Target	Level 0	Level 1	Level 2	Level 3
Engagement	34	213	2,617	2,493
Boredom	2,433	1,696	1,072	156
Confusion	3,616	1,245	430	66
Frustration	4,182	941	191	43

The distributions in Table 2 and Figure 2 are strongly skewed. Engagement levels 2 and 3 account for 95.39% of the training clips, while levels 0 and 1 together account for only 4.61%. Boredom is less concentrated but still contains only 156 level-3 examples. Confusion level 0 represents 67.50% of the training data, and Frustration level 0 represents 78.07%, whereas their level-3 classes contain only 66 and 43 clips, respectively. These differences explain why a model can obtain apparently high accuracy by repeatedly predicting a dominant class. The imbalance pattern is also target-specific. High-intensity labels dominate engagement, whereas very-low labels dominate Confusion and Frustration. Consequently, a single global balancing decision may not affect all tasks equally. The multitask loader, therefore, computes weights separately for each output head. The Validation and Test partitions are never used to calculate training weights, preserving the separation between model fitting and evaluation.

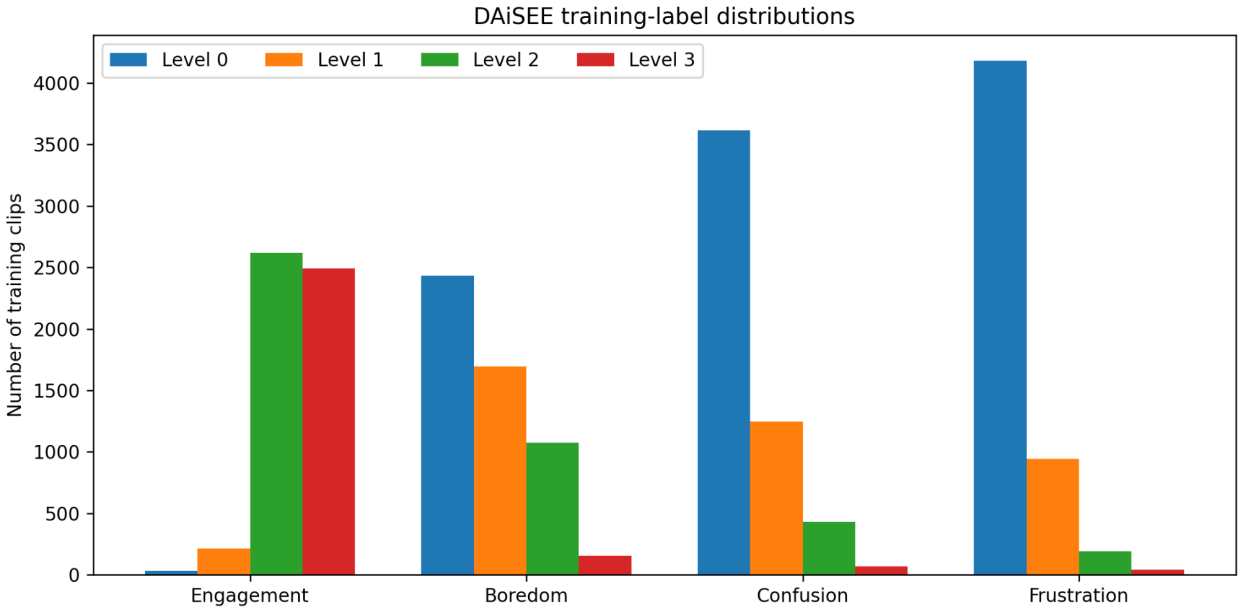

Figure 2. Training-label distributions for Engagement, Boredom, Confusion, and Frustration.

IV. PROPOSED FRAMEWORK

1. Sparse Temporal Input and Frame Encoder

For each clip, the model input is an ordered tensor X = {x1, x2, ..., xT}, where each xt is a 160 × 160 RGB image. Sixteen images are retained in storage, but the training loader can select T = 4, 8, or 16 evenly distributed positions. The primary conference configuration uses T = 8 to balance temporal coverage and computational cost. Each frame is normalized using the selected backbone and then passed through the same TimeDistributed MobileNetV2 encoder. MobileNetV2 is selected because its inverted residual and linear bottleneck designs reduce memory and computational cost for resource-constrained inference [10]. The frame encoder produces one feature vector per sampled image. Sharing the same encoder across time ensures that frame-level representations are comparable and avoids multiplying the number of trainable backbones by the sequence length.

2. Temporal and Multitask Prediction

The final recurrent state is passed through a shared dense representation, followed by four independent softmax layers. Each output contains four probabilities corresponding to levels 0-3 for Engagement, Boredom, Confusion, or Frustration. Task-specific heads allow the shared temporal features to be reused while preserving different decision boundaries for each label. The total multitasking objective is the sum of the four task losses. The ordinary baseline uses sparse categorical cross-entropy without weighting. The imbalance-aware configuration applies effective-number class weights separately to each target [9]. During transfer learning, the MobileNetV2 backbone is first trained with its convolutional layers frozen and can subsequently be fine-tuned at a smaller learning rate. Early stopping, learning-rate reduction, and best-checkpoint saving are used to limit overfitting and preserve the strongest Validation checkpoint.

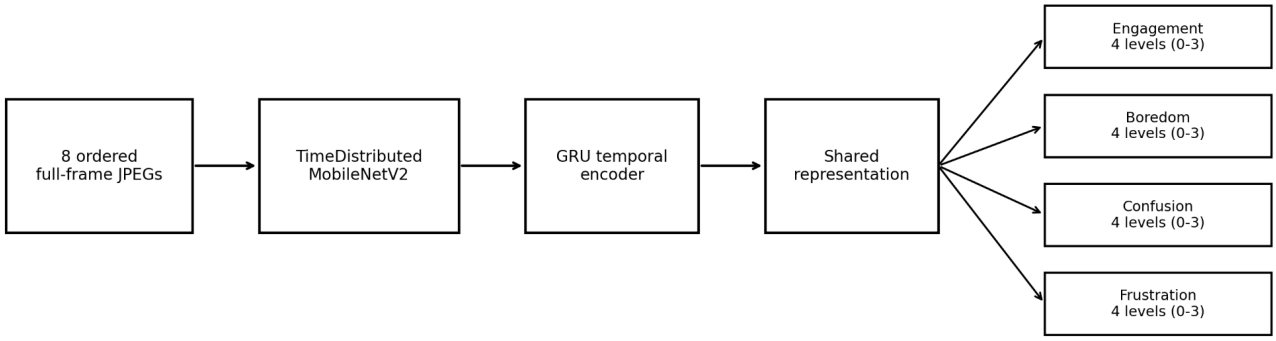

Figure 3. Proposed full-frame sparse temporal multitask architecture.

A static MobileNetV2 model using one central frame is retained as the spatial baseline. The temporal comparison is necessary because a GRU introduces additional parameters and may learn little when consecutive frames are nearly identical. Conversely, subtle transitions that are invisible in one frame may improve the temporal model. The static and temporal configurations, therefore, use the same full-frame preprocessing and output heads so that the principal architectural difference is temporal aggregation. The architecture is also designed for later connection to a rolling webcam buffer. A deployment implementation must reuse the training image size, channel order, normalization, frame-selection rule, and temporal window. Webcam output should initially be interpreted as a qualitative feasibility demonstration, as a live prediction is not quantitative evidence of accuracy without independently labeled participants and a predefined evaluation protocol.

V. EXPERIMENTAL DESIGN AND REPRODUCIBILITY

The official Train split is reserved for optimization, Validation is used for configuration selection, and Test must remain untouched until the final configuration has been locked. Each image associated with a given ClipID remains in the same official split. The supplied experiment design contains four controlled comparisons: a one-frame static MobileNetV2 baseline, an eight-frame MobileNetV2-GRU model without weighting, the same temporal model with effective-number weighting, and a 4/8/16-frame ablation. These comparisons are defined in the reproducibility package, but this paper reports only metrics that have already been generated and verified. For each target, the protocol records accuracy, balanced accuracy, macro precision, macro recall, macro F1-score, quadratic weighted kappa (QWK), mean absolute error (MAE), within-one-level accuracy, classwise recall, and a confusion matrix. Macro F1 and balanced accuracy give rare classes equal importance, whereas QWK and MAE exploit the ordered nature of the four levels. A model should not be selected from accuracy alone, and no Test result should be used to tune frames, weighting, loss, or the temporal encoder. Every run is stored in an independent output directory containing the configuration, random seed, model summary, learning history, checkpoints, predictions, and evaluation files. This separation makes the analysis auditable and prevents Validation and Test outputs from being mixed. The present conference manuscript can therefore be updated directly from generated CSV, JSON, and PNG files while retaining the same definitions and split policy in a later extended study.

VI. DATASET AUDIT AND MAJORITY-CLASS BASELINE RESULTS

1. Dataset Integrity and No-Training Reference

The completed audit verifies all four label ranges, checks the official split counts, and links each usable ClipID to a complete sequence of sixteen full-frame images. The resulting metadata contains 8,570 clips and 137,120 image files. Figure 1 and Figure 2 provide qualitative and quantitative checks on the extracted representation: the sequence figure confirms temporal order within a single clip, while the combined distribution chart reveals that the direction of imbalance differs substantially across targets. The majority class is estimated separately from the Train split and then assigned to every Validation clip. Engagement, therefore, receives a constant level-2 prediction, whereas Boredom, Confusion, and Frustration receive constant level-0 predictions. This simple procedure is deliberately incapable of recognizing minority levels, but it provides an essential lower bound and exposes the extent to which the label distribution can inflate ordinary accuracy. Averaged across the four tasks, the baseline obtains 57.02% accuracy, 25.00% balanced accuracy, 17.79% macro F1, 0.0000 QWK, 0.6149 MAE, and 84.34% within-one-level accuracy. The high within-one-level score occurs because many errors lie near the dominant ordinal level; it must not be interpreted as reliable four-class recognition. Table 3 reports the per-target values used to calculate these averages. The per-target results show two different failure patterns. Engagement appears moderately accurate because levels 2 and 3 dominate, while Confusion and Frustration appear highly accurate because level 0 dominates. In every case, balanced accuracy remains exactly 25%, which is chance-level recall averaged over four classes for a constant predictor. The zero QWK values further confirm that the baseline does not preserve meaningful ordinal agreement.

Table 3. Majority-class baseline on the Validation split

Target	Majority output	Accuracy	Bal. Acc.	Macro F1	MAE	Within ±1
Engagement	High (2)	56.89%	25.00%	18.13%	0.4472	98.39%
Boredom	Very Low (0)	31.21%	25.00%	11.89%	1.2050	57.52%
Confusion	Very Low (0)	65.92%	25.00%	19.87%	0.4647	88.45%
Frustration	Very Low (0)	74.04%	25.00%	21.27%	0.3429	93.00%
Average	**-**	**57.02%**	**25.00%**	**17.79%**	**0.6149**	**84.34%**

The baseline is therefore useful as an evaluation safeguard rather than as a practical classifier. Any learned model should primarily outperform it in macro F1, balanced accuracy, QWK, and minority-class recall. An increase in accuracy without improvement in these measures would indicate that the model has learned the same majority bias rather than the affective distinctions required by the task.

VII. DISCUSSION

The verified baseline demonstrates the central evaluation problem in DAiSEE: a high ordinary accuracy can coexist with no useful recognition of minority levels. Constant prediction of very-low Frustration is correct for 74.04% of Validation clips, but balanced accuracy remains 25%, and QWK remains zero. The same issue appears for Confusion. Consequently, conclusions must be driven by macro F1, balanced accuracy, QWK, MAE, per-class recall, and confusion matrices rather than by a single accuracy value. The sparse temporal

representation offers an explicit efficiency-versus-detail trade-off. Sixteen stored frames cover the entire 10-second clip while reducing storage and preprocessing compared with dense video decoding. The eight-frame main configuration further limits training memory. This is appropriate for rapid experimentation and later webcam deployment, although brief micro-behaviors between sampled positions may be missed. The 4/8/16-frame ablation is therefore necessary before concluding that one temporal density is sufficient. Full-frame input preserves facial appearance, upper-body posture, hand movement, desk interaction, and contextual information. That context may improve recognition, but it also creates a risk of shortcut learning from identity, room, illumination, clothing, or recording background. A strong journal extension should therefore include subject-disjoint evaluation, background sensitivity checks, face-masked or context-masked ablations, and explanation maps that test whether predictions depend on the learner rather than the environment. The current study has four principal limitations. First, DAiSEE labels are assigned at the clip level, so individual frames may not visibly exhibit the annotated state. Second, the rarest classes contain very few training examples, making estimates of classwise performance uncertain. Third, the majority baseline is a lower bound and does not establish the effectiveness of the proposed learned architecture. Fourth, a webcam demonstration without independent labels is qualitative and should not be presented as proof of real-world accuracy. Despite these limitations, the completed audit, figures, metadata, and exact baseline metrics provide a defensible foundation. They define the data that enters the model, expose the imbalance that any method must overcome, and specify which metrics are required for a fair comparison. This evidence is sufficient for a transparent framework-and-baseline study, while learned-model and multimodal claims remain reserved for experiments that can be independently reproduced.

VIII. FUTURE WORK

The next stage of this research will extend the full-frame temporal framework with complementary multimodal behavioral cues extracted from a webcam. MediaPipe-based facial landmarks will be used to derive facial geometry, eye openness, relative iris movement, and head-pose dynamics, including yaw, pitch, and roll. A short participant-specific calibration procedure will be investigated to normalize relative iris displacement and reduce sensitivity to individual differences in camera position and natural gaze behavior. Upper-body and shoulder-pose features may also be incorporated when reliable pose landmarks are available. These modalities will be fused with the visual MobileNetV2-GRU representation using controlled ablation experiments. The extended study will compare full-frame, geometric, and fused configurations under subject-independent evaluation and will examine class-wise performance, ordinal metrics, calibration, failure cases, and computational cost. A separately collected webcam dataset with independently obtained ground-truth annotations will also be required to evaluate real-world generalization. These experiments will determine whether multimodal fusion improves recognition reliability; such improvement is treated as a hypothesis for future evaluation rather than as a result claimed in the present study. Privacy and responsible use will be considered throughout the extension. Whenever possible, processing will be performed locally, and raw webcam video will not be retained after feature extraction. The system will be designed as an assistive analysis tool rather than a mechanism for grading, surveillance, identity recognition, or definitive inference of a learner's internal state.

IX. CONCLUSION

This paper presented a reproducible, full-frame, sparse-temporal, multitask framework and an audited majority-class baseline for recognizing Engagement, Boredom, Confusion, and Frustration on the DAiSEE dataset. The completed preprocessing audit retained 5,357 training, 1,429 validation, and 1,784 test clips, resulting in 8,570 complete sequences and 137,120 stored images. The official dataset partitions were

preserved, and the preprocessing and evaluation procedures were defined to support reproducible temporal experiments. The verified majority-class baseline demonstrates the central difficulty of DAiSEE: conventional accuracy can appear relatively high under strong class imbalance while providing little evidence of minority-class recognition. Therefore, balanced, macro-averaged, ordinal, and class-wise measures are necessary for meaningful evaluation. The reported results establish a transparent lower bound against which the planned MobileNetV2-GRU experiments can be compared. The proposed framework provides a lightweight foundation for temporal multitask learning while avoiding unsupported claims about model performance. Future work will evaluate the trained temporal models and extend the framework to incorporate calibrated facial, relative iris, head-motion, and posture features via multimodal fusion. These extensions will be evaluated through controlled ablations and independently labeled data to determine whether additional behavioral modalities improve generalization and reliability.

Abstract
In software product line engineering (SPLE), a feature model is used to model commonality and variability in a family of products. It is used in all phases of SPLE to define product line scope, requirements, and documentation; to configure products; and to generate product code. Despite the importance of feature models in supporting SPLE, tools for feature model editing and meaningful debugging are lacking, hindering SPLE adoption. We propose a visual feature model editor that provides non-intrusive visual debugging in terms of features and their relations.

Keywords*:* software product line engineering; feature model

I. INTRODUCTION

Software product line engineering (SPLE) is a methodology for developing a family of software products within a particular domain by systematically reusing shared code to improve product quality and reduce development time and cost [1], [2]. A feature is a characteristic, quality, or functionality of a product. Thus, it is more natural to describe a product in terms of its features than in terms of lower-level implementation and design. A feature model describes a product family in terms of common and variant features, as well as any relationships or constraints among them. A feature model should represent all possible products within the product family. Feature models are used in all phases of SPLE: to define product line scope, to create requirements and documentation, to drive or guide the product configuration process, and, in some cases, to generate product code. Because feature models are described using a formal language, automated analysis can be performed to determine the number of possible products or to detect model inconsistency, dead features, or false optional features [3]. A feature model is *inconsistent* when multiple constraints in the model are violated simultaneously in such a way that no product can be represented. When a model becomes inconsistent, the user must debug it to find and correct errors. Current tools for feature models offer little or no support for debugging. They provide little or no explanation of the causes of inconsistency or of any changes that could be made to resolve the inconsistency [3]. These tools can indicate that the model is inconsistent, but the user must find the problem and solution, which can be tedious in a large feature model. It would be easy to blame a problem on the recently added constraint that triggered the inconsistency. Still, it may be that the newly added constraint is correct and has exposed previously unnoticed bugs. Determining this would require the user to trace all the constraints involved in the problem back to the root feature. In a large feature model consisting of hundreds or thousands of features, this would be a daunting task. It would be better to point out to the user, in a meaningful way, the constraints that contribute to the inconsistency [3]. Showing exactly the constraints involved in the conflict would allow the user to more easily find and correct the bug. Tool support is critical to the adoption of SPLE. Hence, we propose a visual editor to support feature model editing and debugging better. The tool detects all errors that cause a model to be inconsistent and provides the user with hints about what the problems are, where they are, and possible fixes. It does all of this visually within the feature model editor in a non-intrusive manner, similar to how modern IDEs hint at errors

and solutions without distracting the user. Our approach affects anyone who uses feature models to develop product-line software.

II. BACKGROUND

1. Feature Model

A *feature* is a product's characteristic, quality, or functionality. Features are organized in a feature model as a tree-like structure. The relationships between parents and children, called *structural constraints*, define commonality and variability of the parent feature and ultimately the variability of the product line. The structural constraints are:

- *Mandatory*: If the parent is in a product, then the child is also in the product and vice versa.
- *Optional*: The child may or may not be in a product regardless of whether the parent is or is not in the product.
- *Alternative*: If the parent is in a product, then exactly one of its children is also in the product.
- *Or*: If the parent is in a product, then at least one of its children is also in the product.

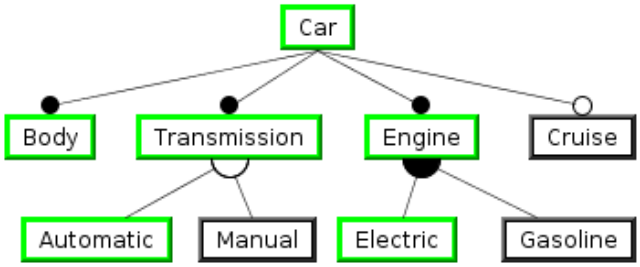

Figure 1. A feature model example of a family of cars. Features highlighted in green indicate one possible car.

When the *parent-child constraints* are insufficient, integrity constraints are used to define relationships between features that are not parent-child. They are:

- *Implies*: if *a* implies *b*, then whenever *a* is in a product, *b* must also be in the product.
- *Excludes*: if *a* and *b* exclude one another, then they can never exist together in any product.

Figure 1 is a simple feature model of a family of cars rendered in our editor. A *Mandatory* constraint is denoted by an edge with a filled small circle—for example, the edge between car and body. An *Optional* constraint is rendered as an edge with an empty circle. *Alternative* and *Or* constraints are rendered as edges with a hollow half circle and edges with a filled half circle, respectively. *Implies* constraints are rendered as unidirectional dashed edges, while *Excludes* constraints are represented as bidirectional dashed edges, as shown in Figure 2. According to the model in Figure 1, a car must have a body, an automatic or manual transmission, an engine that can be electric, gasoline, or both, and may or may not have cruise control.

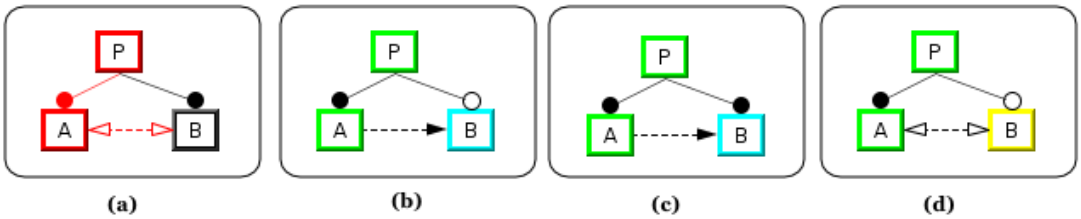

Figure 2. Problems and warnings in the feature model: (a) an inconsistent model, (b) B is a false optional feature, (c) the implication of B is redundant, (d) B is a dead feature.

Figure 2 illustrates how different problems with feature models are displayed in the editor, which currently uses color to highlight them. Figure 2(a) depicts an "inconsistent model" because *P* mandates both *A* and *B,* but *A* and *B* exclude one another; thus, no product can be derived. Figure 2(b) depicts a "*false optional feature*" warning, which is given when an *Implies* constraint effectively mandates a feature that the model labels optional. An "*implies redundancy*" warning occurs when an *Implies* constraint is not needed due to other constraints, as shown in Figure 2(c). Finally, Figure 2(d) shows a "*dead feature*", where another constraint excludes an optional feature. Although the latter three warnings do not create an inconsistent model, they may imply bad design, and thus the user should be warned.

2. Current Support for Editing and Debugging

Currently, there are fewer than a dozen feature model editors, each with a different graphical interface. Most editors provide an interface that allows users to create feature diagrams visually, with features organized into a tree-structured hierarchy. Others provide flat-tree editing, which is less useful for visualizing the feature model but still superior to textual editing. Most of these tools can detect when a model is inconsistent, and some can highlight which integrity constraints are violated [4], [5]. Most editors can detect dead features and false optional features, which are usually easy to spot and can be corrected by simply highlighting the problematic features [4]. A more difficult debugging task is correcting an inconsistent model, for which current tools provide little or no support. Current tools use propositional logic, description logic, and ad hoc methods [6], including XML Schema for validating feature models [7]. To determine if a feature model is consistent or not, it is converted to a propositional formula [4], [8], [9] or description logic [10], [11] and fed to a SAT solver or a description logic reasoner. If it is not satisfiable, then the model is inconsistent.

In general, the error reporting interfaces of current tools are weak. For example, when a new constraint is added to FeatureIDE [4] that makes the feature model inconsistent, the editor will highlight the newly added rule. However, the conflicting constraints are not highlighted, and any highlighting of previously added inconsistent constraints will be lost. Description logic systems can generate compiler-like textual error messages. Still, these messages are expressed in description logic rather than in the feature model diagram the user has been working with [11].

III. APPROACH AND CONTRIBUTION

Our approach uses propositional logic but leverages the concept of minimum unsatisfiable cores [12] and the QuickExplain algorithm [13] to identify conflicting relations and features, and then proposes possible solutions.

We adopt a similar approach to that of the Eclipse plugin dependency management system [14] for detecting errors in plugin dependencies and providing meaningful explanations to the user. This system is scalable even when faced with 10000 installable units [14]. The dependency management technology in Eclipse is also

used in Maven3 and the repository manager Nexus [14]. In addition, a feature model is a relatively easy problem for a SAT solver [8].

1. Feature Model to CNF Formula

To determine if a feature model is consistent or not, we convert a feature model to a CNF boolean formula, for which an off-the-shelf SAT solver can be used to determine the formula's satisfiability. To generate the formula, a depth-first traversal is performed. For each feature and its children, CNF clauses are generated to encode the feature's constraints and its integrity constraints. (and) Boolean operators join together all the clauses. The root feature is encoded as a single literal clause. These are the mappings of features and their constraints to CNF clauses:

- r is root: (r)
- c **mandatory** child of p: $(\neg p \vee c) \wedge (\neg c \vee p)$
- c **optional** child of p: $(\neg c \vee p)$
- $c_1, c_2, \cdots, c_n$ **or** children of p:
  $(\neg p \vee c_1 \vee c_2 \vee \cdots \vee c_n) \wedge (\neg c_1 \vee p) \wedge (\neg c_2 \vee p) \wedge \cdots \wedge (\neg c_n \vee p)$
- $c_1, c_2, \cdots, c_n$ **alternative** children of p:
  $(c_1 \vee c_2 \vee \cdots c_n \vee \neg p) \wedge (\neg c_1 \vee \neg c_2) \wedge \cdots \wedge (\neg c_1 \vee \neg c_n) \wedge (\neg c_1 \vee p) \wedge (\neg c_2 \vee \neg c_3) \wedge \cdots \wedge$
  $(\neg c_2 \vee \neg c_n) \wedge (\neg c_2 \vee p) \wedge (\neg c_{n-1} \vee \neg c_n) \wedge (\neg c_{n-1} \vee p) \wedge (\neg c_n \vee c)$
- a **implies** b: $(\neg a \vee b)$
- a **excludes** b: $(\neg a \vee \neg b)$

If a SAT solver evaluates the CNF formula to be satisfied, then the model is consistent, and inconsistent otherwise. Editors that use propositional formulas for inconsistency checking stop their debugging support here, leaving the user to identify errors and find solutions. Although our approach uses propositional formulas, we are interested in identifying the clauses responsible for the inconsistency, which is where we can provide visual debugging.

2. Supporting Debugging

Error explanation is key in helping users to understand and fix errors. To support error explanation, we need to find the minimum number of violated constraints [3] and the least number of modifications needed to correct the violation [14]. This is a problem of finding the minimum unsatisfiable cores (MUS) [12], the smallest set of clauses that makes the formula unsatisfiable, such that the removal of any clause from the set causes the formula to be satisfiable.

The MUS yields one error that contributes to a feature model's inconsistency. But it is not useful to indicate only one error when there are many. Rather, the user should be able to review all errors to plan which to fix and in what order. To detect all errors in the model, we need to remove one clause representing an integrity constraint that caused the conflict, without changing the feature model tree, and then find the next MUS to determine the next conflict. We repeat this until the formula is satisfiable, by which point all errors have been detected. This entire process is described in Algorithm 1.

1	**input** : *model*: feature model
2	**output**: *conflicts*: conflicts
3	*formula* ← toCNF(*model*);
4	**while** ¬ isSatisfiable(*formula*) do
5	

```
    mus ← getMUS(formula);
    foreach clause ∈ mus do
      conflicts ← conflicts + clause;
      if isExcludesRelation(clause) then
        formula ← formula − clause;
      end
    end
end
return conflicts;
```

Algorithm 1: Extracting conflicts in a model

Once the editor has collected all possible errors, the conflict visualization conveys as much information as possible by tracing all conflicting constraints back to the root feature and indicating which constraints and features are involved in the conflict. Any constraint in this trace is a solution; the conflict can be removed by simply removing or changing conflicting constraints. If a user adds a constraint and causes the model to be inconsistent, but the constraint is correct, then there must have been a bug in the model before adding the constraint. An example of a bug is an optional constraint created as a mandatory constraint. The constraints trace lets the user visually inspect the constraints involved in the conflict to determine which is the bug.

Figure 3 shows two errors and three warnings in the model within our editor. Errors are highlighted in red. One error is *A-B-G-F-C-A*, and another is A-H-J-K-I-H. Excluded constraints cause both, but any highlighted constraint is a possible bug and a possible solution. The warnings include *Untitled*, *D*, and *L*. *Untitled* is a dead feature because it has no parent and would never be in any product. *D* is excluded by *F,* and so *D* could never be any product. The *Implies* constraint between *G* and *L* is not needed because *L* is included in all products.

In the first error, changing any of the *Mandatory* constraints highlighted to an *Optional* constraint would remove the first error. Alternatively, the *Excludes* constraint between *G* and *F* could be removed. Removing the second error follows the same idea. Only someone with domain knowledge can decide what action to take, just as fixing a program bug requires semantic knowledge of the problem.

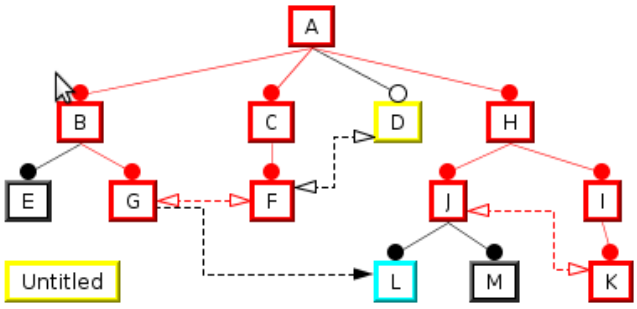

Figure 3. Editor: highlighting errors and warnings in the model.

IV. IMPLEMENTATION

The visualization of the feature model and constraints is implemented using NetBeans Visual Library [15]. The Visual Library provides basic widgets and edges for rendering an underlying model. In our case, we customized the node widgets, anchors, anchor shapes, and edge connections. The underlying models of our data structure are both a graph and a tree. A graph models the entire feature model, including constraints, while the tree data structure models the parent- child hierarchy of features. We take this approach because, in the future, we want to provide a tree rendering of the model as an alternative editing mode and for product configuration. The graph model allows greater flexibility in labeling every edge. The SAT solver we use is Sat4j [16], an open-source library that enables Java programmers to access cross-platform SAT solvers. It is used by many projects, such as FeatureIDE [4] and in Eclipse's plugin management system [14].

V. CONCLUSIONS AND FUTURE WORK

We have presented a visual feature model editor that non-intrusively hints at errors and provides a natural debugging and editing workflow. It uses the concept of minimal unsatisfiable cores to identify the constraints and features involved in a model's inconsistency and to determine the minimal change needed to fix errors visually. Other tools only report that the feature model is inconsistent. They do not provide help on how to fix the model, do not report all the errors a model may have, nor do they help the user spot bugs far from the constraints that have been causing the issue of inconsistency. Improved tool support for feature model editing and debugging will help domain and application engineers create and use feature models, thereby encouraging the adoption of feature models and SPLE as a whole.

We plan to evaluate our prototype for scalability and usability on realistic feature models; extend the tool to support cardinality-based feature model editing and debugging, product configuration, and feature model evolution; and support collaborative editing. Visual editing of complex Boolean constraints, other than implies and excludes, is in progress.

Abstract
This study presents an Issue Analyzer for centralized analysis of mobile errors and crash logs in large software organizations. The system maps heterogeneous records to a canonical schema, performs build-aware symbolication and normalization, represents each issue through message, stack-trace, and contextual views, and groups related records by a mathematically defined composite similarity score. The reference implementation uses a Sentence-BERT message encoder, cosine similarity, weighted stack-frame overlap, normalized longest-common-subsequence similarity, and a gradient-boosted routing model. Candidate teams are returned with confidence scores, supporting evidence, and an option to abstain. To reduce historical routing bias, training labels are based on the final resolving team rather than the initial assignee, while reassignment histories and human corrections are retained as audit signals. Offline routing results are complemented by a controlled-replay benchmark and a limited, non-randomized shadow-mode workflow evaluation; neither is treated as definitive production evidence. The approach positions issue analysis as an explainable, human-in-the-loop decision-support capability accessible through a Slack-like conversational interface.

Keywords: mobile application, crash logs, log normalization, crash clustering, bug triage, team routing, explainability, conversational analytics.

I.INTRODUCTION

Mobile applications are primary service channels for e-commerce, payment, logistics, communication, and content platforms. A recurring crash can interrupt a transaction, increase support effort, and weaken confidence in releases. In large engineering organizations, however, crash and error records are distributed across monitoring tools, applications, versions, devices, ticket systems, and internal data stores. Similar failures are reported repeatedly with different variable values or partially different traces, and the first team assignment often depends on individual experience. The proposed Issue Analyzer converts these fragmented records into normalized issue families and evidence-backed routing recommendations. Unlike classification frameworks that treat a predicted label as the final output, the approach is designed around operational use: users can inspect similar historical cases, understand why a team was suggested, correct the result, and query release-level patterns through a Slack-like interface. This design extends access beyond developers to stakeholders in quality, product, and operations. The main contributions are fourfold. First, the study defines a build-aware normalization process that uses Android R8/ProGuard mapping files and iOS symbol files before frame extraction. Second, it specifies

the exact representations, distance measures, and mathematical formulation used for multi-view issue similarity. Third, it introduces routing safeguards that learn from the final resolving team, audit reassignment paths, and abstain when evidence is weak or conflicting. Fourth, it separates offline model evaluation from production workflow and scalability validation, avoiding unsupported production claims.

II.RELATED WORK

Bug-triage research has shown that historical assignments can support semi-automated fixer recommendation [1], while bug-tossing graphs and data-reduction methods can improve routing quality and reduce noisy training evidence [2], [3]. Studies on report quality, duplicate detection, and mobile bug-report completion further show that text alone is insufficient when technical context is missing or inconsistent [4]–[7]. Crash bucketing and localization methods therefore exploit stack structure and execution context [8]–[12]. The log-analysis literature provides complementary methods for template extraction, clustering, anomaly detection, and evaluation [13]–[20]. Sentence-BERT offers compact semantic representations for short issue messages [21], and gradient-boosted trees provide a practical supervised model for mixed numerical and categorical routing features [22]. The present work combines these ideas in a workflow-centered mobile issue-analysis architecture with explicit human feedback and conversational access.

III.SYSTEM ARCHITECTURE AND METHOD

1. Architecture and Canonical Issue Schema

Historical backfill and streaming events are validated and mapped to a canonical record that contains the raw and normalized message, exception class, original and symbolicated frames, application and build identifiers, platform, device family, operating system version, timestamp, release window, feature/module hints, source link, and data quality flags. The same schema is used for training, cluster construction, online scoring, and audit. Figure 1 shows the end-to-end architecture.

2. Build-Aware Normalization and Ambiguous Traces

Normalization first replaces unstable values with typed placeholders such as <UUID>, <HEX>, <INT>, <URL>, <PATH>, <TIME>, and <TOKEN>. The system retains both the raw text and the normalized template so that information is not irreversibly lost. Token replacement is applied only after source-specific parsing; for example, line numbers and addresses are masked, while exception classes, method names, package paths, and stable error codes are preserved.

Table 1. Core Pipeline Layers And Outputs

Layer	Main operation	Output
Ingestion	Validate backfill and streaming mobile issue events	Canonical raw events
Normalization	Symbolicate, parse, mask unstable tokens, and rank frames	Stable issue representation
Grouping	Compute multi-view similarity and update clusters	Issue families and profiles

Layer	Main operation	Output
Routing	Rank candidate teams, score confidence, and abstain	Explainable team suggestions
Access/feedback	Answer grounded queries and record corrections	Operational insight and audit signals

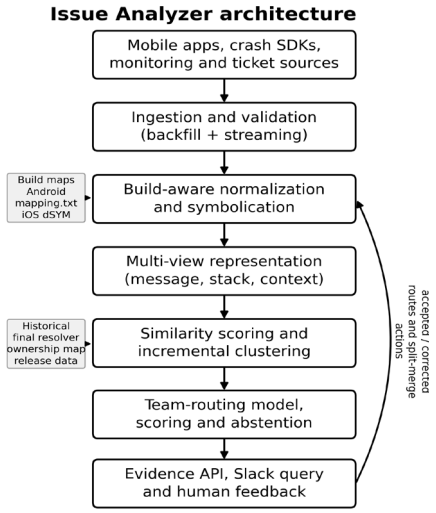

Figure 1. Build-aware Issue Analyzer architecture and human-feedback loop.

Frame extraction is build-aware. For Android, the application identifier, version code, and build identifier select the corresponding R8/ProGuard mapping.txt file; retracing is completed before package parsing and library filtering. For iOS, the bundle identifier, build number, architecture, and binary UUID select the matching dSYM and, where applicable, BCSymbolMap. Each frame stores the raw symbol, mapped symbol, mapping-file version, application-versus-library flag, and symbolication status. Missing or conflicting mappings are not silently accepted: the record is marked as partially symbolicated and its stack contribution is down-weighted.

Mobile traces can remain ambiguous due to obfuscation, asynchronous callbacks, shared framework frames, truncation, or different execution paths that lead to the same exception. The analyzer, therefore, does not use a single trace hash as a universal identifier. It separates records by application/build/ABI when necessary, uses only the top K application frames for ordered comparison, and avoids deterministic merging when symbolication confidence is low. In such cases, message semantics, exception class, release context, and module evidence receive greater weight; low-margin cases are sent for manual split-or-merge review.

3. Similarity Representation and Grouping

The reference configuration uses the 384-dimensional all-MiniLM-L6-v2 Sentence-BERT encoder for normalized messages [21]. Embeddings are L2-normalized and compared by cosine similarity. A character 3–

5-gram TF–IDF vector is retained as a lexical safeguard for short error templates and product-specific codes. The message score is

$$s_msg(i,j) = \rho\, cos(e_i,e_j) + (1-\rho)\, cos(v_i,v_j), \quad 0 \le \rho \le 1 \quad (1)$$

where e is the Sentence-BERT vector and v is the TF–IDF vector. Stack similarity combines weighted frame overlap and order. Let F_i be the ordered top-K application frames, and let ak = 1/log2 (k+1) be the rank weight. The stack score is

$$s_stack(i,j) = \alpha\, J_w(F_i,F_j) + (1-\alpha)\, LCS(F_i,F_j)/max(|F_i|,|F_j|) \quad (2)$$

J_w is weighted Jaccard similarity, and LCS is the longest common subsequence. Context similarity compares application, platform, build, version, environment, device family, and release window. Exact categorical matches are combined with an exponential time-decay kernel:

$$s_ctx(i,j) = [\Sigma_k\, q_k\, I(x_{ik}=x_{jk}) + q_t\, exp(-|t_i-t_j|/h)] / [\Sigma_k\, q_k + q_t] \quad (3)$$

The final issue-pair score is a convex combination of message, stack, context, and module evidence:

$$S(i,j) = w_m\, s_{msg} + w_s\, s_{stack} + w_c\, s_{ctx} + w_o\, s_{owner}, \quad \Sigma_w=1,\ w\ge 0 \quad (4)$$

The weights and merge threshold are selected only on validation data by maximizing pairwise F1 subject to a maximum acceptable over-merge rate. The selected validation values were w_m=0.30, w_s=0.40, w_c=0.15, w_o=0.15, ρ=0.75, α=0.60, and τ_{merge}=0.82. A record joins the highest-scoring compatible cluster only when $S \ge \tau_{merge}$ and no hard conflict exists in application, build, or exception family; otherwise, a new cluster is opened. Manual split and merge decisions are versioned as feedback.

4. Team Routing, Explainability, and Bias Control

Routing is formulated as a ranked team recommendation rather than a forced assignment. The supervised component is an XGBoost multiclass classifier [22] that uses cluster-level features: top-message and stack similarities to resolved clusters, exception and module indicators, application/build/platform metadata, release-change overlap, frequency trend, and ownership-map compatibility. Model confidence is reported without post-hoc calibration; the abstention thresholds are applied directly to the model output. A final score combines the model probability with independent historical, ownership-map, and release evidence:

$$R(t|c) = \eta_p\, p_{XGB}(t|c) + \eta_h\, h(t|c) + \eta_m\, m(t|c) + \eta_r\, r(t|c) - \lambda\, b(t|c) \quad (5)$$

Here, h is similarity-weighted evidence from previously resolved clusters, m is module-map compatibility, r is release-change evidence, and b is a misrouting penalty derived from reassignment history. The interface returns the top-k teams, confidence, supporting traces/tickets, and the contribution of each evidence group. The system abstains when the top score is below δ, or the margin between the first two teams is below μ; the abstention thresholds were δ = 0.62 and μ = 0.10.

Table 2. Reference Representations And Similarity Functions

Signal	Representation	Comparison
Message	all-MiniLM-L6-v2 (384-D) + char 3–5-gram TF–IDF	Cosine mixture, Eq. (1)
Stack	Exception + ordered top-K symbolicated application frames	Weighted Jaccard + normalized LCS, Eq. (2)
Context	App, platform, build, version, device, release, and time	Weighted match + time kernel, Eq. (3)
Ownership	Versioned module-to-team map and resolved-ticket evidence	Probabilistic/binary compatibility

The abstention thresholds were selected empirically rather than by search over a reserved partition. During development, routing suggestions were reviewed by domain experts and marked correct or incorrect; the resulting outcomes were used to identify a confidence level at which the proportion of incorrect routed suggestions became acceptable to the operating teams, and a top-1/top-2 margin below which reviewers frequently disagreed with the ranking. The values $\delta = 0.62$ and $\mu = 0.10$ reflect the chosen operating point. Because the same judgments informed both the choice of thresholds and the observed behavior at those thresholds, the operating point is fitted to the observed data, and its selective risk on unseen data may be higher than observed. Five design measures are intended to limit historical assignment bias. Training labels use the final resolving team, not the first assignee. Tickets that were repeatedly bounced, reopened, or closed without a verified owner are excluded or given lower weight. Reassignment paths are monitored as a separate error signal rather than treated as ground truth. Ownership maps are versioned and applied based on the issue date to prevent present-day mappings from leaking into older records. Finally, per-team precision, correction rate, and confidence behavior are audited; any conflict between historical evidence and the current ownership map triggers abstention or human review rather than automatic routing. The Slack-like layer interprets a question, converts it into a restricted query over canonical issue tables and cluster profiles, and summarizes the returned evidence. The language model does not independently create ownership or diagnostic facts. Each response includes the query scope, time window, affected versions, cluster identifiers, confidence, and links to source records. Role-based views allow developers to inspect raw traces while product and operations users receive concise impact summaries. Accepted and corrected routes, as well as manual cluster split/merge actions, are written back to the feedback store.

IV.EVALUATION METHODOLOGY

Table 3 reports measurements collected during the iterative development of the routing component on operational data rather than results from a held-out benchmark evaluation. The working corpus contained 48,736 issue records grouped into 2,614 issue families, collected from January to December 2025, across 10 candidate software teams. The system operated continuously over this period, and issue records were added to the training data as they were resolved, so each configuration was trained on all records resolved up to the point of its introduction. Each configuration was assessed by domain experts from the engineering organization, who reviewed the routing suggestions produced by that configuration and marked each as correct or incorrect. Precision, recall, accuracy, and F1 in Table 3 are computed from these expert judgments. This procedure reflects

how the system was actually developed and evaluated in its operating environment; its limitations are stated in Section VI. Experiments were run on a 32-core AMD EPYC 7543P CPU, an NVIDIA A10 GPU with 24 GB of memory, and 128 GB of RAM, using Ubuntu 22.04, Python 3.11, sentence-transformers 2.6.1, XGBoost 2.0.3, and FAISS 1.8.0. Grouping behavior is qualitatively characterized in this study. Pairwise precision, recall, F1, cluster purity, and over- and under-merge rates require an independently labeled reference partition and are identified as required instrumentation in Section VI. Routing is assessed using precision, recall, accuracy, and F1 computed from developer judgments, along with the observed correction rate. Expected calibration error, top-3 accuracy, per-team breakdowns, abstention coverage, and selective risk require a reserved evaluation partition with independently assigned labels and are not reported here; they are identified as required instrumentation in Section VI. The development trace in Table 3 shows the order in which message, stack, and ownership evidence were introduced. Still, it is not a controlled ablation: the training corpus grew as issues were resolved, so later configurations were trained on more data and on additional evidence sources. The contributions of the individual signals cannot be separated from the effect of the additional training data. A controlled ablation, in which each signal is removed from the full configuration while the training corpus is held fixed, has not been performed and is identified as required work in Section VI. Workflow validation requires time-to-first-owner, number of reassignments, analyst effort, and user-rated explanation usefulness; these outcomes cannot be inferred from offline classification scores.

1. Scalability and Workflow Validation

A controlled replay benchmark was conducted with events that preserved the observed distributions of message length, stack depth, build, platform, and cluster size. Each test used a five-minute warm-up and three measured repetitions; Table 4 reports the median p50, p95, and p99 values across repetitions. A two-week shadow-mode evaluation was also used to compare routing workflow indicators without automatically changing ticket ownership. The shadow-mode comparison was observational rather than randomized and therefore supports only descriptive comparison. These results characterize the stated test environment and should not be interpreted as a guaranteed production service-level agreement. Each iteration adds one source of evidence to the preceding configuration, and the routing model is XGBoost throughout. Four properties of this assessment should be noted. First, the training corpus grew continuously as issues were resolved, so later configurations were trained on more data than earlier ones, and the effect of the added evidence cannot be separated from that of the added data. Second, the configurations were reviewed sequentially during development rather than simultaneously on a fixed record set, so the issues reviewed differ across rows, and the values are not paired measurements. Third, reviewers were not blind to the routing suggestion when making their judgment. Fourth, no held-out partition was reserved. We therefore read Table 3 as a record of the system's development trajectory rather than as a controlled comparison between configurations.

Table 3. High-Load And Workflow Measurements

Iteration	**Message representation**	**Stack evidence**	**Ownership evidence**	**Precision**	**Recall**	**Acc.**	**F1**
1	Char 3–5-gram TF–IDF over crash title and error message	-	-	0.55	0.48	0.52	0.51

Iteration	Message representation	Stack evidence	Ownership evidence	Precision	Recall	Acc.	F1
2	+ Sentence-BERT over the same fields	-	-	0.67	0.71	0.69	0.69
3	as Iteration 2	Weighted frame overlap + normalized LCS	-	0.72	0.68	0.70	0.70
4	as Iteration 3	as Iteration 3	Versioned ownership-map compatibility	0.86	0.89	0.87	0.87

Across the four configurations in Table 3, expert-reviewed routing precision rose from 0.55 to 0.86, recall from 0.48 to 0.89, and F1 from 0.51 to 0.87. The largest single increments followed the introduction of the Sentence-BERT message encoder and the ownership-map evidence. Because the configurations were reviewed sequentially on different issues, the training corpus grew over the same period, and no held-out partition was used, these values reflect the system's development trajectory rather than its expected accuracy on unseen data. They cannot be compared directly with published benchmark figures. In the controlled replay, the system sustained 165 events/s, with p95 ingestion and incremental-cluster latencies of 34 ms and 57 ms, respectively; the p95 natural-language query response time was 910 ms. During the two-week shadow-mode period, median time-to-first-owner was 17 minutes, compared with 41 minutes in the preceding baseline window, and the mean number of reassignments per issue was 0.6, compared with 1.6; users corrected 12.8% of routing suggestions. Because the shadow-mode evaluation was observational rather than randomized and ran concurrently with ordinary release activity, these differences are reported as observed associations rather than as causal effects of the Issue Analyzer. These measurements provide initial evidence of workflow and scalability, but they do not establish long-term production performance across every release, traffic pattern, or organizational structure.

Table 4. High-Load And Workflow Measurements

Measurement	Reporting unit	Result
Daily ingested volume and sustained throughput	events/day; events/s	96,000/day; 165/s sustained
Ingestion-to-canonical-record latency	p50/p95/p99 ms	11/34/68 ms
Incremental cluster update latency	p50/p95/p99 ms/event	18/57/109 ms
Full cluster compilation time	s per 10k/100k events	38/412 s
Natural-language query response time	p50/p95/p99 ms	390/910/1,380 ms
Embedding and index footprint	CPU %, RAM GB, GPU GB, index GB	36%; 10.8 GB; 4.7 GB; 0.76 GB

Measurement	Reporting unit	Result
Workflow indicators (shadow period vs. baseline window, non-randomized)	time-to-owner; reassignments; correction rate	41 vs. 17 min; 1.6 vs. 0.6; 12.8%

Qualitatively, the architecture is designed to address a common usability gap. Stakeholders can work with issue-family summaries instead of isolated logs, inspect release-level growth, and receive ranked teams with evidence rather than an unexplained label. Build-aware symbolication and abstention are particularly important in mobile settings because variable replacement alone cannot resolve ambiguous or partially mapped traces.

V.DISCUSSION

The Issue Analyzer extends classical bug triage by combining technical similarity with the operational path from evidence to action. The classifier is not treated as an end state: users see comparable clusters, current ownership metadata, confidence scores, alternative teams, and the reason for abstention. Corrections become versioned signals for later model and rule updates. We argue that this human-in-the-loop structure is preferable to a black-box auto-assignment mechanism, especially during incidents or organizational changes; this is a design position rather than an empirically tested comparison. The proposed safeguards are intended to reduce, but cannot eliminate, historical bias; their actual effect has not been quantified in this study. Even the final resolver may reflect organizational constraints rather than ideal ownership, and teams with more tickets may dominate the training data. Regular label audits, class-balanced learning, per-team confidence auditing, recency weighting, and current ownership-map checks are therefore required. Similarly, multi-view similarity cannot guarantee root-cause equivalence. Low-confidence symbolication, shared library frames, and asynchronous execution can still produce over-merging or under-merging; split/merge review and uncertainty reporting remain necessary. The main limitation is external validity. The corpus represents one organization and one annual period, the load results come from a controlled replay rather than unrestricted production traffic, and the workflow comparison was a two-week shadow-mode evaluation rather than a randomized field experiment. Future work should repeat the evaluation across applications and organizations, compare routing against initial-assignee and current-ownership baselines, report ablations and confidence intervals, and conduct a longer controlled pilot using time-to-owner, reassignment, and user-effort outcomes. The measurements in this study were collected as part of the system's ongoing operation rather than as a reproducible experimental artifact. Engineers reviewed routing suggestions during normal work, and the resulting correct/incorrect judgments were recorded as operational indicators; the intermediate evaluation records from that period were not retained for later re-analysis. The system itself remains operational, but the specific record sets underlying Tables 3 and 4 cannot be reconstructed. Several evaluations described in Section IV are therefore not reported here. Specifically, we do not report a controlled ablation with a fixed training corpus, a comparison against non-learned routing baselines such as historical-majority or ownership-map assignment, pairwise grouping metrics against an independently labeled reference, per-team performance breakdowns, expected calibration error, abstention coverage, and selective risk, confidence intervals, or a sensitivity analysis over δ and μ. Each of these requires measurement on a reserved partition with independently assigned labels, which the available records do not support. The consequence is that the quantitative values in this paper should be read as operational observations from a single organization over a single 12-month period, not as benchmark results. They indicate the trajectory the system followed during development and the workflow indicators observed during the shadow period. Still, they do not establish how the approach would perform on unseen data or how it compares with alternative designs. Because the system remains operational, a prospective evaluation on a chronologically reserved partition, with labels assigned independently of the system's output, is feasible and is the primary direction for future work.

VI.CONCLUSION

This study presented a centralized Issue Analyzer for mobile crash and error records. The revised method specifies build-aware symbolication, typed normalization, exact multi-view similarity equations, a Sentence-BERT message representation, stack-aware comparison, XGBoost-based team ranking, abstention, historical-bias controls, grounded Slack-style access, and a human-feedback loop. These elements are intended to make the approach operationally useful without turning routing into an unsupported automatic decision. The available development measurements and the controlled-load benchmark indicate that the architecture is technically feasible in the evaluated setting, and the shadow-mode indicators are favorable. Because that comparison was not randomized and the underlying evaluation records were not retained for re-analysis, these observations do not establish that the Issue Analyzer caused the observed workflow differences. They do not, however, constitute a universal guarantee of production scalability. Broader longitudinal and multi-organization validation is required before the reported thresholds and capacity values can be generalized. Within these limits, the Issue Analyzer provides a reproducible quality-intelligence layer for centralized mobile issue analysis and evidence-based team routing.

Abstract
The application of Design Science Research (DSR) in resource-constrained environments presents unique challenges distinct from those in well-resourced research settings. This paper presents a methodological framework for conducting DSR in developing-economy contexts, illustrated through the development and evaluation of Lumikiza, a digital advisory-matching platform for Zambian Small and Medium Enterprises (SMEs). Using a sequential exploratory mixed-methods design, we show how the three DSR cycles (relevance, design, and rigor) were operationalized in a context marked by limited digital infrastructure, trust deficits, and regulatory complexity. Ten purposively sampled advisory experts (semi-structured interviews) informed the design of a transparent Weighted Multi-Criteria Decision Analysis (MCDA) matching engine, which was then evaluated with 200 SME founders using an integrated Task-Technology Fit (TTF), UTAUT, and DeLone and McLean instrument (Cronbach's α = 0.69–0.82 across constructs). The overall evaluation model was not statistically significant (R^2 = 0.066, F = 1.95, p = 0.064); within this weak model, Information Quality was the only significant predictor of Net Benefits (β = 0.167, p = 0.038, f^2 = 0.071). We interpret this as a preliminary, context-specific signal which is a tentative "Utilitarian Priority Pattern" rather than an established finding. Methodological contributions include: (1) a framework for adapting expert interviews to inform MCDA-based design in low-data environments, (2) strategies for maintaining theoretical rigor in scenario-based prototype evaluation, and (3) approaches for integrating qualitative and quantitative data across DSR cycles, with implications for SDG 8 (Decent Work and Economic Growth) and SDG 9 (Industry, Innovation and Infrastructure).

Keywords: Design Science Research, Methodology, Developing Economies, Digital Platforms, SMEs, Applied Computing

I.INTRODUCTION

Design Science Research (DSR) has emerged as a dominant methodological paradigm within Information Systems research for creating and evaluating purposeful artifacts that address real-world problems [1]. Unlike behavioral research, which seeks to explain existing phenomena, DSR is oriented toward generating knowledge

through the systematic creation and evaluation of artifacts. This process yields both practical solutions and theoretical contributions [2].

While DSR has been widely applied in well-resourced research settings, its application in resource-constrained environments—particularly in developing economies—presents distinctive methodological challenges that remain underexplored in the literature. These challenges include limited access to participants, unreliable digital infrastructure, trust deficits in digital platforms, regulatory complexity, and the need to balance theoretical rigor with practical utility in contexts with scarce research resources. This paper addresses the following research question: How can the DSR methodology be effectively operationalized for digital platform development in resource-constrained developing-economy contexts? We position this contribution carefully. Individually, purposive expert sampling, open-source development, scenario-based evaluation, and effect-size reporting are established research practices rather than novel inventions in themselves [3]. What this paper contributes is not a new method in isolation, but (a) a specific combination and sequencing of these practices into an operationalized framework for DSR in resource-constrained developing-economy contexts, and (b) an instrumental case, Lumikiza, through which that combination is demonstrated and critically examined, including where the evaluation did not perform as strongly as hoped. We treat the framework's elements as propositions for testing in other resource-constrained contexts rather than as settled, generalized guidance. Drawing on the development of this digital advisory matching platform for Small and Medium Enterprises (SMEs) in Zambia, we present a methodological framework that addresses the distinctive challenges of conducting DSR in resource-constrained settings. The paper contributes:

- A framework for adapting expert interviews to inform Multi-Criteria Decision Analysis (MCDA) weighting in low-data environments
- Strategies for maintaining theoretical rigor in scenario-based prototype evaluation
- Approaches for integrating qualitative and quantitative data in DSR cycles
- Practical guidance for researchers developing digital platforms in similar contexts

The paper is structured as follows: a review of relevant literature; a methodological framework; an application of the framework through the Lumikiza case study, including its sampling, instrumentation, and ethical procedures; results; a discussion of findings; limitations; contributions; and conclusion.

II.LITERATURE REVIEW

1. Design Science Research in Information Systems

Design Science Research occupies a distinct methodological position within Information Systems. Where behavioral research seeks to explain phenomena that already exist, DSR is oriented toward creating something new and evaluating its effectiveness [1]. The methodology is structured around three overlapping cycles: relevance, design, and rigor. The relevance cycle grounds the research in real-world practice, ensuring that the artifact addresses an actual organizational problem and is evaluated in an appropriate context. The design cycle guides iterative development, involving the construction and evaluation of artifacts. The rigor cycle ensures theoretical accountability, anchoring evaluation in established theoretical constructs rather than ad hoc criteria [1]. Reference [2] distinguishes four types of DSR contributions based on artifact novelty and knowledge contribution: invention, improvement, exaptation, and routine design. Recent scholarship further cautions that DSR contributions are frequently judged narrowly on the artifact produced, when equal attention is warranted to the theoretical knowledge generated [3]—a balance we return to in Section VI when weighing what this case does and does not establish. A defining characteristic of DSR is the status it accords to the artifact itself. Rather

than treating the prototype as a means to an end, DSR positions the artifact as the primary instrument through which assumptions are tested and new knowledge is generated. Insight emerges not solely from what participants report, but from how they actually engage with a functioning system.

2. DSR in Resource-Constrained and Developing Economy Contexts

Questions have been raised in the literature regarding whether DSR can yield credible results outside of well-resourced research or commercial environments. However, recent scholarship provides substantive evidence to the contrary. Reference [4] demonstrates the successful application of DSR in the development of Ethiopian government digital platforms, while [5] reports comparable results in resource-constrained Tanzanian contexts. Reference [6] further establishes that for early-stage artifacts, a mixed-methods approach incorporating scenario-based evaluation constitutes a methodologically rigorous basis for assessment. Reference [7] similarly confirms that DSR is well-suited to the complexities of digital innovation in organizationally demanding environments. Earlier work on ICT service development in low-resource settings emphasizes iterative, context-sensitive design over the transplantation of best practices [8]. More recently, Guracho et al. [9] applied a DSR methodology to develop a mobile mental health application for a low-resource Ethiopian setting, illustrating that structured DSR activities—from problem identification through evaluation—remain applicable even when infrastructure, workforce, and data constraints depart substantially from those assumed in mainstream IS research. Despite these advances, the literature reveals persistent gaps in understanding how DSR can be effectively operationalized in resource-constrained contexts. Studies applying DSR in developing economies have focused primarily on government or health systems rather than SME services, and few have detailed the practical methodological adaptations required for low-resource settings.

3. Digital Platforms for African SMEs

Beyond DSR methodology specifically, a growing body of work examines digital platforms as vehicles for value co-creation in African entrepreneurship ecosystems. Oredo et al. [10] document the design and implementation of a digital platform supporting entrepreneurship ecosystems in sub-Saharan Africa, while Hlongwane and Grobbelaar [11] propose an ecosystem-level framework for value creation through health information platforms in South Africa. Noutchie [12] finds that digital-platform maturity and entrepreneurial digital literacy vary considerably across African economies, cautioning against assuming that design lessons transfer uniformly across the continent. Trust is a recurring theme in this literature. Mou, Shin, and Cohen [13] show that perceived trust and usefulness jointly shape consumer acceptance of e-services, consistent with the trust-centered design emphasis adopted in this study. More broadly, the digital transformation of advisory and consulting services themselves remains comparatively understudied outside high-income markets [14].

4. The Zambian SME Context

Small and Medium Enterprises comprise the vast majority of registered businesses in Zambia and are widely cited as key drivers of inclusive economic growth [15]. Despite this, SME founders frequently lack access to strategic, governance, or compliance guidance that could meaningfully improve their prospects for survival and growth [16]. The advisory gap in Zambia is characterized by: (1) reliance on informal peer networks rather than structured professional relationships [17], a pattern consistent with broader accounts of urban informal-sector SME dynamics in Zambia [18]; (2) limited access to formal advisory and trade-support services [19]; (3) significant information asymmetry between founders and potential advisors; and (4) a regulatory landscape that includes the Zambia Data Protection Act No. 3 of 2021, which imposes compliance obligations that under-resourced SMEs are ill-equipped to navigate without specialist guidance [20]. This context provides an ideal

setting for examining the application of DSR in resource-constrained environments, as it presents the full range of challenges typical of developing economy contexts.

III.METHODOLOGICAL FRAMEWORK

1. Methodological Overview

Our methodological framework extends the standard DSR model [1] by incorporating adaptations specific to resource-constrained settings. The framework comprises five components:

- **Relevance Cycle Adaptation**: Grounding requirements through purposive expert sampling and sectoral diversity
- **Design Cycle Adaptation**: Iterative development with transparency-oriented design choices (MCDA over machine learning)
- **Rigor Cycle Adaptation**: Integrated theoretical evaluation using multiple frameworks (TTF, UTAUT, D&M)
- **Mixed-Methods Integration**: Sequential exploratory design with qualitative interviews informing quantitative instrumentation
- **Contextual Sensitivity**: Addressing trust deficits, infrastructure constraints, and regulatory complexity

2. Relevance Cycle: Grounding Requirements

In well-resourced settings, requirements gathering typically involves large-scale surveys, extensive user testing, and access to diverse participant pools. In resource-constrained contexts, these approaches are often impractical. Our framework addresses this through:

- **Purposive Expert Sampling:** Rather than attempting statistical representativeness, we employ purposive sampling across diverse sectors to ensure informational depth and theoretical relevance.
- **Semi-Structured Expert Interviews:** We use semi-structured interviews rather than structured surveys to allow participants to raise contextually relevant issues that researchers might not anticipate.
- **Flexible Data Capture:** Participants were offered a choice between audio-recording and non-recorded interviews captured through contemporaneous field notes, in recognition of confidentiality concerns common in advisory and business contexts.
- **Thematic Analysis for Design Requirements:** Thematic analysis of interviews informs both the artifact's feature set and its evaluation criteria.

3. Design Cycle: Iterative Development

The design cycle in resource-constrained contexts requires trade-offs that differ from well-resourced settings. Our framework includes:

- **Transparency-Over-Adaptivity:** We deliberately chose Weighted Multi-Criteria Decision Analysis (MCDA) over machine learning approaches. While MCDA may be less adaptive, it produces transparent, explainable rankings—critical in contexts where digital trust is still developing.
- **Open-Source Technology Stack:** Using standard, open-source frameworks ensures the platform can be maintained without specialist vendor support—essential in resource-constrained settings where ongoing commercial licensing may be unaffordable.

- **Controlled Evaluation Environment:** Early-stage DSR evaluation can be conducted in a controlled, scenario-based environment rather than requiring full operational deployment. This is appropriate for early-stage DSR artifact evaluation and captures user perceptions without the risks and costs of live deployment.

4. Rigor Cycle: Theoretical Evaluation

Standard DSR rigor typically involves evaluation against established theoretical constructs. In resource-constrained settings, we recommend:

- **Parallel Application of Multiple Frameworks:** Rather than testing a single theoretical lens, we apply three complementary frameworks in parallel: Task-Technology Fit (TTF), UTAUT, and the DeLone and McLean IS Success Model. This provides richer evaluation than any single framework alone and reveals context-specific design priorities.
- **Scenario-Based, Prototype-Level Evaluation:** For early-stage artifacts, scenario-based evaluation can yield theoretically meaningful results without requiring full operational deployment. Participants interact with the prototype through guided scenarios before completing evaluation instruments.
- **Effect Size and Power Reporting:** Given the modest sample sizes often feasible in resource-constrained settings, we emphasize reporting effect sizes (f^2) and confidence intervals alongside significance tests, enabling readers to assess practical significance independent of statistical significance.

A notational clarification is necessary here, since three unrelated quantities in this paper are conventionally denoted with the same Greek letters. Sample size ($N = 200$) was planned using an a priori power analysis with a Type I error rate (α) of 0.05 and statistical power ($1-\beta$) of 0.80. α and β strictly refer to power-analysis parameters. They are distinct from (i) Cronbach's alpha (α) internal-consistency coefficients reported per construct and (ii) the standardized regression coefficients (β) reported per predictor. We use the fuller notation "Cronbach's α" and "regression β" throughout the results to avoid ambiguity.

5. Mixed-Methods Integration

Our framework employs a sequential exploratory mixed-methods design [21] that serves two integration functions:

- **Qualitative Phase Informs Prototype Requirements:** Thematic analysis of qualitative interviews directly shapes the prototype's requirements.
- **Qualitative Phase Informs Quantitative Instrument:** The same analysis informs the item pool and construct emphasis of the subsequent quantitative questionnaire.

This integration ensures that the artifact is built around the actual informational environment of its intended users rather than assumptions suited to formalized markets.

6. Contextual Sensitivity

Our framework explicitly addresses three contextual challenges:

- **Trust Deficits:** In low-trust markets, the artifact must function as a verification engine rather than a simple directory [13]. Design choices (transparent MCDA, explainable recommendations) must prioritize trust-building.
- **Infrastructure Constraints:** Designs must account for variable internet connectivity and mobile data costs. The framework includes UI design considerations for low-bandwidth environments.

- **Regulatory Complexity:** The design must address local regulatory requirements (e.g., Zambia Data Protection Act No. 3 of 2021) while helping users navigate compliance obligations.

IV.CASE STUDY: LUMIKIZA APPLICATION

1. Research Context

Zambia lacks a structured digital mechanism for SME-advisor matching. Lumikiza aimed to design, build, and evaluate a prototype addressing this gap. Figure 1 summarizes how the DSR cycles, the integrated theoretical framework, and the Lumikiza artifact relate to one another and to the study's academic and practical contributions.

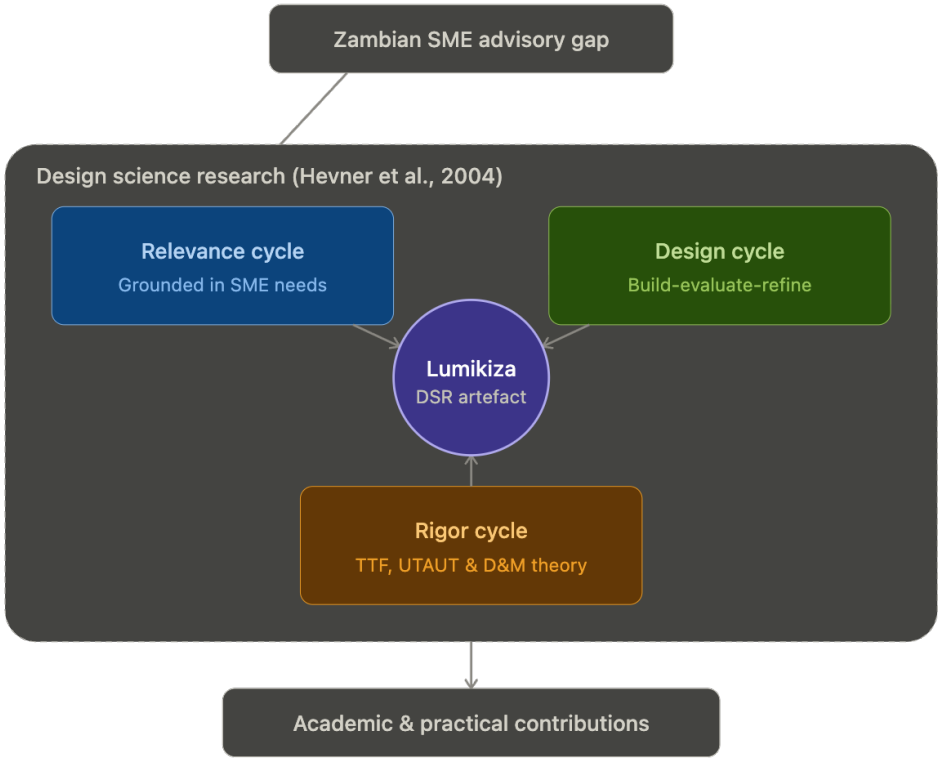

Figure 1. Lumikiza's integrated conceptual framework for digital platform development in a resource-constrained DSR context.

The research was conducted in Lusaka and Livingstone, Zambia, during March-April 2026. These cities were selected because: (1) they have the highest concentration of formally registered SMEs, (2) they represent diverse business models (Lusaka: urban commercial hub; Livingstone: tourism-focused), and (3) both have adequate digital connectivity for platform evaluation

2. Study Site, Population, and Sampling

Qualitative phase (expert advisors): The population was professional advisors and domain experts working with Zambian SMEs. A purposive sample of n = 10 was recruited to ensure sectoral diversity and depth rather than statistical representativeness, consistent with the exploratory, design-oriented nature of DSR evaluation. Inclusion criteria were a minimum of 5 years of professional experience and active engagement in SME advisory work. Participants were purposively drawn across six sectors: Agribusiness, Manufacturing, Mining, Fintech, Retail, and Services.

Quantitative phase (SME founders): The population was SME founders and key decision-makers operating in Lusaka and Livingstone. A purposive sample of N = 200 was recruited, with inclusion criteria requiring that the business have been registered and operating for at least 1 year and that the respondent be involved in strategic decision-making. The sample size was determined using an a priori power analysis for the planned regression analysis ($\alpha = 0.05$, power = $1- \beta = 0.80$).

3. Data Collection, Instrumentation, and Ethics

Qualitative interviews: Semi-structured interviews were conducted with the ten SME advisors and domain experts (coded AD-01 to AD-10). One interview (AD-01) was audio-recorded with explicit consent and transcribed verbatim; the remaining nine participants preferred non-recorded interviews, and their contributions were captured through contemporaneous field notes, which were expanded into thematic memos for coding. An interview guide was used to ensure consistency across interviews while allowing participants to raise contextually relevant issues.

Quantitative instrument: A structured questionnaire was administered to 200 SME founders using a five-point Likert scale (1 = Strongly Disagree, 5 = Strongly Agree). Items were mapped to eight theoretical constructs drawn from TTF [22], UTAUT [23], and the DeLone and McLean model [24]: System Quality, Information Quality, Task-Technology Fit, Performance Expectancy, Effort Expectancy, Social Influence, Facilitating Conditions, and Net Benefits. All 200 participants completed the full questionnaire (100% response rate); therefore, no missing-data procedures were required.

Validity and reliability: Content validity for both instruments was established through expert review before data collection. Construct validity was addressed by adapting measurement items from previously validated IS instruments [22], [23], [24]. Internal consistency of the quantitative scales was assessed using Cronbach's alpha, reported by construct. For the qualitative data, trustworthiness was addressed through credibility (member checking where appropriate), dependability (a maintained interview protocol), and confirmability (documented coding decisions).

Ethics: Ethical clearance was obtained from The Copperbelt University before data collection. Participation was voluntary; all participants received a written information sheet and gave written informed consent before any interview was recorded or survey completed. Responses were anonymized using participant codes (SME01–SME200; EXP01–EXP10/AD-01–AD-10), and no identifying information appears in any research output. All data were stored on password-protected devices accessible only to the researcher and supervisor, in compliance with the Zambia Data Protection Act No. 3 of 2021.

4. Application of the Framework

Relevance Cycle

Analysis of the ten expert interviews revealed:

- Trust is the absolute prerequisite for digital adoption
- Word-of-mouth serves as the only current verification system
- A "Diagnostic Gap" prevents SMEs from accessing high-quality information
- Sector-specific expertise is critical
- Cost and credibility concerns are the primary barriers

These findings translated into concrete design requirements: a Trust Assurance score in the matching algorithm, a pre-matching diagnostic survey for SMEs, certification filters and "Verified" expert badges, fee-transparency indicators, and an explicit distinction between "Strategic" and "Technical" experts.

Design Cycle

The Lumikiza prototype was implemented as a modular, decoupled web-based platform as outlined in Table 1 below.

Table 1. Lumikiza Platform Architecture

Layer	Technology
Frontend	Vite, React, TypeScript, Tailwind CSS, shadcn-ui
Application logic	Modular service architecture
Database	PostgreSQL (relational)
Matching engine	Weighted Multi-Criteria Decision Analysis (MCDA)

Matching Engine

The MCDA engine scores registered advisors against five criteria for each advisory request: domain relevance, years of professional experience, sector familiarity, regulatory knowledge, and availability, and returns a ranked list of the top matches.

Each of the five criteria is assigned a weight reflecting its relative importance, informed qualitatively by the thematic emphasis participants placed on domain relevance and sector familiarity during the relevance-cycle interviews. We are explicit about a limitation here: the current implementation uses a fixed, qualitatively-derived weighting scheme. A formal normalization procedure, an explicit aggregation equation, and a quantitative sensitivity analysis of the weights were not conducted at this stage of the evaluation. This was a deliberate scope decision—our priority was demonstrating that expert-interview-derived weighting is feasible and produces explainable rankings—but it is also a genuine limitation of the current prototype. We identify formal weight elicitation (e.g., pairwise comparison or conjoint methods) and sensitivity analysis as the necessary next steps before the matching engine can be considered validated.

MCDA was chosen deliberately over machine learning for its transparent, explainable rankings [25]. One design-evaluation iteration was completed before formal testing, consistent with early-stage DSR evaluation practice [6]; we return to the limits this places on our iterative-DSR claim made above.

Rigor Cycle

The evaluation used an integrated framework combining TTF [22], UTAUT [23], and DeLone and McLean [24], applied as parallel predictors of Net Benefits rather than as a mediated or sequential model (Figure 2). Each evaluation scenario was designed to operationalize specific theoretical constructs, from advisory-request submission (TTF) through recommendation interpretation (information quality, net benefits) to a global post-task assessment (social influence, facilitating conditions, net benefits), consistent with meta-analytic evidence on the determinants of task-technology fit more broadly [26].

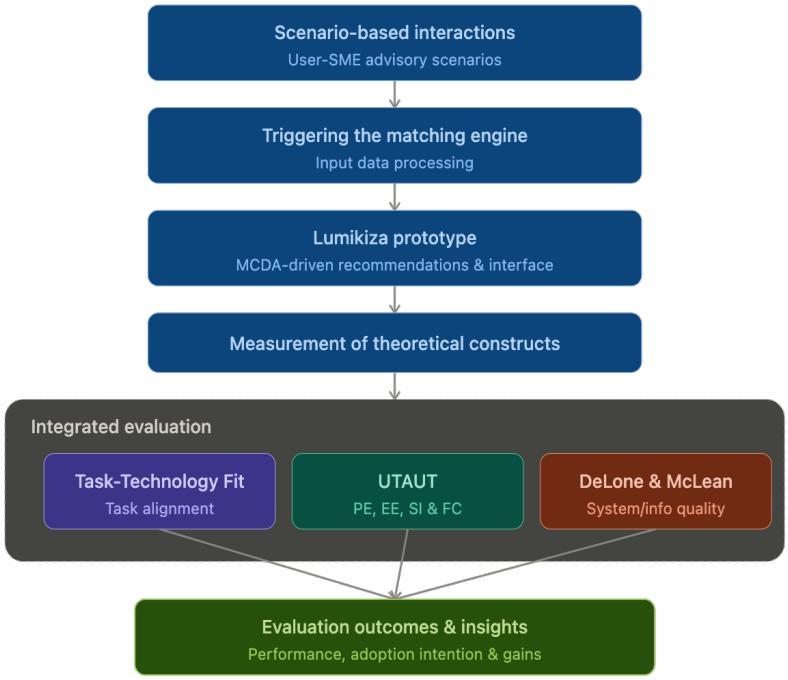

Figure 2. Prototype evaluation and procedural flow, mapping scenario-based interactions to the integrated TTF/UTAUT/D&M measurement framework.

Mixed-Methods Integration

The sequential exploratory design served two integration functions: qualitative interviews shaped the Lumikiza prototype's requirements (particularly the weighting given to regulatory knowledge and sector familiarity), and the same analysis informed the item pool and construct emphasis of the quantitative questionnaire. This integration ensured the prototype was built around the actual informational environment of its users.

Methodological Contributions from the Case

- **Framework for MCDA Weighting:** In the absence of formal ranking exercises, MCDA weights can be derived from thematic analysis of qualitative interviews, with themes that emerge most consistently given greater emphasis—while acknowledging, as above, that this substitutes for rather than replaces formal weight elicitation.
- **Scenario-Based Evaluation:** For early-stage DSR artifacts, scenario-based evaluation can yield theoretically meaningful results without requiring full operational deployment.
- **Integrated Multi-Theoretic Evaluation:** Parallel application of TTF, UTAUT, and DeLone and McLean provides richer evaluation than any single framework alone and can reveal context-specific design priorities.
- **Effect Size Reporting:** In resource-constrained settings with modest samples, reporting effect sizes (f^2) alongside statistical significance enables assessment of practical significance independent of sample size.

V.RESULTS

This section reports the empirical results underlying the evaluation summarized in Section IV. It is presented separately from the Discussion (Section VI) so that findings and their interpretation remain clearly distinguishable.

1. Sample Characteristics

Table 2 summarizes the demographic and firmographic profiles of the 200 SME founders who completed the quantitative questionnaire. The sample skews male (75.0%) and highly educated (94.0% hold at least a Bachelor's degree), and is concentrated in the 35–44 age range and in the Agriculture, Retail, and Services sectors. This profile should be borne in mind when interpreting the generalizability of the findings.

Table 2. Sample Characteristics (N = 200)

Characteristic	Category	n (%)
Gender	Male	150 (75.0%)
	Female	50 (25.0%)
Age	35–39 years	65 (32.5%)
	40–44 years	39 (19.5%)
	Other brackets	96 (48.0%)
Education	Postgraduate	102 (51.0%)
	Bachelor's degree	86 (43.0%)
	Diploma	12 (6.0%)
Sector	Agriculture	64 (32.0%)
	Retail	45 (22.5%)
	Services	44 (22.0%)
	Other	36 (18.0%)
	Manufacturing	11 (5.5%)

2. Reliability and Validity

Internal consistency for each of the eight theoretical constructs was assessed using Cronbach's alpha (Table 3). All constructs exceeded the generally accepted 0.70 threshold except Facilitating Conditions ($\alpha = 0.688$). Because the Facilitating Conditions scale comprised only three items, and Cronbach's alpha is known to be attenuated in short scales [27], an alpha in the 0.65–0.70 range was treated as acceptable for this exploratory evaluation; item-total correlations for all three items exceeded 0.45.

Table 3. Internal Reliability (Cronbach's α) by Construct

Construct	Items	Cronbach's α
Task-Technology Fit (TTF)	7	0.812
Performance Expectancy (PE)	5	0.784
Effort Expectancy (EE)	5	0.821
Social Influence (SI)	3	0.745
Facilitating Conditions (FC)	3	0.688
System Quality (SQ)	6	0.712

Construct	Items	Cronbach's α
Information Quality (IQ)	6	0.756
Net Benefits (NB)	6	0.793

3. Descriptive Construct Scores

All eight constructs achieved mean scores above the 3.0 neutral midpoint of the five-point scale. Effort Expectancy (M = 4.14) and Facilitating Conditions (M = 4.11) scored highest; System Quality (M = 3.71) scored lowest. Task-Technology Fit averaged M = 3.79 across the sample. Standard deviations were tightly bound across constructs, indicating a reasonable degree of consensus among the 200 participants. Inter-construct correlations were consistently positive, and were notably stronger between Net Benefits and both Performance Expectancy and Information Quality than between Net Benefits and the remaining constructs.

4. Predicting Net Benefits: Regression Results

An Ordinary Least Squares (OLS) multiple regression was conducted to predict Net Benefits from the TTF, UTAUT, and D&M constructs. The overall model was not statistically significant ($F = 1.95$, $p = 0.064$) and explained only 6.6% of the variance in Net Benefits ($R^2 = 0.066$; adjusted $R^2 = 0.032$). Within this weak and non-significant overall model, Information Quality ($\beta = 0.167$, $p = 0.038$) was the only predictor to reach the 0.05 significance threshold; System Quality ($p = 0.720$) and Effort Expectancy ($p = 0.534$) were not significant. Table 3 reports the coefficients available for the six predictors captured in the regression output.

Table 4. OLS Regression Results (Dependent Variable: Net Benefits)

Variable	β	SE	95% CI	t	p
(Constant)	2.352	0.520	[1.326, 3.378]	4.525	<.001
Task-Technology Fit	0.113	0.066	[−0.017, 0.243]	1.700	.091
Performance Expectancy	0.073	0.072	[−0.069, 0.215]	1.011	.313
Effort Expectancy	0.035	0.057	[−0.077, 0.147]	0.623	.534
Social Influence	0.036	0.057	[−0.076, 0.148]	0.620	.536
Facilitating Conditions	−0.040	0.055	[−0.148, 0.068]	−0.727	.468
System Quality	0.026	0.074	[−0.120, 0.172]	0.359	.720
Information Quality	0.167	0.080	[0.009, 0.325]	2.085	.038

[a] Note: 95% CIs computed as $\beta \pm 1.972 \times SE$ (t-critical, df = 192). Model fit: $R^2 = 0.0664$, adjusted $R^2 = 0.0324$, $F = 1.9523$ ($p = 0.0636$).

The effect size for the overall model, $f^2 = R^2/(1-R^2) = 0.066/(1-0.066) = 0.071$, exceeds Cohen's [28] convention for a small effect ($f^2 = 0.02$). This indicates a non-trivial effect, but given the model's overall non-significance, we treat both the effect size and the Information Quality coefficient as a preliminary signal rather than a confirmed predictive relationship.

5. Subgroup Analysis: Gender Invariance

A Welch's t-test was used to compare male and female respondents across all eight constructs (Table 4). No statistically significant differences were found (all $p > 0.05$), suggesting that perceived usefulness, effort expectancy, and information quality did not differ by gender in this sample.

Table 5. Independent-Samples t-Test Results (Male vs. Female)

Construct	Male M	Female M	t	p	Sig.
Effort Expectancy	4.147	4.128	0.268	.789	No
Facilitating Conditions	4.111	4.093	0.245	.807	No
Social Influence	3.969	3.980	−0.164	.870	No
Net Benefits	3.907	3.963	−1.029	.306	No
Performance Expectancy	3.899	3.884	0.267	.790	No
Information Quality	3.811	3.803	0.147	.883	No
Task-Technology Fit	3.788	3.814	−0.449	.654	No
System Quality	3.696	3.753	−1.154	.251	No

6. Information Asymmetry Reduction

Before prototype exposure, 76% of participants reported being unable to confidently assess advisors' expertise before first contact, 68% did not know whether advisors understood local regulations, and 62% lacked information about advisors' sector experience. After prototype evaluation, participants were asked whether the platform reduced their uncertainty about advisor fit (Table 5).

Table 6. Response to “Does this platform reduce your uncertainty about advisor fit?”

Response	Frequency	Percentage
Strongly Agree (5)	115	57.5%
Agree (4)	58	29.0%
Neutral (3)	15	7.5%
Disagree (2)	8	4.0%
Strongly Disagree (1)	4	2.0%

Overall, 87% of participants (n = 173) responded positively (4–5 rating), with a mean response of 4.05 (SD = 0.72). This was corroborated qualitatively: Expert AD-04 observed that “*the matching criteria clearly show why each advisor was recommended. This transparency builds confidence in the match*.”

VI.DISCUSSION

1. Key Methodological Insights

Preliminary Signal on Information Quality

Information Quality was the only construct to reach the conventional significance threshold as a predictor of Net Benefits. We emphasize that the overall regression model was not statistically significant ($F = 1.95$, $p = 0.064$) and explained only 6.6% of the variance. We therefore read the Information Quality coefficient as a preliminary, single-sample signal—not as evidence that information quality is established as the dominant driver of platform value in resource-constrained settings generally.

Methodological Implication: Evaluation frameworks for early-stage DSR artifacts should include information quality as a candidate construct, but claims based on an overall model that is not significant should be flagged as preliminary rather than presented as confirmed findings.

Expert Interviews as a Design Tool

Thematic analysis of expert interviews informed both artifact requirements and evaluation instrumentation, supporting the use of small-n purposive sampling for requirements elicitation in resource-constrained settings where large-scale user testing is impractical.

Methodological Implication: Purposive expert sampling combined with thematic analysis can effectively ground DSR requirements when representative sampling is infeasible.

Scenario-Based Evaluation

Scenario-based, prototype-level evaluation yielded theoretically interpretable results without requiring full operational deployment, which is particularly relevant for researchers in resource-constrained settings where live deployment during the research phase is often impractical.

Methodological Implication: Early-stage DSR artifacts can be evaluated in controlled, scenario-based environments, though this comes at the expense of behavioral realism relative to authentic use.

Integrated Theoretical Evaluation

The parallel application of three complementary evaluation frameworks (TTF, UTAUT, D&M) revealed that task alignment and adoption readiness both scored strongly. At the same time, the overall predictive power of the regression model remained weak—a pattern consistent with concerns raised elsewhere about the risk of single-theory technology-adoption studies in MSME contexts [29].

Methodological Implication: Integrated, multi-theoretic evaluation approaches can reveal where constructs diverge, which is analytically useful even when the combined predictive model is not itself significant.

2. Methodological Framework Proposal

Based on our experience, we propose the following framework for DSR in resource-constrained contexts, offered as propositions for testing in other settings rather than as settled guidance:

Table 7. Framework for DSR in Resource-Constrained Contexts

DSR Component	Standard Approach	Adapted Approach
Relevance Cycle	Large-scale surveys, extensive user testing	Purposive expert sampling, semi-structured interviews, thematic analysis
Design Cycle	Adaptive algorithms, proprietary/commercial technology stack	Transparency-oriented algorithms (MCDA), open-source technology stack

DSR Component	Standard Approach	Adapted Approach
Rigor Cycle	Single theoretical framework, full-scale deployment	Integrated theoretical framework, scenario-based evaluation
Evaluation	Large sample sizes for statistical power	Effect size reporting alongside significance tests
Ethics	Standard consent procedures	Address trust deficits explicitly; document consent through accessible mechanisms.
Context	Generic design considerations	Explicitly address trust deficits, infrastructure constraints, and regulatory complexity.

3. Limitations and Considerations

Several limitations bound the interpretation of these findings.

- Single case and context: The methodological insights derive from a single case study in one developing-economy context (Zambia). Generalizability to other resource-constrained settings has not been tested.
- We are explicit about a limitation here: the current implementation uses a fixed, qualitatively derived weighting scheme. A formal normalization procedure, an explicit aggregation equation, and a quantitative sensitivity analysis of the weights were not conducted at this stage of the evaluation. This was a deliberate scope decision. The priority was to demonstrate that expert-interview-derived weighting is feasible and produces explainable rankings. We identify formal weight elicitation (e.g., pairwise comparison or conjoint methods) and sensitivity analysis as the necessary next steps for future iterations.
- One design-evaluation iteration: Only a single build-evaluate-refine cycle was completed before formal testing. This is consistent with early-stage DSR practice, but it limits how strongly we can claim that the iterative character of DSR was demonstrated, rather than asserted.
- Non-significant, low-power regression model: The overall regression model was not statistically significant ($R^2 = 0.066$; $F = 1.95$, $p = 0.064$). The one significant predictor (Information Quality, $\beta = 0.167$, $p = 0.038$) should be interpreted as preliminary and warrants replication with a larger sample before being treated as a settled finding. The "Utilitarian Priority Pattern" language we use is a working label for this preliminary result, not a claim of a generalizable property of SME technology adoption in Zambia or Sub-Saharan Africa.
- Sample composition: The evaluation was conducted in a controlled, scenario-based environment with an educated, urban/peri-urban sample (94% held at least a Bachelor's degree). Findings should not be assumed to generalize to SME founders with only secondary or vocational qualifications, or to rural populations.

4. Implications for Practice

For researchers applying DSR in resource-constrained contexts, we recommend:

- Prioritize transparency over adaptivity in algorithm design to build trust, while budgeting time to formalize and validate any qualitatively derived weighting scheme
- Use expert interviews for requirements elicitation when large-scale user testing is impractical
- Adopt integrated, multi-theoretic evaluation frameworks, but report overall model significance alongside individual predictors so readers can weigh both
- Report effect sizes alongside significance tests, and state plainly when a model is not statistically significant
- Design for low-bandwidth environments and explicitly address trust deficits

- Plan for regulatory compliance as a core design consideration, not an afterthought

VII.CONCLUSION

This paper presented a methodological framework for applying Design Science Research in resource-constrained developing-economy contexts, demonstrated through the Lumikiza digital advisory-matching platform for Zambian SMEs. We showed how the relevance, design, and rigor cycles were operationalized under limited digital infrastructure, trust deficits, and regulatory complexity, and we reported the evaluation results, including a non-significant overall regression model and a single preliminary significant predictor (Information Quality), transparently rather than overstating them.

The framework's five adaptations (Table 6) and the case's methodological lessons are offered as propositions for other researchers to test in resource-constrained contexts, not as generalized findings. Future work should prioritize: replicating the evaluation with a larger and more educationally diverse sample; formally normalizing and sensitivity-testing the MCDA weighting scheme; completing further design-evaluation iterations; and testing the framework's transferability in other developing-economy settings. With these next steps in place, the approach outlined here may support digital platform development work relevant to SDG 8 (Decent Work and Economic Growth) and SDG 9 (Industry, Innovation and Infrastructure).

Abstract
The paper comments on the Brain-Computer Interface, which relies on brain rhythms and other brain signals. It presents a reasoning in Brain Science, particularly regarding brain waves for the Brain Computer Interface. Also, the paper presents a relation between brain rhythms and choice, as a notion of Intelligence.

Keywords: Brain Computer Interface, Artificial Intelligence, brain rhythms.

I. INTRODUCTION

Brain rhythms are oscillations in a human electroencephalogram (EEG) defined by their frequency ranges. The ranges are defined *empirically*, and their definitions vary from one research report to another. For example, one study may define the alpha rhythm range as 8-13 Hz (oscillations per second), and another study as 8-12 Hz. Brain rhythms are an important area of Brain Computer Interface (BCI) research, i.e., research on directly controlling external objects with EEG signals. This paper first provides a brief review of the origins of Brain-Computer Interface (BCI) research, highlighting the role of the alpha rhythm in the pioneering control of a robot using BCI. The paper seeks a mathematical basis for a theoretically grounded definition of the frequency ranges of brain rhythms.

II. BRAIN-COMPUTER INTERFACE

Research on Brain-Computer Interface (BCI) began with the BCI challenge [1]. The challenge was to find a way to control external objects (outside the human body) using EEG signals. He advised using various EEG signals, including EEG rhythms and event-related potentials. Specifically, he challenged the use of the Contingent Negative Variation (CNV) potential. Also, he mentioned using electrooculography (EOG) signals. The first five applications of BCI, after Vidal's (1973) challenge were: control of a cursor-like object on a screen [2], using the Visual Evoked Potential (VEP); control of a buzzer [3-6] using the CNV potential; control of a physical object (a robot) [7-10] using the alpha rhythm; and writing text on a screen [11] using the P300 potential. Brain rhythms have been used in BCI since the beginning of BCI [8] when the alpha rhythm was used to control a physical object to solve the long-lasting psychokinesis challenge. A review on the Brain Computer Interface is given in [12-15].

III. BRAIN THEORY

Brain Theory seeks to explain phenomena in the brain, including those related to electrical signals. The electrical oscillations in the brain were first observed in animals [16] and later in humans [17]. Berger named it Elektrenkephalogramm, which, in English literature, is translated as electroencephalogram (EEG). He also observed that, in an EEG, a certain frequency rhythm is dominant under certain conditions, and named it the

alpha rhythm. Since then, various other rhythms have been observed and named delta, theta, beta, and gamma, with additional variants. The alpha rhythm has three variants, depending on the location from which it is recorded. If recorded from the sensorimotor area, it is often called the mu rhythm. If recorded from the auditory area, it is often called the tau rhythm. The alpha rhythm from the visual area and all other areas is named the alpha rhythm. Brain signals can be divided into ongoing brain oscillations and transient potentials. Both transient potentials and brain oscillations can be event-related. Oscillations can be event-related because an event, internal or external, can change the amplitude and frequency of a brain oscillation. Later in the text, we will focus more on brain rhythms. Figure 1 shows the obtaining (filtering out) of classical brain rhythms (alpha, beta, delta, and theta) from an EEG signal.

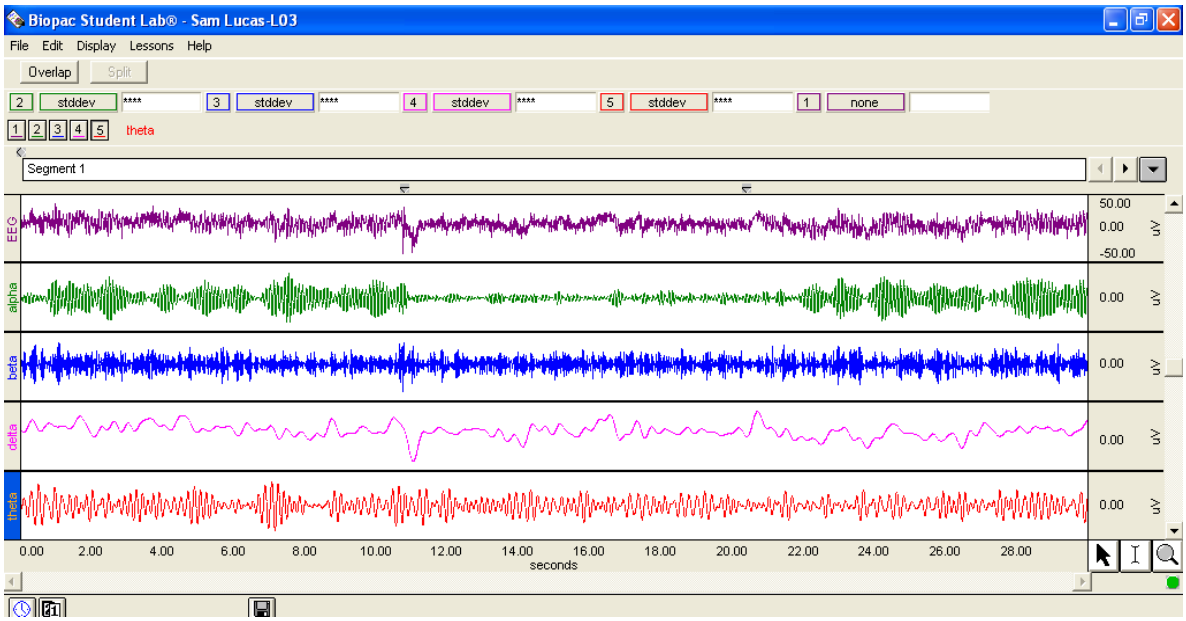

Figure 1. EEG rhythms obtained by Biopac equipment

On top of Figure 1 is the EEG signal obtained from a subject. The unprocessed EEG signal is shown above, whereas the signals below it are obtained after the unprocessed EEG is band-pass filtered. The definitions of the frequency ranges of the filtered signals in Figure 1 are: delta (1-5 Hz), theta (4-8 Hz), alpha (8-13 Hz), and beta (13-30 Hz), all computed using Biopac equipment [18]. There are various interpretations of brain states associated with a particular brain rhythm. According to one interpretation, the alpha rhythm has its highest amplitudes when the visual system is not doing any processing. For example, closing the eyes and not thinking about something will produce high amplitudes in the alpha band. The beta rhythm is dominant in an EEG when the brain is engaged in calculations or image processing. Basically, the appearance of the beta rhythm blocks the alpha rhythm. The border between the alpha and beta can be used as a BCI switch. The first BCI control of a physical object (a robot) used the alpha/beta switch [8].

IV. BRAIN FREQUENCIES AND NUMBER SEQUENCES

The brain rhythms are defined by their frequency bands. The long-lasting issue in Brain Theory is that the frequency bands are defined empirically. As a consequence, in one study, the alpha band is defined as 7-13Hz, in another as 8-12Hz, and in another as 8-14Hz, among other empirical definitions. Thus, a challenge in Brain

Theory and Information Science in general is to find a theoretical process underlying the definition of brain rhythms. Our approach toward brain rhythms is that they are connected to the operation of choice. The intuition is that the brain works on higher frequencies depending on the choice it makes at a particular moment. In the case of two choices (e.g., open-close), the brain operates predominantly within the alpha-frequency range. A question that emerges is: what is a known mathematical concept dealing with choices? It is Pascal's triangle. Pascal's triangle is a pattern for generating integers, level by level, starting with the number 1 at level n=0. It can be constructed using the rule that each number in a level n is the sum of the two numbers above it in level n-1, and each level starts and ends with the number 1. A well-known interpretation of the rows of Pascal's Triangle is that they represent the coefficients of the expansion of (a+b) ^n for n=0, 1, etc.

The known sequences of integers are listed in the Online Encyclopedia of Integer Sequences (OEIS). Examples of sequences in the OEIS are obtained in our previous work [19]. In OEIS, one can find sequences of integers generated by Pascal's triangle. Our contribution is that the central frequencies of the brain rhythms can be defined by the median values of Pascal's Triangle. Figure 2 illustrates our proposed definition of the central frequencies of brain rhythms. The idea is simply that the central frequencies of brain rhythms are the medians of each row of the Pascal triangle. Note that the median in rows with an even number of values is the average of the adjacent values. Each central frequency, along with its range, can be considered a fuzzy number.

n=0											1								
n=1										1		1							
n=2									1		2		1						
n=3								1		3		3		1					
n=4							1		4		6		4		1				
n=5						1		5		10		10		5		1			
n=6					1		6		15		20		15		6		1		
n=7				1		7		21		35		35		21		7		1	
n=8			1		8		28		56		70		56		28		8		1
n=9		1		9		36		84		126		126		84		36		9		1

Figure 2. Pascal's triangle: Our definition of the central frequencies and ranges of brain rhythms

The obtained sequence is 3,6,10,20,35,70,126. With it, we present a mathematical process that defines the central frequencies of brain rhythms. Based on such an analysis, we can write a mathematical formula that defines the frequency bands of brain rhythms.

Let $S(n,k) = 2 \times 1\ matrix, n\ , sonraki\ satır, k\ son\ matris\ , sağ\ parantez\ n = 0,1,\ldots,9;\ k = 0,\ldots,n;\ be\ coefficients\ of\ the\ expansion\ of\ (a+b)\text{^}n$ n = 0,1,...,9; k=0,...,n; be coefficients of the expansion of the $(a+b)^n$.

kkk = k $\binom{n}{M}$ be a median value of $\binom{n}{k}$, k= 0, ..., n.

Then, the brain rhythms' frequency bands are defined by the following mathematical formula:

$$B(n)=\binom{n+2}{M} \pm \binom{n}{M} \quad (1)$$

Over a band B(n), n = 0,...,7, we define a naming function name(B(n)) = (Ldelta, Hdelta, theta, alpha, beta, gamma, gamma2, gamma3), which yields a sequence of names for the brain rhythms.

Equation (1), along with the names, defines the brain rhythms as shown in Table 1.

Table 1. Brain frequency ranges, defined using central frequencies and ranges

Brain Rhythm	Central Frequency and Deviation	Frequency Range
Ldelta	2 ± 1 Hz	1-3 Hz
Hdelta	3 ± 1 Hz	2-4 Hz
theta	6 ± 2 Hz	4-8 Hz
alpha	10 ± 3 Hz	7-13 Hz
beta	20 ± 6 Hz	14-26 Hz
gamma	35 ± 10 Hz	25-45 Hz
gamma2	70 ± 20 Hz	50-90 Hz
gamma3	126 ± 35 Hz	91-161 Hz

A comparison between our theoretically derived ranges and empirical ranges for brain rhythms reported in the literature is shown in Table 2.

Table 2. A comparison of our theoretical ranges of brain rhythms and empirical ranges in the literature

Therein, in green, are the frequency ranges that exactly match our theoretical ranges to the empirical frequency ranges. In yellow are the frequency ranges that match only one end of our theoretical ranges. For example, the empirical range 18-26 Hz matches only the 26-border of the theoretical range 14-26 Hz. Our theoretically derived central frequencies and ranges of brain rhythms align well with the empirical definitions in the literature [17],[20-31]. So, according to our analysis, the central frequencies are defined from the median values of the rows of Pascal's Triangle. The deviations around the central frequency of a band are also defined with values from Pascal's Triangle. However, while the central frequencies have fixed values and represent a fuzzy number, the definition does not require that the deviations be fixed. There is a possibility that deviations are defined using different values than those in Pascal's Triangle. For example, instead of defining the delta band as 3±1 Hz, it can be defined as 3±2 Hz (range 1-5Hz).

V. ARTIFICIAL INTELLIGENCE AND ENGINEERED PSYCHOLOGY

The Pascal Triangle can be observed as an expansion of $(a+b)^n$, where the coefficients represent the operation of choice. This suggests that the brain rhythms are related to the very important *cognitive operation of choice*. Indeed, the numbers inside Pascal's Triangle represent the number of combinations (choices) when one chooses a k-element subset from a set of n elements. The most commonly used notation is sol parantez 2 denklem denklem dizisi n son denklem, k son denklem dizisi, sağ parantez, which is read as "n choose k". The n-th row of Pascal's Triangle gives the number of choices for each k from 0 to n. We do not claim that the choice defined in the Pascal Triangle is the same as the one defined in cognitive science. However, we found that it is an interesting relation. Artificial Intelligence has many directions, and one of them is Engineered Psychology [32], in which concepts of human psychology, such as motivation, expectation, choice, emotion, and personality, are explored.

VI. CONCLUSION

Starting our discussion with the Brain-Computer Interface, an application of Brain Theory, we focused on brain rhythms and a theory for their definition. We found that the median sequence of Pascal's Triangle can serve as a theoretical basis for the central frequencies and ranges of brain rhythms. Viewing the extension of Artificial Intelligence toward Engineered Psychology, the paper also suggests that the operation of choice, as an important feature of Intelligence, lies in the background of brain rhythms.

Abstract
Surface electromyography (sEMG)-based hand movement recognition systems have been widely employed in various applications, including prosthetic control, rehabilitation, and human–machine interaction. In these applications, evaluating the effects of movement repertoire size and electrode configuration on classification performance is essential to developing systems that reliably recognize a larger number of hand movements. In this study, the scalability of sEMG-based hand movement recognition systems was evaluated by progressively expanding the movement repertoire, and the effects of different electrode configurations were systematically investigated. Experiments were conducted on the GrabMyo dataset, with four movement-repertoire scenarios comprising 4, 8, 12, and 16 movements. For each scenario, the same Convolutional Neural Network (CNN) architecture was evaluated under three different electrode configurations: wrist (12 channels), forearm (16 channels), and combined wrist–forearm (28 channels). The results demonstrated that classification performance decreased across all electrode configurations as the movement repertoire increased. However, the 28-channel electrode configuration consistently achieved the highest classification accuracy across all scenarios and exhibited greater robustness to the increase in movement repertoire size. These findings provide practical insights into selecting an appropriate movement repertoire size and electrode configuration for different sEMG-based hand movement recognition applications.

Keywords: surface electromyography (sEMG), hand movement recognition, movement repertoire size, class scalability, electrode configuration, convolutional neural network (CNN)

I. INTRODUCTION

Electromyography (EMG) is a biophysiological signal obtained by recording the electrical activity generated during voluntary muscle contractions, providing valuable information about muscle function. Surface electromyography (sEMG) is one of the most widely used physiological data sources in hand movement recognition systems because it enables the non-invasive measurement of these electrical signals. sEMG-based hand movement recognition systems have been employed in a wide range of applications, including prosthetic control, rehabilitation, human–computer interaction, virtual and augmented reality, sign language recognition, assistive technologies, and intelligent robotic systems [1-6]. In recent years, advances in sensor technologies, wearable electronic systems, and artificial intelligence-based methods have enabled these systems to move beyond controlled laboratory environments and become increasingly applicable to real-world scenarios. Accordingly, there has been growing interest in and need for scalable sEMG-based hand movement recognition systems that reliably recognize larger movement repertoires while accommodating the diverse requirements of real-world applications.

The movement repertoire is the complete set of distinct hand and forearm movements that the system is intended to discriminate. The movement repertoire size refers to the number of movement classes included in the classification problem. Different sEMG-based applications exhibit substantial differences in the movement repertoires they require. For example, recognizing a limited number of hand movements may be sufficient for basic prosthetic control or simple human–computer interaction applications [7], [8]. In contrast, advanced prosthetic systems, robotic manipulation, sign language recognition, and virtual/augmented reality applications [9], [2] require the reliable classification of substantially larger movement repertoires. However, increasing the movement repertoire size increases the number of classes that must be discriminated, thereby making the classification problem more complex and directly affecting system performance [10]. Therefore, evaluating how classification performance changes with increasing movement repertoire size is important for assessing the scalability of sEMG-based hand movement recognition systems. Nevertheless, most studies in the literature have evaluated performance using a fixed number of movements. In contrast, systematic investigations into the effect of progressively increasing the size of the movement repertoire on classification performance remain limited.

In addition to movement repertoire size, electrode configuration is another important factor influencing the performance of sEMG-based hand movement recognition systems. Electrode placement, the number of channels, and the muscle groups covered are fundamental hardware parameters that directly affect the representation of muscle activity and the information content and discriminative characteristics of the recorded sEMG signals. Various electrode configurations involving the wrist, forearm, or both regions have been proposed in the literature, and their effects on classification performance have been evaluated across different datasets and applications [11], [12]. However, the vast majority of existing studies have used fixed movement repertoires. In contrast, systematic studies of how performance across different electrode configurations changes as the movement repertoire size increases remain limited. This limitation makes it challenging to determine the most appropriate electrode configuration for different application requirements. It highlights an important research gap concerning the scalability of sEMG-based hand movement recognition systems.

In this study, the effects of progressively expanding the movement repertoire and employing different electrode configurations on the scalability of sEMG-based hand movement recognition systems were systematically investigated. To this end, the GrabMyo dataset was employed, and the movement repertoire was progressively expanded from gross motor movements to fine motor movements. Specifically, following forearm rotation and grasping movements, isolated single- and two-finger movements, as well as more complex finger combinations, were progressively incorporated into the repertoire, resulting in four experimental scenarios comprising 4, 8, 12, and 16 movements. This experimental design enabled the evaluation of the increasing complexity of the classification problem associated with an expanding movement repertoire within a controlled experimental framework.

Each experimental scenario was analyzed using the same Convolutional Neural Network (CNN) architecture across three electrode configurations: wrist-only (12 channels), forearm-only (16 channels), and combined wrist and forearm (28 channels). The same network architecture and training strategy were employed across all experiments to ensure that the observed differences in performance were attributable solely to movement repertoire size and electrode configuration. Accordingly, changes in classification performance with increasing movement repertoire, as well as the effects of different electrode configurations on these changes, were directly compared. The study aims to inform design decisions on selecting an appropriate movement repertoire size and electrode configuration for different application requirements.

II. METHODOLOGY

1. Dataset

The GrabMyo dataset was employed in this study because it provides three different channel configurations and includes a diverse range of finger, hand, wrist, and forearm movements. The dataset contains EMG recordings from 43 healthy participants, collected over three separate sessions, comprising 17 classes corresponding to 16 movements and a rest condition. In this study, signals corresponding to the 16 movement classes were used. The data were recorded at a sampling frequency of 2048 Hz using 28 channels, including 12 placed around the wrist and 16 around the forearm [13], [14].

2. The Proposed CNN Model

In this study, a lightweight one-dimensional Convolutional Neural Network (CNN) model was employed to classify sEMG signals. As illustrated in Fig. 1, the proposed architecture consists of three sequentially arranged Conv1D blocks. The first convolutional layer contains 32 filters, whereas the second and third layers contain 64 filters. A kernel size of 7 samples, same padding, and L2 regularization ($\lambda = 1 \times 10^{-5}$) were applied to all convolutional layers. The input to the model consists of segmented sEMG signals with dimensions of (204 x C). Local temporal patterns are extracted through the following one-dimensional convolution operation:

$$y_f[t] = \sum_{c=0}^{C-1} \sum_{k=0}^{K-1} W_f[c,k] \cdot x_c[t+k] + b_f \ , \quad f = 0,1,2,\dots F-1 \tag{1}$$

where (C) denotes the number of input channels, (K) represents the kernel size, and (W) and (b) denote the filter weights and bias parameters, respectively.

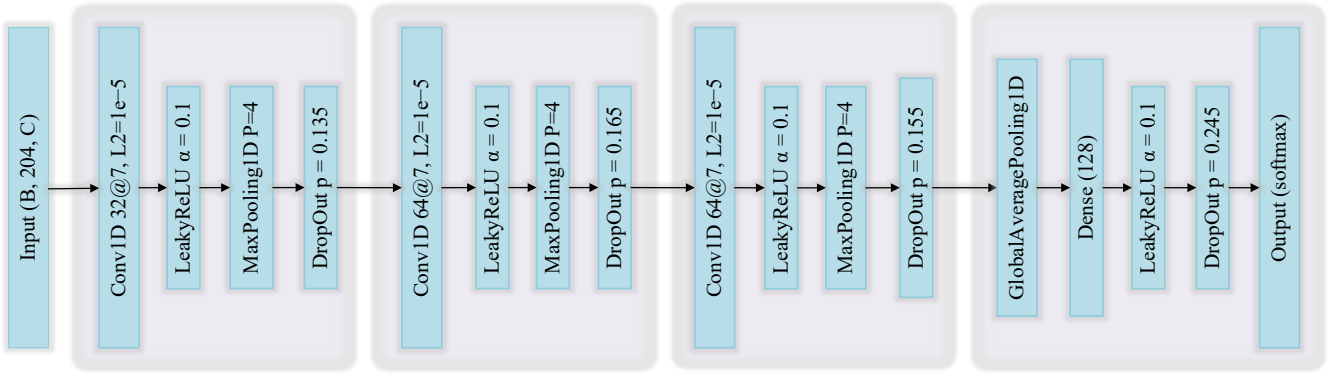

Figure 1. Proposed model flowchart

Each convolutional layer is followed by a LeakyReLU activation function ($\alpha = 0.1$), MaxPooling1D (pool size = 4), and Dropout with rates of 0.135, 0.165, and 0.155, respectively. The feature maps generated by the final convolutional block are summarized using GlobalAveragePooling1D and subsequently processed by a fully connected layer with 128 neurons. The output layer consists of 4–16 neurons with a Softmax activation function, depending on the movement repertoire scenario. The model was trained for a maximum of 100 epochs with a batch size of 64 using the Adam optimization algorithm with a learning rate of (1×10^{-4}) and the categorical cross-entropy loss function. To mitigate overfitting, Early Stopping with a patience of 5 epochs was employed. In addition, when the validation loss failed to improve, the learning rate was dynamically reduced using the ReduceLROnPlateau strategy, with a reduction factor of 0.7, a patience of 3 epochs, and a minimum learning rate of (1×10^{-7}).

3. Expansion of the Movement Repertoire

To evaluate the effect of movement repertoire size on classification performance, the movements in the GrabMyo dataset were grouped into four experimental scenarios comprising 4, 8, 12, and 16 movements, respectively. The movement repertoire was constructed by progressively adding movements from the categories of Gross and Whole-Hand Movements; Forearm Rotation and Grasping Movements; Isolated Single- and Two-Finger Movements; and Complex Finger Combination Movements, thereby representing increasing levels of biomechanical complexity. This progressive design enabled the increasing complexity of the classification problem associated with an expanding movement repertoire to be evaluated within a controlled experimental framework.

Each experimental scenario was analyzed using the same Convolutional Neural Network (CNN) architecture under three different electrode configurations: wrist (12 channels), forearm (16 channels), and combined wrist and forearm (28 channels). The grouping strategy used to construct the movement repertoires is illustrated in Fig. 2.

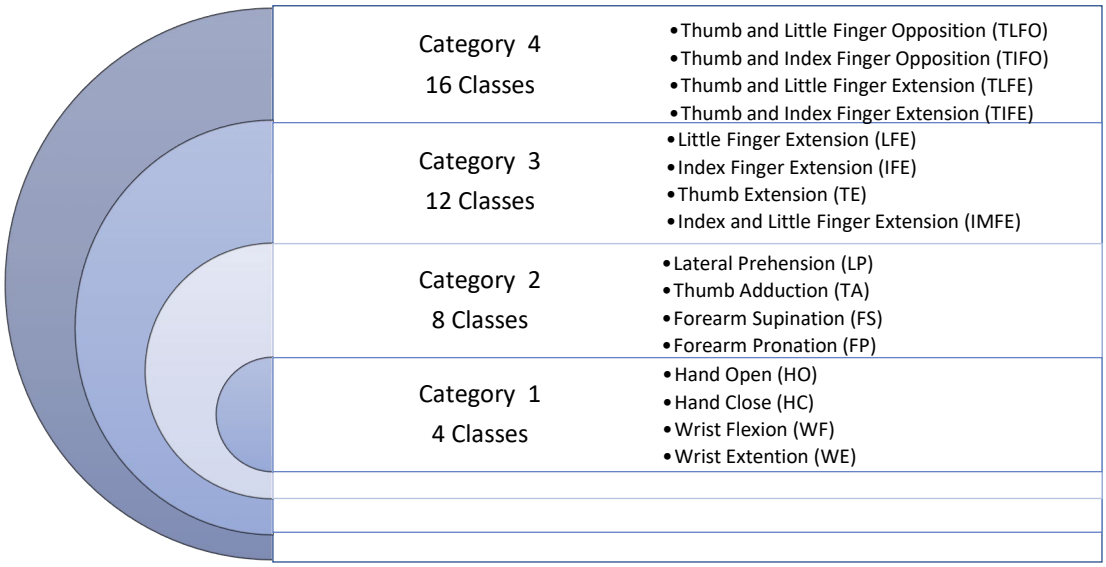

Figure 2. Movement Repertoire Expansion

III. RESULTS

This section evaluates the effects of movement repertoire size and electrode configuration on the performance of sEMG-based hand movement recognition. The experiments were conducted using four different movement repertoires comprising 4, 8, 12, and 16 movements, respectively, and three electrode configurations: wrist (12 channels), forearm (16 channels), and combined wrist and forearm (28 channels). The resulting accuracy, loss, precision, recall, and F1-score values are presented in Table 1.

For the 12-channel wrist electrode configuration, a consistent decrease was observed across all performance metrics as the movement repertoire increased. Test accuracy decreased from 96.18% for the 4-movement scenario to 81.30% when the movement repertoire was expanded to 16 movements. Similarly, the F1-score

decreased from 96.19% to 81.28%. These findings indicate that sEMG signals acquired exclusively from the wrist exhibit high discriminative capability for limited movement repertoires; however, classification performance decreases substantially as the movement repertoire expands.

Table 1. Classification performance of different electrode configurations across movement repertoire sizes, in terms of accuracy, loss, precision, recall, and F1-score.

Gesture Repertoire	Performance Metric	Electrode Combination		
		12	16	28
Category 1 (4 Classes)	Test Accuracy (%)	96.18	97.93	98.43
	Test Loss (%)	10.92	05.60	04.21
	Precision (%)	96.22	97.94	98.45
	Recall (%)	96.18	97.94	98.44
	F1 score (%)	96.19	97.93	98.44
Category 2 (8 Classes)	Test Accuracy (%)	88.31	87.48	95.35
	Test Loss (%)	33.72	31.18	13.56
	Precision(%)	88.35	87.63	95.40
	Recall (%)	88.29	87.48	95.37
	F1 score (%)	88.29	87.50	95.36
Category 3 (12 Classes)	Test Accuracy (%)	86.77	85.75	94.53
	Test Loss (%)	40.43	40.67	17.77
	Precision(%)	86.91	85.81	94.56
	Recall (%)	86.76	85.71	94.53
	F1 score (%)	86.76	85.70	94.53
Category 4 (16 Classes)	Test Accuracy (%)	81.30	81.31	92.31
	Test Loss (%)	57.01	54.20	24.78
	Precision(%)	81.48	81.41	92.36
	Recall (%)	81.28	81.27	92.30
	F1 score (%)	81.28	81.25	92.31

The 28-channel combined wrist–forearm electrode configuration achieved the highest classification performance across all movement repertoire scenarios. An accuracy of 98.43% was obtained for the 4-movement scenario, while an accuracy of 92.31% was maintained even in the most challenging 16-movement classification scenario. Furthermore, the performance advantage of the 28-channel configuration over the single-region configurations became increasingly pronounced as the movement repertoire expanded. While the difference in accuracy was approximately 2% in the 4-movement scenario, it increased to approximately 11% in the 16-movement scenario. These findings indicate that complementary sEMG data from different anatomical regions make a substantial contribution to the discrimination of movement classes, particularly when larger movement repertoires are considered.

Figure 3 compares the classification accuracies obtained using the three electrode configurations across different movement repertoire sizes. A consistent decrease in classification accuracy was observed across all electrode configurations as the movement repertoire size increased. Nevertheless, the 28-channel configuration combining wrist and forearm electrodes achieved the highest accuracy across all movement repertoires and maintained its

performance at a higher level than the other configurations. Notably, in the 16-movement scenario, the 28-channel configuration achieved an accuracy of 92.31%, whereas the wrist-only and forearm-only configurations achieved accuracies of 81.30% and 81.31%, respectively. Furthermore, the performance advantage of the 28-channel configuration over the single-region configurations became increasingly pronounced as the movement repertoire size increased. These findings indicate that complementary sEMG data from different muscle groups play an important role in maintaining classification performance as the movement repertoire expands.

Figure 4 presents the confusion matrices obtained for the 28-channel electrode configuration across movement repertoires comprising 4, 8, 12, and 16 movements. In the 4-movement scenario, the correct classifications are concentrated along the diagonal, while misclassifications remain negligible. As the movement repertoire size increases to 8 and 12 movements, a limited increase in inter-class confusion is observed; however, the diagonal structure remains largely preserved. In the most challenging 16-movement scenario, misclassifications become more frequent; nevertheless, these errors are concentrated between specific pairs of movements rather than being

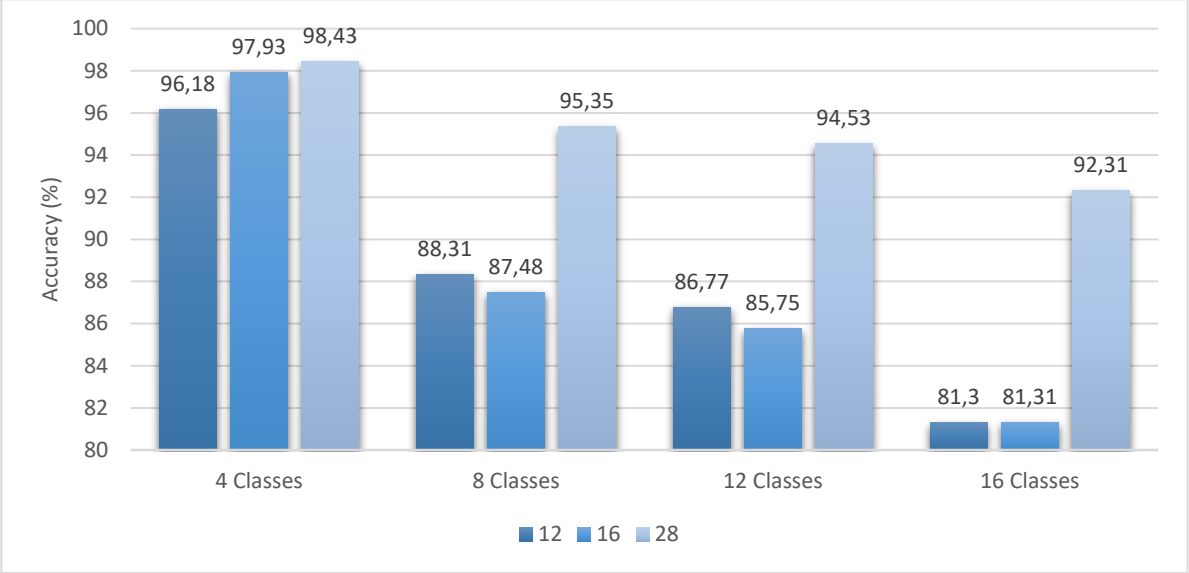

Figure 3. Comparison of classification accuracies obtained for different electrode configurations across different movement repertoire sizes.

randomly distributed across the classes. These findings indicate that the classification problem becomes increasingly complex as the movement repertoire size expands; despite this increased complexity, the 28-channel electrode configuration maintains a high level of discriminative capability even for larger movement repertoires.

This study systematically investigated the effects of movement repertoire size and electrode configuration on the classification performance of sEMG-based hand movement recognition systems. To this end, the GrabMyo dataset was used to evaluate four movement repertoires comprising 4, 8, 12, and 16 movements under three electrode configurations: wrist (12 channels), forearm (16 channels), and combined wrist and forearm (28 channels), all using the same CNN architecture. The results demonstrated that classification performance decreased across all electrode configurations as the movement repertoire size increased; however, the extent of this degradation varied by configuration.

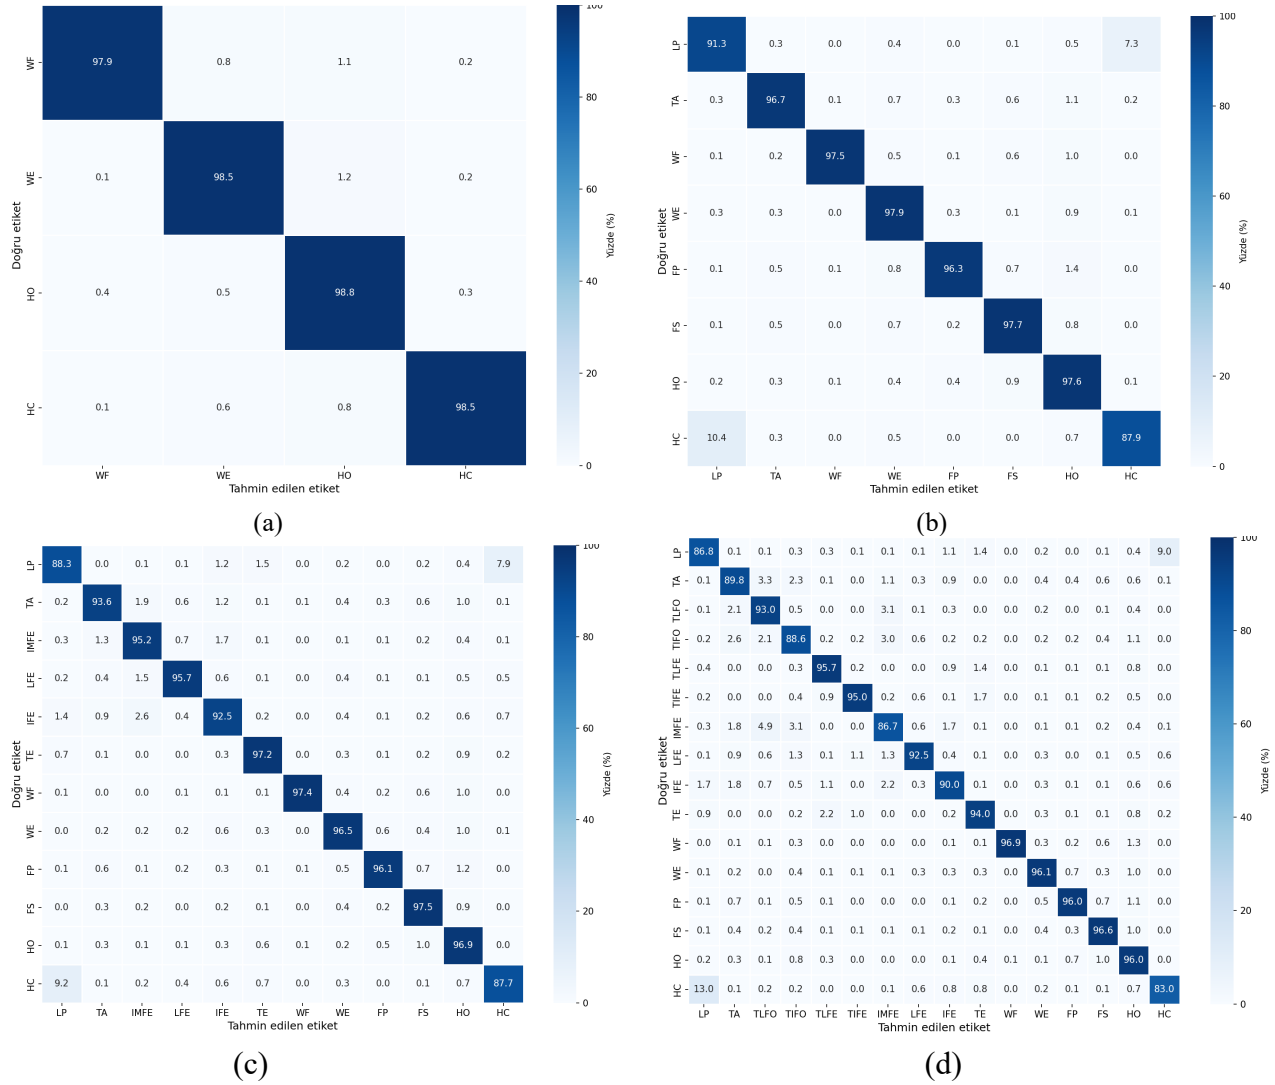

Figure 4. Confusion matrices obtained for the 28-channel electrode configuration across different movement repertoire sizes: (a) 4 movements, (b) 8 movements, (c) 12 movements, and (d) 16 movements.

III. CONCLUSION

The 28-channel combined wrist–forearm electrode configuration achieved the highest classification performance across all movement repertoires and, particularly for larger movement repertoires, maintained its performance more effectively than the other configurations. In contrast, the performance of the wrist-only and forearm-only configurations gradually converged as the movement repertoire increased. These findings indicate that complementary sEMG data from different anatomical regions make a substantial contribution to discriminating among movement classes, particularly when larger movement repertoires are considered. Overall, the findings highlight the importance of jointly considering movement repertoire size and electrode configuration in line with the requirements of different applications and provide useful insights for the design of scalable sEMG-based hand movement recognition systems.

Abstract
Although many studies have examined the flipped classroom model and the use of AI chatbots in education, there is still little research on the educational potential of AI assistants such as NotebookLM in this context. This study investigates how pre-service mathematics teachers perceive the use of NotebookLM when planning mathematics lessons based on the flipped classroom model and preparing accompanying teaching materials. The study involved eleven fourth-year undergraduate mathematics students enrolled in a teacher education program. Using NotebookLM, they created presentations, video materials, and quizzes for mathematics lessons. After completing and presenting their lesson plans, the participants answered an open-ended questionnaire. Their responses were analyzed using thematic analysis and interpreted through the TPACK framework. The results show that the participants considered NotebookLM a useful tool for preparing instructional materials and for checking students' basic understanding before class. However, they also pointed out that teachers need to review, adapt, and improve the generated materials before using them in practice. The findings suggest that incorporating NotebookLM into pre-service mathematics teacher education can contribute not only to the development of digital competencies but also to strengthening critical AI literacy and to integrating the technological, pedagogical, and mathematical knowledge required for effective lesson planning.

Keywords: *NotebookLM, flipped classroom, pre-service mathematics teachers, TPACK*

I. INTRODUCTION

In recent years, innovation in mathematics education — and education more broadly — has been increasingly driven by the integration of technology, particularly artificial intelligence (AI). Unlike general-purpose chatbots such as Gemini, ChatGPT, and similar systems that generate responses based on knowledge acquired from vast amounts of internet data, NotebookLM generates responses grounded in the user's provided sources. (e.g., PDF files, text documents, web links, etc.). Consequently, NotebookLM generates responses grounded in the provided sources, substantially reducing the likelihood of AI "hallucinations." Moreover, generated responses include citations that allow users to trace information back to the relevant parts of the uploaded materials. A particularly valuable feature for educators is its ability to rapidly generate summaries, presentations, study guides, and even video or audio overviews (podcasts) from uploaded instructional materials. In addition, a growing body of educational research highlights the benefits of instructional approaches that enable students to construct knowledge as independently as possible. One such approach is the flipped classroom model. Although numerous studies have examined the implementation, advantages, and limitations of the flipped classroom, as well as the integration of AI chatbots into teaching and learning, research combining the flipped classroom model with AI-based technologies remains remarkably scarce in the contemporary educational literature.

The present study aims to address this evident gap in the literature by exploring pre-service mathematics teachers' perceptions of using NotebookLM for mathematics lesson planning and for developing instructional materials based on predefined teaching guidelines. To this end, fourth-year undergraduate mathematics students at the Faculty of Science, University of Kragujevac, designed mathematics lessons following the flipped classroom model with the support of the AI assistant NotebookLM. After implementing and presenting their lesson plans, the students completed an open-ended questionnaire. For this study, we analyzed their responses to two open-ended questions through the lens of the TPACK framework to investigate how, following this experience, pre-service mathematics teachers perceive and integrate technological, pedagogical, and mathematical content knowledge during the lesson-planning process. The contribution of this paper, therefore, lies in the use of a source-grounded assistant NotebookLM for mathematics lesson planning and in interpreting pre-service teachers' reflections through TPACK.

II. LITERATURE REVIEW

In this chapter, we briefly present the characteristics of the flipped classroom, the application of AI in pre-service teacher education, and the TPACK framework for integrating AI into education.

1. Flipped classroom and mathematics education

In their theoretical framework for the flipped classroom, Tomas, Evans, Doyle & Skamp [1] summarize the characteristics of the flipped classroom model compared with traditional instruction (Table 1). As can be observed, activities typically conducted in the classroom, such as learning through direct teacher exposition, are performed individually outside the classroom. In contrast, activities like practice exercises and research, which are typically carried out outside school, are conducted in the classroom under the teacher's guidance [2].

Table 1. Differences between traditional lectures and the flipped classroom (adapted from Tomas et al., 2019, p. 17)

Traditional Instruction	Flipped Classroom Model
The teacher provides a high level of guidance to students.	The student exercises a high level of autonomy.
Students acquire knowledge and skills through direct instruction delivered by the teacher in the classroom.	Students acquire knowledge through the provided materials before class.
During the lesson, an approach centered on content and activities addressing lower cognitive levels is adopted.	Emphasis is placed on the development of higher-order cognitive skills.
Acquired knowledge is applied after class through task analysis and practice exercises.	Through an active-learning approach in complex and novel contexts, knowledge is applied and expanded during class.

The results of the meta-analysis conducted by Sopamena [3] indicate that students who learned new mathematical concepts through the flipped classroom model achieved significantly better learning outcomes than those taught using traditional instructional approaches. One of the key advantages of the flipped classroom over traditional teaching is its ability to accommodate diverse students' learning needs and learning pace while optimizing instructional time [4]. The flipped classroom model overcomes the time constraints of conventional instruction by extending learning beyond the classroom, thereby giving students more time to engage in learning activities outside school. This approach also enables students to become more autonomous in managing their

own learning. Students acquire new concepts, rules, and procedures through instructional videos and other learning materials at their own pace. Rather than merely transmitting information, teachers facilitate learning by encouraging students to become active and independent participants in the learning process [4].

2. Generative AI and teacher education

In a review paper by Tan [5], which analyzed 22 empirical studies, the author identified seven outcomes regarding teachers' use of GenAI: improved learning, teacher knowledge, lesson design and implementation, higher-order thinking, AI literacy, self-worth and self-confidence, positive attitudes, and usage intentions. Nyaaba and Zhai [6] argue that teachers need to become familiar with generative AI tools during their initial studies as a core component of teacher education and continuous professional development programs, highlighting the importance of strengthening educators' skills in innovative assessment practices. Similarly, Panday-Shukla [7] notes that pre-service teachers hold both positive and skeptical views toward GenAI technologies, emphasizing that their general digital literacy is far more developed than their AI literacy. Consequently, pre-service teachers are not yet fully prepared to teach in AI-dominated learning environments, underscoring the need to design and implement additional professional development opportunities to learn to use GenAI tools. While AI tools can significantly boost creativity and confidence in lesson planning for future math teachers, special attention must be paid to the pedagogical approach to avoid superficial learning [8].

3. AI and TPACK

The Technological Pedagogical Content Knowledge (TPACK) framework, introduced by Mishra and Koehler [9], has become one of the most widely adopted theoretical models for understanding how teachers effectively integrate technology into instructional practice. Rather than viewing technological, pedagogical, and content knowledge as separate domains, the framework emphasizes their interaction and teachers' ability to combine these forms of knowledge to support meaningful learning experiences [10]. Within this perspective, technology is not regarded as an isolated instructional component but as a resource whose educational value depends on how it is aligned with pedagogical approaches and subject-specific content. Recent studies have increasingly employed the TPACK framework to examine teachers' readiness to adopt generative AI in educational settings. For example, Bautista et al. [11] reported that prospective teachers in the Philippines generally demonstrated positive attitudes toward integrating AI tools into their professional preparation, indicating a growing acceptance of AI-supported teaching practices. Similarly, Cun and Huang [12] investigated pre-service teachers' perceptions of generative AI through semi-structured interviews interpreted within the TPACK framework. Their findings revealed two dominant perspectives. On the one hand, participants viewed generative AI as a valuable resource that could support teachers in planning and delivering instruction. On the other hand, they expressed concerns regarding the responsible implementation of AI in the future.

4. Research question

Despite the growing body of research on generative AI in education, empirical evidence concerning NotebookLM remains scarce. Little is currently known about how pre-service mathematics teachers incorporate NotebookLM into lesson planning, especially within the flipped classroom model, or how they integrate its use with their technological, pedagogical, and mathematical content knowledge. The present study seeks to address this gap by examining pre-service mathematics teachers' experiences with NotebookLM through the conceptual lens of the TPACK framework.

R.Q. How do pre-service mathematics teachers perceive the use of AI assistant NotebookLM for planning mathematics lessons and creating instructional materials within the flipped classroom model?

III. METHOD

The study was conducted as part of a fourth-year undergraduate mathematics teacher education course involving pre-service mathematics teachers. As part of their instruction on the flipped classroom model, the students were introduced to the AI assistant NotebookLM and its capabilities for generating instructional videos, PowerPoint presentations, and quizzes. The flipped classroom instruction lasted for two weeks (8 classes), with two additional classes dedicated to explaining the features and usage of NotebookLM. Subsequently, they were assigned to develop instructional materials for planning and implementing mathematics lessons based on the flipped classroom model, and were encouraged to use NotebookLM. The resources used by the students to create video materials, PowerPoint presentations, and comprehension check questions included textbooks, problem books, and other instructional materials they typically use for lesson planning. The materials were then presented in class, discussed, and evaluated by both peers and the teacher. Direct interaction with primary or secondary students was not included in this course module. The study was conducted with 11 students enrolled in a course that introduces the flipped classroom model. None of the students had formal teaching experience as employed schoolteachers; however, as part of their pedagogical practice, they had completed an 8-week school placement in primary and secondary schools, where they observed and participated in classes under the guidance of a mathematics mentor teacher. Additionally, none of them had received formal training in integrating AI tools into teaching before being introduced to NotebookLM. The course syllabus was updated to incorporate this AI tool to generate instructional materials for the flipped classroom model; however, the use of NotebookLM was optional, allowing students to create their materials without AI or with alternative tools. Interestingly, all 11 students who participated in both the course and the study chose to use NotebookLM to develop their instructional materials. They created both learning materials for students to study independently at home before the mathematics lesson (Figures 1 and 2) and quizzes (Figure 3) to assess whether pupils had reviewed the assigned materials and acquired the fundamental concepts and knowledge related to the instructor's assigned topic.

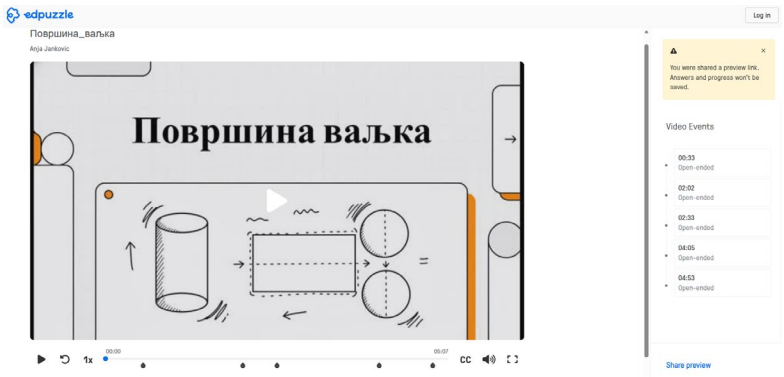

Figure 1. Video material for the lesson Surface Area of a Cylinder, created by a student in NotebookLM and then uploaded to the EdPuzzle platform for a flipped classroom lesson

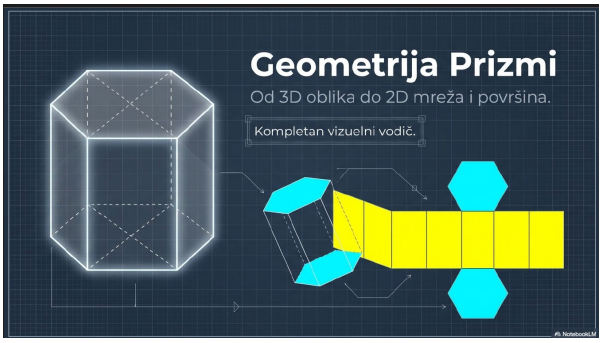

Figure 2. Presentation for the lesson Surface Area of a Prism, created by a student in NotebookLM for a flipped classroom lesson

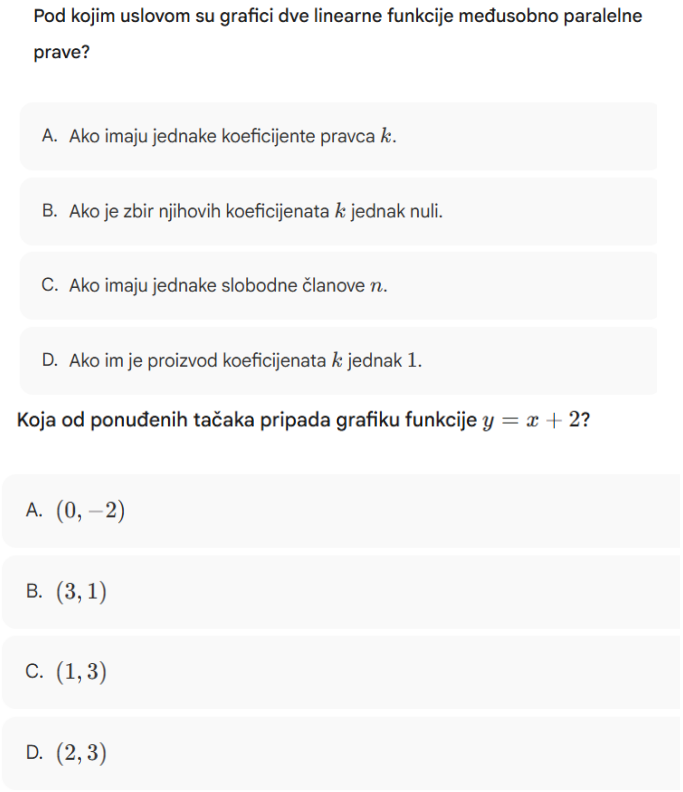

Figure 3. Quiz questions created by a student in NotebookLM to check content comprehension at home, before in-class learning for a flipped classroom model

The lesson topics corresponded to the final grade of elementary school (pupils aged approximately 15 years). The assigned topics covered geometry (similarity of triangles, Thales' theorem, polyhedra, solids of revolution, and their surface area and volume), algebra (linear equations and inequalities, and systems of linear equations), as well as an introductory topic in mathematical analysis (the linear function and its graph). Following the implementation of flipped mathematics lesson plans using the AI tool NotebookLM, pre-service teachers completed an open-ended questionnaire to provide insights into their perceptions of using this technology in

lesson planning and in the methodical design of instructional materials. For this study, we analyzed the responses to the following questions:

How do you evaluate the pedagogical quality of the knowledge assessment tests generated by NotebookLM?

How did using NotebookLM affect your perception of the teacher's role in a flipped classroom? Do you see AI as a collaborator that frees up time for more creative work with students, or as a factor that could uniformize and impoverish the instructional process?

Participation in the study was voluntary. Students were informed about the purpose of the research, and all responses were anonymized before analysis. The study was conducted after the end of the semester, so the students were under no obligation to answer the questions, and their participation had no bearing on their final course grades. The responses were analyzed using thematic analysis, following the guidelines outlined by Braun and Clarke [13]. First, the researchers independently familiarized themselves with the complete dataset, and initial codes were generated inductively from the participants' responses without assigning them to predefined TPACK categories. The researchers then compared related codes, grouped conceptually similar codes into broader categories, and iteratively refined the emerging themes. TPACK was not used as a predefined coding scheme during the initial coding stage. Instead, after the themes were established from the data, they were interpreted using the TPACK framework to examine the types of knowledge reflected in participants' responses. For this study, Technological Knowledge (TK) refers to familiarity with NotebookLM's capabilities, functionalities, practical applications, and potential limitations. Pedagogical Knowledge (PK) encompasses an understanding of learning processes, instruction, assessment, student engagement, and the teacher's role, independent of specific technology or mathematical content. Content Knowledge (CK) refers to the understanding of mathematical concepts, processes, and core mathematical activities that should be embedded in the developed materials, including conceptual understanding, reasoning, problem-solving, and real-world applications. Technological Pedagogical Knowledge (TPK) was identified when participants linked specific features or limitations of NotebookLM to concrete pedagogical considerations. Technological Content Knowledge (TCK) was recognized when participants connected the use or constraints of NotebookLM to how mathematical content is represented and processed. Pedagogical Content Knowledge (PCK) was coded when participants addressed pedagogically sound approaches to teaching mathematics in which the technological component played a secondary role. Finally, Technological Pedagogical Content Knowledge (TPACK) was identified when participants simultaneously aligned the technical capabilities or constraints of NotebookLM with pedagogical goals and the unique demands of mathematics learning. This operationalization was used to distinguish between statements that merely expressed a positive or negative stance toward artificial intelligence and those reflecting integrated professional knowledge.

IV. RESULTS AND DISCUSSION

The thematic analysis of student responses revealed that students generally perceive NotebookLM as a useful technological tool for preparing instructional materials within the flipped classroom model. At the same time, their responses indicate a strong critical awareness regarding the pedagogical limitations of this tool. Rather than unquestioningly accepting AI-generated content, students emphasize the importance of teachers' professional and critical judgment, highlighting the need to adapt, refine, and contextualize NotebookLM-generated materials. The identified themes were interpreted through the TPACK framework, providing insight into how pre-service teachers integrate technological, pedagogical, and mathematical content knowledge during lesson planning.

Theme 1: NotebookLM Effectively Supports Basic Knowledge Verification but Has Limited Capacity for Assessing Conceptual Understanding. The first and most prominent theme relates to the assessment of the pedagogical quality of tests generated by NotebookLM. Nearly all pre-service teachers (9 of them) believe that the tool successfully generates questions that verify whether students have reviewed the instructional materials and acquired the foundational concepts necessary for in-class activities. They describe the generated questions as "solid (P1)," "well-aligned with the presentation (P4)," and "suitable for basic knowledge checking (P5)." Seven students emphasize that this specific type of verification is an important function of the flipped classroom model—providing the teacher with information about whether students are prepared for subsequent classroom activities. In doing so, the students demonstrated that they evaluated the questions through an appropriate lens, analyzing them specifically within the context of their implementation in a flipped classroom model. One student noted that the generated questions are "solid for basic verification and recall, which is essentially the goal before students enter the classroom (P1)." In contrast, another student stated that the quiz "serves as an excellent check of whether students viewed the presentation and acquired what was necessary for that particular lesson (P7)." Similar views emerged across the majority of respondents, indicating a high degree of consensus regarding NotebookLM's core function during the student pre-class preparation phase. Conversely, 8 students simultaneously draw a clear distinction between verifying rote knowledge and evaluating true mathematical understanding. In their view, the questions generated by the tool primarily require recalling definitions, recognizing formulas, or remembering information explicitly presented in the slides. One respondent stated that students could successfully pass the test "simply by memorizing details they had previously seen (P8). It is particularly notable that students spontaneously differentiated between reproductive knowledge and conceptual understanding. They highlighted that high-quality assessment in mathematics instruction must incorporate tasks requiring analysis, knowledge integration, logical reasoning, and the application of mathematical concepts to novel situations. Such responses demonstrate a developed pedagogical awareness of the nature of mathematical comprehension, indicating that students do not equate successful quiz completion with genuine learning. Viewed through the TPACK framework, this theme primarily reflects the Technological Pedagogical Knowledge (TPK) component. Pre-service teachers demonstrate an understanding that a specific technology can effectively support a particular pedagogical goal—checking student readiness before class—while simultaneously recognizing the technology's limits when evaluating deeper mathematical comprehension.

Theme 2: The Pedagogical Value of AI Materials Emerges Only After Teacher Intervention

The second dominant theme concerns the need for teachers to adapt and refine the questions generated by NotebookLM. The majority of pre-service teachers (7 of them) believe that the generated quizzes serve as a solid starting point, but are not ready for immediate classroom application without further modification. Students reported rephrasing certain items, adding simpler problem-solving tasks, or incorporating questions that require applying knowledge in novel situations. One student noted that she "had to manually modify several questions and add problem-based tasks that require applying knowledge in a new context (P2)." At the same time, another mentioned reshaping the questions to demand analysis and application rather than mere recall. Interestingly, students do not view this additional refinement as a shortcoming of NotebookLM, but rather as an integral component of a teacher's professional practice. In other words, they perceive AI as a tool that accelerates the preparation of instructional materials, while the ultimate responsibility for quality rests with the mathematics teacher.

Within the TPACK framework, this theme represents the clearest illustration of Technological Pedagogical Content Knowledge (TPACK) in action. Pre-service teachers do not merely evaluate the tool's technological capabilities; rather, they synthesize AI affordances with pedagogical principles and the specific demands of mathematical content. Their pedagogical interventions demonstrate an understanding that high-quality

assessment in mathematics requires carefully designed tasks that foster reasoning, problem-solving, and conceptual understanding—elements that highlight why technology cannot replace teacher expertise.

Theme 3: NotebookLM Transforms the Role of the Teacher, but Does Not Replace It

Responses to the second questionnaire question provided rich insights into how pre-service teachers perceive the transformation of their professional role in an environment that integrates generative AI. Regardless of varying degrees of enthusiasm for NotebookLM, nearly all students (8) maintain that AI cannot replace the mathematics teacher. Six students described NotebookLM as a collaborator that handles routine technical tasks, allowing the teacher to devote more time to lesson planning, direct interaction with students, and the design of creative learning activities. They particularly emphasize the time savings achieved in creating presentations, video materials, and quizzes. One student noted that NotebookLM "freed up a vast amount of time that could be redirected toward creatively designing in-class activities (P3)." At the same time, another highlighted that the tool allows her to focus on "the essence of the profession—more creative engagement with students and tailoring instruction to their individual needs (P11). Simultaneously, pre-service mathematics teachers stress that the responsibility for quality control of instructional materials must remain with the teacher. Five respondents indicated that AI-generated materials should be carefully vetted before implementation, while some cautioned that uncritical reliance on NotebookLM could lead to a decline in instructional quality. One student observed that NotebookLM "merely helps prepare materials faster, but the teacher must judge whether it is of sufficient quality (P6)." At the same time, another emphasized that "the teacher's role remains pivotal because AI cannot function independently without constant oversight and correction (P9)." These findings suggest that pre-service teachers do not view AI as a replacement for the educator, but rather as an instrument that alters the nature of teaching practice. Instead of spending the majority of their time on technical material preparation, the teacher becomes an instructional designer, mentor, and professional decision-maker in lesson planning. Viewed through the TPACK framework, this theme illustrates that pre-service teachers are developing an understanding that successful technology integration requires more than digital proficiency alone; it demands the ability to thoughtfully embed tools into the instructional process while upholding professional pedagogical responsibility.

Theme 4: Critical AI Literacy as a Prerequisite for the Effective Integration of NotebookLM

Although pre-service teachers generally hold a positive attitude toward NotebookLM, a significant number of responses indicate a clear awareness of the potential risks associated with its uncritical application. Interestingly, however, students almost unanimously maintain that the problem lies not in the technology itself but in how the teacher uses it. Four student respondents noted that instructional standardization or homogenization could occur only if teachers uncritically accepted everything generated by NotebookLM. One student noted that AI could impoverish the educational process only if a teacher "blindly copies whatever the AI outputs (P10)," while other respondents cautioned that automatically generated materials must not become the sole source of instructional activities. These responses demonstrate that pre-service teachers do not view technology as an end in itself, but rather as a means whose value hinges directly on teacher competence. Their answers point to the development of critical AI literacy—specifically, the teacher's capacity to evaluate the quality of AI-generated content, recognize its limitations, and adapt it to the needs of a specific instructional setting. From the perspective of the TPACK framework, this theme confirms that the successful integration of AI technologies requires the simultaneous development of technological, pedagogical, and content (specifically mathematical) competencies. Only through their mutual synthesis will teachers be equipped to make sound didactic decisions when planning mathematics instruction using AI technology.

General Interpretation of Results Through the TPACK Framework

Taken as a whole, the results suggest that pre-service mathematics teachers do not perceive NotebookLM as an autonomous solution for instructional planning, but rather as a technological resource whose educational value hinges directly on the teacher's pedagogical and domain-specific knowledge. Their responses consistently emphasize the necessity for critical evaluation, adaptation, and refinement of AI-generated instructional materials. It is particularly noteworthy that students do not merely debate whether NotebookLM is useful; instead, they reflect deeply on the specific contexts, instructional goals, and pedagogical strategies through which it should be employed. Such reflection extends beyond the mere adoption of a new technology. It serves as a clear indicator of the development of integrated professional knowledge, as described by the TPACK framework, the harmonious synthesis of technological, pedagogical, and content competencies. Consequently, the findings suggest that embedding NotebookLM into lesson-planning activities within initial teacher education can not only enhance pre-service teachers' digital skills but also cultivate their capacity to critically and thoughtfully integrate generative artificial intelligence into mathematics instruction. The results of our research align with the pedagogical principles of the flipped classroom. Namely, pupils emphasize that students should study the material thoroughly at home and master foundational concepts before class [2],[4]. Accordingly, our students perceived NotebookLM-generated quizzes as appropriate tools for verifying pupils' readiness rather than for assessing higher-order mathematical thinking. They noted that the generated materials were visually appealing and engaging. These findings are also consistent with previous studies reporting that pre-service teachers generally perceive generative AI as a valuable assistant rather than a replacement for teacher expertise [5],[7],[8]. Participants in this study emphasized that instructional quality depends on teachers' judgment and their ability to adapt AI-generated materials to specific mathematical content and classroom activities. From the perspective of the TPACK framework, the results suggest that participants did not perceive technology as an isolated competence. They viewed NotebookLM as a technological resource whose educational value depends on pedagogical decisions and content knowledge. This supports the central assumptions of the TPACK framework [9] and suggests that learning to work with an AI assistant should focus not only on developing digital skills but also on cultivating integrated professional knowledge.

V. CONCLUSION

This study explored pre-service mathematics teachers' perceptions of using NotebookLM for planning mathematics lessons within the flipped classroom model through the lens of the TPACK framework. The findings suggest that the participants perceived NotebookLM as a useful tool for developing instructional materials, including presentations, video content, and quizzes, particularly for supporting pupils' pre-class preparation. At the same time, they emphasized that high-quality mathematics instruction cannot rely solely on AI-generated materials. Instead, effective lesson planning requires teachers to critically evaluate, adapt, and enrich the generated content by drawing on their pedagogical expertise and mathematical knowledge. The findings also underline the importance of developing critical AI literacy alongside digital competencies in initial teacher education. Providing pre-service teachers with opportunities to work with source-based generative AI tools, such as NotebookLM, may not only improve their technological skills but also foster more reflective, pedagogically informed, and critically aware approaches to integrating artificial intelligence into mathematics education. This study has several limitations. First, the sample consisted of only eleven pre-service mathematics teachers from a single teacher education program, limiting the transferability of the findings. Second, the results were based exclusively on participants' self-reported perceptions. Finally, the study examined only short-term experiences with NotebookLM, which may have been influenced by the researcher, subject to social desirability bias, and limited to a narrow two-question dataset. Future research should therefore investigate the long-term integration of source-based generative AI tools in teacher education and compare NotebookLM with other generative AI systems used for instructional planning.

SpecGuard: Multi-Layer Quality Assessment of Natural-Language FPGA Requirements

Anton Striapunin
Department of Cybersecurity and Intelligent Information Technologies, National Aerospace University "Kharkiv Aviation Institute"
Kharkiv, Ukraine
a.o.striapunin@csn.khai.edu

Abstract
Natural-language specifications remain an important input artifact in the development and verification of FPGA-based components, including safety-critical airborne electronic hardware. Although natural language processing for requirements engineering has been widely studied for software requirements, open FPGA specifications remain underexplored as a target for automated quality assessment. This paper presents SpecGuard, a multi-layer framework for assessing the quality of natural-language FPGA requirements before downstream verification and formalization activities. SpecGuard combines rule-based requirements-smell detection, linguistic metrics, composite quality scores, and PASS/WARN/FAIL gating rules. The smell catalog is mapped to ISO/IEC/IEEE 29148 quality characteristics and prioritized with respect to DO-254-oriented verification concerns. A pilot study of 64 requirements from the open-source CVA6 RISC-V specification evaluates the distribution of smells, readability, and syntactic complexity metrics, the behavior of scores, and sensitivity to seeded defects. The results show that SpecGuard can process a mature industrial open-source FPGA specification and produce a diagnostic baseline for future comparative studies. The study is limited by the single-corpus design, the author-proposed severity weights, which are not yet empirically calibrated, and the absence of independent expert annotation.

Keywords: requirements engineering, requirements smells, FPGA, DO-254, NLP4RE, quality assessment, verification.

I. INTRODUCTION

Natural-language requirements remain the primary means of expressing the functional and non-functional properties of engineering systems. In safety-critical domains, the quality of these requirements directly affects the feasibility of subsequent review, verification, traceability, and certification-related activities. ISO/IEC/IEEE 29148:2018 defines several characteristics of a well-formed requirement, including unambiguity, completeness, singularity, feasibility, verifiability, correctness, and conformance to the prescribed style [1]. However, the standard defines desired properties rather than operational procedures for automated measurement. For airborne systems, the situation is further complicated by the separation between software assurance and airborne electronic hardware assurance. Software components are typically considered in relation to RTCA DO-178C, while FPGA, ASIC, and PLD components fall under the design-assurance guidance of RTCA DO-254 [2], [3]. In this context, natural-language specifications of FPGA components are early-life-cycle inputs that influence subsequent verification activities, including test development, assertion synthesis, traceability analysis, and the review of design-assurance evidence. By FPGA requirements, we mean natural-language requirements for HDL-implemented digital hardware (soft IP cores and FPGA/ASIC designs described in VHDL or Verilog), as distinct from requirements for software running on a fixed microprocessor. The distinction is regulatory rather than stylistic: such hardware falls under DO-254 design-assurance guidance, whereas microprocessor-hosted software falls under DO-178C, even though both share the natural-language specification medium. In this paper,

the unit of analysis is the HDL design at the core or IP level, not a full board- or system-level integration; system-level hardware/software interaction is out of scope and noted as future work. Natural language processing for requirements engineering has become an active research field. Existing work covers tasks such as requirements classification, ambiguity detection, traceability, and quality assessment [4], [5]. At the same time, most existing work focuses on software requirements or specific regulated domains, while natural-language FPGA specifications remain underrepresented as a research object. This creates a methodological and empirical gap: it is unclear which quality indicators are suitable for FPGA specifications and how they behave in realistic industrial open-source artifacts. This paper introduces SpecGuard, a lightweight multi-layer framework for automated assessment of natural-language FPGA requirements. The framework is not intended to prove certification readiness or replace expert review. Instead, it acts as a diagnostic quality gate, identifying rule-based quality issues before requirements are used in downstream verification or formalization activities. The main contributions are: (1) a multi-layer framework for assessing natural-language FPGA requirements; (2) a DO-254-oriented adaptation of requirements-smell analysis; and (3) a pilot empirical evaluation on the CVA6 RISC-V specification, including smell distribution, linguistic metrics, composite scores, gate decisions, and a seeded-fault sensitivity check.

II. RELATED WORK

1. Requirements Quality and Quality Characteristics

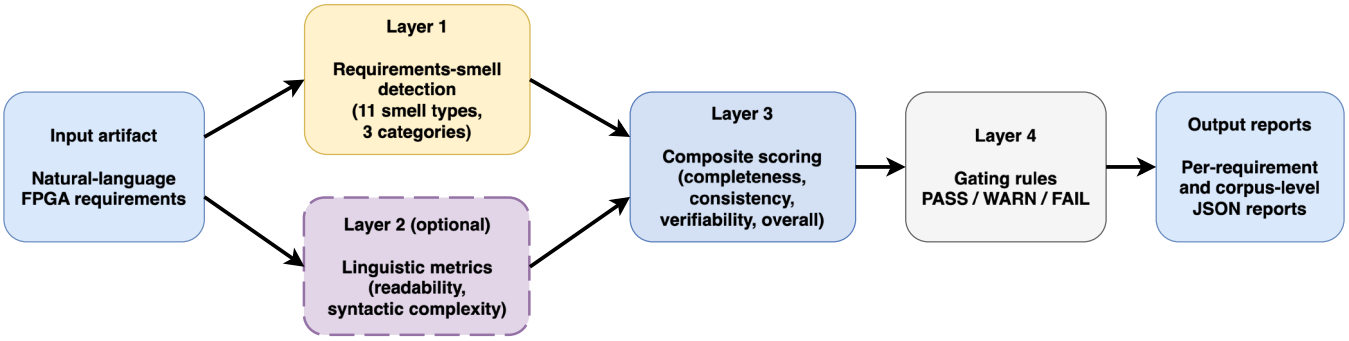
The normative basis for requirements quality is commonly associated with ISO/IEC/IEEE 29148:2018, which defines quality characteristics of individual requirements and requirements specifications [1]. These characteristics provide a useful vocabulary for discussing the quality of requirements, but they do not directly define measurable indicators or automated procedures. Systematic studies of requirements quality indicate that the field remains methodologically fragmented. Different studies use different attribute definitions, datasets, measurement procedures, and validation strategies [6]. This motivates the use of a transparent and diagnostic framework rather than a single scalar quality score.

2. Requirements Smells

Requirements smells provide an operational bridge between abstract quality characteristics and detectable linguistic symptoms. Femmer et al. framed smells as concrete indicators of potential quality problems in natural-language requirements [7]. Later studies demonstrated that smell catalogs can be adapted to specific domains and industrial contexts, including finance, safety-critical defense systems, and aircraft systems [8–10]. For the present work, requirements smells are attractive because they are interpretable, deterministic, and actionable. Each detected smell can be associated with a specific text fragment, a quality characteristic, and a recommendation for review.

3. Quantitative Quality Metrics

Several approaches aggregate quality indicators into composite metrics. Some frameworks use rule-based compliance with requirement-writing guidelines, while others focus on testability, readability, or syntactic complexity [11], [12]. However, a single aggregate score may hide diagnostic information. SpecGuard, therefore, combines composite scores with explicit smell reports and gating decisions. Linguistic metrics such as Flesch Reading Ease, Flesch-Kincaid Grade Level, and Mean Dependency Length provide an additional layer of analysis [13], [14]. They do not directly measure correctness or verification readiness, but they can reveal readability and syntactic-complexity patterns that smell detectors do not capture.



4. FPGA Specifications and Regulated Environments

Existing work on regulated requirements engineering has mainly focused on software-intensive systems and standards such as DO-178C, IEC 62279, and IEC 62304 [15], [16]. FPGA-specific natural-language specifications are less visible in NLP4RE research, despite the importance of FPGA-based components in critical systems. Open-source hardware projects such as CVA6 offer a practical way to study industrial-grade FPGA documentation without relying on proprietary artifacts. CVA6 has been used as a benchmark in hardware verification research, including studies on HDL and assertion synthesis [17]. However, its natural-language requirements have not been systematically analyzed as part of a requirements-quality corpus.

III. SPECGUARD FRAMEWORK

1. Framework Overview

SpecGuard is organized as a four-layer pipeline. Layer 1 detects requirements smells in individual requirements. Layer 2 computes linguistic metrics, including readability and syntactic-complexity indicators. Layer 3 aggregates smell and metric information into composite quality indicators. Layer 4 assigns a PASS, WARN, or FAIL decision based on the gating rules. The purpose of this layered architecture is to avoid two extremes. Isolated low-level metrics do not provide an actionable per-requirement verdict (PASS / WARN / FAIL) that an engineer can act on during review. Conversely, a single aggregate score hides the nature of the detected problem. SpecGuard, therefore, preserves diagnostic information while still producing a practical gate decision. Figure 1 summarises the pipeline overview.

Layer 2 (dashed border) is an optional component that requires textstat and spaCy.
When enabled, its linguistic metrics are aggregated into Layer 3 alongside smell signals from Layer 1.

Figure 1. Pipeline overview of the SpecGuard framework. Layer 2 (dashed border) is an optional component; when enabled, its linguistic metrics are aggregated with smell signals from Layer 1 into Layer 3.

2. Smell Catalog

The current SpecGuard catalog contains 11 smell types grouped into three categories. Table 1 records a diagnostic ISO/IEC/IEEE 29148 association, not a one-to-one scoring map. The implementation penalizes verifiability for ambiguity, vagueness, subjectivity, comparative, and missing_unit, and completeness for placeholder, implicit_reference, and optionality. Weakness, non-verifiable, and negative statements remain report-only diagnostics; consistency is determined using separate text heuristics. Severity, therefore, affects the

score only for smells in the implemented scoring set. The mappings and severity values are author-assigned and require expert calibration (Section VI).

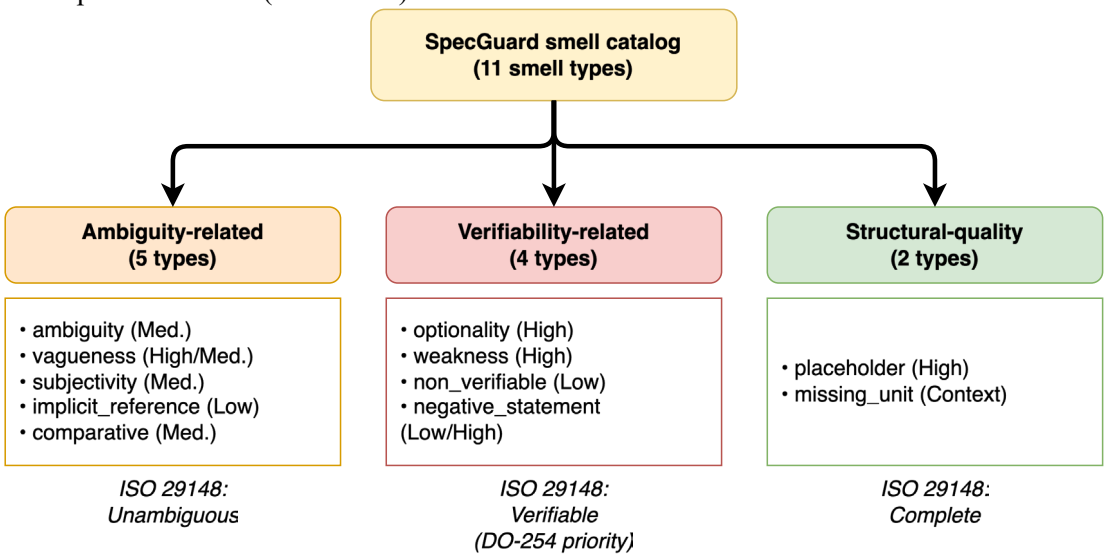


Figure 2. Hierarchy of the SpecGuard smell catalog: three categories aligned with ISO/IEC/IEEE 29148 quality characteristics.

Table 1. REQUIREMENTS-SMELL CATALOG USED IN SPECGUARD Cat. is the catalog grouping (ambiguity/verifiability / structural) used to organize detectors; Quality is the ISO/IEC/IEEE 29148 quality characteristic that the smell violates.

Type	Cat.	Quality	Sev.
ambiguity	Amb.	Unambiguous	Med.
vagueness	Amb.	Unambiguous	High/Med.
subjectivity	Amb.	Unambiguous	Med.
implicit_reference	Amb.	Unambiguous	Low
comparative	Amb.	Unambiguous	Med.
optionality	Verif.	Verifiable	High
weakness	Verif.	Verifiable	High
non_verifiable	Verif.	Verifiable	Low
negative_statement	Verif.	Verifiable	Low/High
placeholder	Struct.	Complete	High
missing_unit	Struct.	Complete/Verif.	Context

3. Linguistic Metrics and Gating Rules

The linguistic layer computes Flesch Reading Ease, Flesch-Kincaid Grade Level, Mean Dependency Length, token count, sentence count, average sentence length, and lexical density. These metrics are not interpreted as

direct evidence of correctness. Instead, they serve as supplementary indicators of cognitive load and syntactic complexity.

SpecGuard computes completeness, consistency, verifiability, and overall = 0.30 × completeness + 0.25 × consistency + 0.45 × verifiability. Scores are bounded to [0, 1] and rounded to three decimals; absence of a smell does not necessarily yield 1.0. Completeness starts at 0.70, adds 0.20 for modal commitment and 0.10 for an uppercase subject identifier, then subtracts mapped penalties; placeholders incur the normal penalty plus an additional 1.5 × severity. Verifiability starts at 0.50, adds 0.30 for a measurable criterion, and up to 0.20 for modal strength, then subtracts mapped penalties. Consistency starts at 1.0 and subtracts 0.20 for co-occurring positive and negative mandatory forms and 0.15 for mixed mandatory and optional modality. Cross-requirement consistency is outside the present gate. Layer 4 assigns PASS for overall ≥ 0.75, WARN for 0.50 ≤ overall < 0.75, and FAIL otherwise. PASS means only that the weighted score meets the threshold; smells may remain, and the requirement is not thereby correct or certification-ready. The weights are author-proposed, following prior composite-quality practice [18], and require expert calibration and sensitivity analysis.

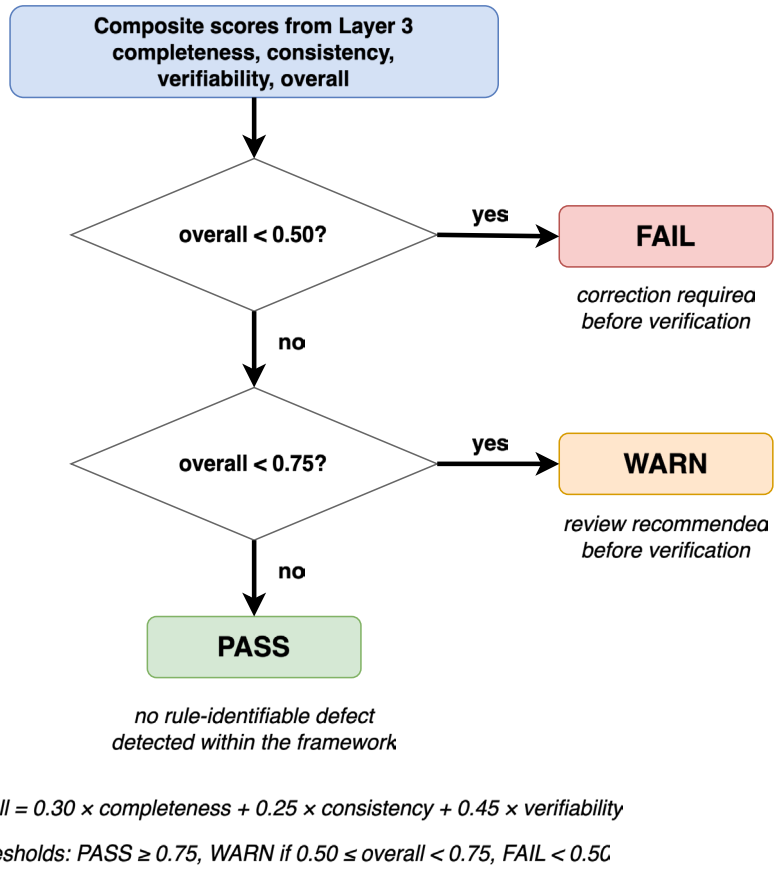

Figure 3. Layer 4 gating decision flow. Thresholds applied to the composite overall score: PASS ≥ 0.75, WARN if 0.50 ≤ overall < 0.75, FAIL < 0.50.

IV. IMPLEMENTATION AND STUDY DESIGN

1. Prototype Implementation

SpecGuard was implemented as a Python package with a deterministic core and optional extensions. The core implements smell detection, composite scoring, and gating decisions using standard Python facilities and curated lexical patterns. The optional linguistic layer uses Textstat for readability metrics and spaCy for dependency parsing [19], [20]. The tool produces per-requirement and corpus-level JSON reports to support reproducibility. SpecGuard uses no machine-learning models. Smell detection is deterministic, based on regular expressions and curated lexicons derived from Femmer et al. [7]; the optional linguistic layer uses spaCy solely for dependency parsing and textstat for classical readability formulas. This is a deliberate design choice favoring transparency, auditability, and amenability to future DO-330 tool-qualification analysis, rather than the higher recall an opaque machine-learning classifier might offer. The current prototype implements 11 active smell detectors and includes automated tests for core detector behavior, scoring, pipeline integration, and selected auxiliary modules.

2. Research Questions and Corpus

The pilot study is organized around four research questions: RQ1 asks how detected requirements smells are distributed across the CVA6 specification; RQ2 examines the linguistic-metric profile of the CVA6 requirements; RQ3 investigates whether the layers of SpecGuard provide complementary signals; and RQ4 evaluates the sensitivity of SpecGuard to controlled, seeded defects. The empirical study uses a corpus of 64 requirements from the CVA6 RISC-V specification [21]. CVA6 is an open-source 64-bit RISC-V processor core developed by the OpenHW Group. It is used here as an industrial-grade representative open-source FPGA specification of comparable complexity, not as a DO-254-certified product. The single WARN requirement (L1W-60) contains a vagueness smell triggered by the quantifier "some". The two FAIL requirements (PPA-50 and PPA-60) contain explicit "TBD" placeholders and receive high-severity completeness penalties. Because their texts contain neither a modal commitment nor a measurable target, verifiability remains at the 0.50 baseline; the placeholder itself does not penalize verifiability. The detected smells are concentrated in five types. Table 3 shows the distribution.

Table 2. Detected Smell Distribution in the CVA6 Corpus

Smell type	**Count**
implicit_reference	4
negative_statement	3
missing_unit	2
placeholder	2
vagueness	1

V. RESULTS

1. RQ1: Smell Distribution

SpecGuard detected 12 smell events across 11 of the 64 requirements (17.2% flag rate); the event count exceeds the requirement count because one requirement carries two distinct smells. This corresponds to a relatively low concentration of detected smells, which is expected for a mature open-source specification. Table 2 summarises the corpus-level results.

Table 3. Corpus-Level Specguard Results On Cva6

Indicator	Value
Requirements	64
Req. with smells	11
Smell events	12
PASS	61
WARN	1
FAIL	2
Avg. overall	0.888
Avg. verifiability	0.777
Avg. completeness	0.961

Six of the eleven smell types in the SpecGuard catalog were not triggered on the CVA6 corpus. This pattern is consistent with the description of CVA6 as a mature open-source specification: ambiguity, subjectivity, comparability, optionality, weakness, and non-verifiability are typically associated with under-specified or stylistically weak requirements, which are less common in projects that have undergone multiple rounds of community review.

2. RQ2: Linguistic Metrics

The linguistic metrics show a profile consistent with technical requirements: moderate readability, relatively short requirements, and moderate syntactic complexity. Table 4 reports the descriptive statistics.

Table 4. Descriptive Statistics Of Linguistic Metrics

Metric	Mean	Median	Max
FRE	46.04	47.60	78.87
FKGL	10.84	10.10	30.97

Metric	Mean	Median	Max
MDL	3.06	2.89	5.88
Max dep.	16.41	12.00	91.00
Tokens	22.20	19.50	101.00
Lex. density	0.40	0.40	0.60

The average Flesch Reading Ease score of 46.04 falls within the range expected for technical specifications. The average FKGL value of 10.84 is lower than might be expected for complex engineering prose, which the short, structured form of many CVA6 requirements can help explain. The average MDL of 3.06 indicates moderate syntactic complexity.

3. RQ3: Complementarity of Framework Layers

Correlation analysis was used to examine whether different layers of the framework provide complementary information. Table 5 reports selected Spearman correlations between SpecGuard indicators.

Table 5. Spearman Correlations Between Selected Indicators

Pair	Coeff.	Interpretation
Smell count − overall	−0.531	strong neg.
Smell count − verifiability	−0.474	moderate neg.
MDL − overall	+0.447	moderate pos.
MDL − verifiability	+0.420	moderate pos.
FRE − overall	+0.215	weak pos.
FKGL − overall	−0.073	negligible
Token count − MDL	+0.598	strong pos.

The weak or negligible relationship between Flesch-based metrics and composite scores supports the use of multiple layers. Readability formulas alone are insufficient for assessing the quality of technical FPGA requirements. The positive correlation between MDL and overall score is counterintuitive at first glance. Still plausible: in the CVA6 corpus, longer requirements with higher MDL tend to contain more explicit quantification, protocol references, and standard citations, thereby improving their verifiability.

4. RQ4: Seeded-Fault Sensitivity Check

A seeded-fault experiment was conducted to evaluate the detectors' sensitivity to controlled, rule-detectable defects. For each of the five mutation types (ambiguity, vagueness, optionality, placeholder, and comparative forms without a baseline), ten PASS requirements were sampled and mutated, producing 50 seeded-defect cases.

Across these 50 controlled mutations, every injected defect was detected (10/10 per type). This result should be interpreted as a sanity check of detector behavior, not as a general precision or recall estimate for industrial requirements. The experiment does not evaluate semantic defects or false-positive rates on independently annotated corpora.

Because these mutations are drawn from the detector's own trigger lexicon, the 50/50 result (100%; 10/10 per type) is expected by construction and is only an end-to-end implementation check. Two additional checks probe coverage. None of the 50 mutations using expressions verified as disjoint from the same-category trigger vocabulary was detected (0/50, 0%). An LLM-authored blind set yielded 14/49 detections (28.6%). Thus, the closed catalog does not generalize reliably to unseen forms. The repository also reports an exploratory estimate of 8/64 (12.5%) clean-corpus flag after an author-defined exclusion of three known defects; without independent expert ground truth, it is not a formal false-positive rate. Generalization and precision require annotated data, expert calibration, lexicon expansion, or complementary semantic analysis independently.

5. Worked Example: From Detected Smell to Gate Decision

To illustrate how an individual smell propagates to the gate decision, we trace two CVA6 requirements through the scoring pipeline.

Requirement L1W-60 — "Some physical memory regions shall be configurable as not L1WTD cacheable at design time." — triggers a single vagueness smell on the quantifier "some" (high severity). Vagueness is a verifiability-related smell, so the penalty is applied to the verifiability sub-score, which drops to 0.10, while completeness and consistency remain at 1.00. The overall score is $0.30 \cdot 1.00 + 0.25 \cdot 1.00 + 0.45 \cdot 0.10 = 0.595$, which falls in the WARN band [0.50, 0.75). The requirement is structurally complete but not yet objectively testable, so it is flagged for review rather than rejected.

Requirement PPA-50 — "TBD: Placeholder for single-precision floating performance per MHz." — triggers a single placeholder smell on "TBD" (high severity). Completeness starts at 0.80 for this text and receives both the ordinary high-severity penalty and the additional 1.5 × placeholder penalty, yielding 0.00 after bounding. The placeholder does not directly penalize verifiability; the score remains at its 0.50 baseline because the text has neither a modal commitment nor a measurable target. Consistency remains 1.00. Overall is $0.30 \cdot 0.00 + 0.25 \cdot 1.00 + 0.45 \cdot 0.50 = 0.475$, below the 0.50 FAIL threshold. The requirement must be completed before HDL design or verification.

These cases show that outcomes depend on both text-derived baselines and the implemented mappings (Table 6): vagueness reduces verifiability in L1W-60, whereas the placeholder reduces completeness in PPA-50. SpecGuard emits the smell, trigger, severity, sub-scores, and gate decision as JSON for review and reproducibility.

Table 6. Worked Example: Smell-To-Score Propagation

Req.	**Smell (trigger)**	**Sev.**	**Comp.**	**Cons.**	**Verif.**	**Overall**	**Gate**
L1W-60	vagueness ("some")	High	1.00	1.00	0.10	0.595	WARN
PPA-50	placeholder ("TBD")	High	0.00	1.00	0.50	0.475	FAIL

VI. DISCUSSION AND THREATS TO VALIDITY

The pilot study indicates that SpecGuard can be applied to a mature open-source FPGA-related specification without rewriting the requirements into a controlled template language. The results also support the design decision to preserve both diagnostic details and aggregate indicators. A single score would not explain whether a requirement is problematic because of vagueness, missing units, weak modality, or syntactic complexity. In practical terms, SpecGuard is intended for the requirements author or verification engineer at the point before requirements enter HDL design and assertion development. It acts as an automated pre-review gate in the requirements-capture phase of a DO-254 lifecycle: the engineer runs it on a draft specification, receives a per-requirement smell report and a PASS/WARN/FAIL verdict, and resolves flagged issues before the requirements are baselined. The practical value is reduced downstream rework, since vague, unverifiable, or incomplete requirements are caught at authoring time rather than during a Stage-of-Involvement review or test development, when correction is substantially more expensive.

The study does not demonstrate certification readiness, nor does it claim that CVA6 is DO-254 compliant. CVA6 is used as a representative open-source artifact of comparable hardware complexity.

Construct validity is limited because requirements smells are only proxies for quality problems. A smell-free requirement may still be incorrect, incomplete, or inconsistent with stakeholder intent, and no independent expert annotation is available as ground truth. The distribution of smells is therefore an output of the current operational definitions, not a validated defect distribution. Lexicon coverage is limited: recall was 0/50 (0%) on the deliberately disjoint tier and 14/49 (28.6%) on the LLM-authored blind tier, versus 50/50 on the own-lexicon sanity check. The first measures the closed-vocabulary boundary; the second is less constrained but not expert-authored. Neither is a validated industrial precision/recall estimate.

External validity is limited by the single-corpus design. Results may differ for other FPGA projects such as Ibex, OpenTitan, CV32E40P, or proprietary industrial specifications. Conclusion validity is also limited because the study is descriptive and exploratory. Correlation values and seeded-fault results should not be interpreted as statistically generalizable claims. A further limitation on construct validity is that the current smell catalog does not distinguish among requirement abstraction levels. In a hierarchical specification, high-level (parent) requirements are expected to be more abstract and to tolerate a degree of ambiguity that is inappropriate at the low-level (child) requirement layer, where requirements should be concrete and directly verifiable. SpecGuard currently applies a single rule set to all requirements, regardless of level; consequently, the reported flag rate may overstate the number of quality issues for intentionally high-level requirements. Level-aware smell thresholds, relaxing ambiguity penalties for parent requirements while tightening verifiability penalties for child requirements, are identified as future work.

VII. CONCLUSION

This paper presented SpecGuard, a multi-layer framework for assessing the quality of natural-language FPGA requirements. The framework combines deterministic requirements-smell detection, linguistic metrics, composite quality scores, and PASS/WARN/FAIL gate decisions. A pilot study on 64 CVA6 RISC-V requirements demonstrated that the framework can process an industrial open-source FPGA-related specification and produce diagnostic outputs suitable for further review. The main contribution is not a claim of certification readiness, but a reproducible quality-assessment baseline for natural-language FPGA specifications. Future work will extend the evaluation to additional open-source hardware corpora, introduce expert annotations, empirically calibrate severity weights, and investigate graph-based traceability and compliance analysis.

Abstract
Gallstone disease is a common gastrointestinal disorder for which non-invasive pre-imaging risk prediction using routine clinical and bioimpedance data may serve as a low-cost screening aid. Beyond predictive performance, counterfactual explanations can show clinicians how changes in input features could alter a model's decision, without implying that such changes represent actionable clinical recommendations. However, the consistency and trade-offs of different counterfactual generation methods remain insufficiently characterized in gallstone prediction. This study compares two counterfactual explanation methods, DiCE and PertCF, using 31 test-set patients predicted as gallstone-positive by a tree-based ensemble trained on clinical and bioimpedance data from 319 patients. The methods were evaluated using matched, paired statistical tests under a common backward-elimination post-processing protocol. DiCE and PertCF did not differ significantly in sparsity (median 2.0 features for both, Holm-adjusted p=0.313) or proximity (Holm-adjusted p=0.544). In contrast, PertCF was substantially faster (median 0.625 s vs. 3.80 s; Holm-adjusted $p < 0.001$). PertCF also exhibited a numerically higher rate of one-sided changes within strongly correlated feature pairs than DiCE (54.8% vs. 38.7%), although this difference was not statistically significant (exact McNemar p=0.125). The ensemble classification backbone showed no significant advantage over a simpler two-model average under nested cross-validation (p=0.206). SHAP analysis and univariate comparisons provided convergent evidence highlighting C-Reactive Protein and Vitamin D. Overall, neither counterfactual method was uniformly superior: PertCF demonstrated a clear computational advantage, while differences in the preservation of strong empirical feature dependencies remained statistically inconclusive.

Keywords: counterfactual explanations, DiCE, PertCF, explainable AI, gallstone disease, clinical decision support

I. INTRODUCTION

Gallstone disease (cholelithiasis) is a common gastrointestinal disorder worldwide, with prevalence varying across populations, sex, and age [1]. Although many gallstones remain asymptomatic, symptomatic disease may progress to biliary colic, cholecystitis, or pancreatitis and may ultimately require surgical management [2]. Abdominal ultrasonography is the standard first-line imaging modality for suspected gallstone disease [2]. Non-invasive risk prediction using routinely available clinical, laboratory, and bioimpedance measurements may therefore provide a low-cost pre-imaging screening aid. A publicly available dataset comprising 319 individuals with clinical, laboratory, and bioimpedance measurements [3] has enabled several machine-learning studies of gallstone prediction. Across these studies, C-reactive protein (CRP) and Vitamin D have repeatedly emerged among prominent predictive features [3-6]. Existing work has also incorporated post-hoc explanation methods such as SHAP and LIME, while DiCE has been used to generate individual counterfactual explanations [5]. However, to our knowledge, existing studies on this benchmark have not systematically compared multiple

counterfactual generation methods using paired measures of coverage, sparsity, proximity, computational cost, and preservation of empirical feature dependencies. Beyond predictive performance, counterfactual explanations provide instance-level information about how changes in the input space could alter a model's prediction, complementing feature-attribution methods that primarily characterize feature contributions [7]. This study considers two structurally distinct approaches: DiCE [8], implemented with its genetic search strategy, and PertCF [9], a perturbation- and ablation-based approach designed for computational efficiency. Previous counterfactual benchmarking studies have shown that generation strategies can differ substantially in validity, proximity, sparsity, and computational cost [10]; however, these trade-offs have not been systematically characterized for the gallstone prediction benchmark considered here. Accordingly, the primary objective of this study is to conduct a paired comparison between DiCE and PertCF on the same patient cohort using a common backward-elimination post-processing protocol. Both methods are evaluated against the same fixed tree-based classification backbone, thereby isolating differences attributable to the counterfactual generation procedure. The classification backbone is assessed separately using nested cross-validation to determine whether its optimized weighting provides a measurable benefit over a simpler ensemble strategy. The main contributions are:

- A matched, paired evaluation of DiCE and PertCF in terms of coverage, sparsity, proximity, and computational cost; paired differences in sparsity, proximity, and computational cost were assessed using Holm-adjusted Wilcoxon signed-rank tests.
- A dependency-consistency analysis quantifying one-sided counterfactual changes within strongly correlated feature pairs ($|r| \geq 0.80$) identified from the training data, with paired differences evaluated using an exact McNemar test.
- A complementary analysis examining convergence among univariate associations, SHAP-based feature attribution, and features modified by counterfactual explanations.

II. RELATED WORK

Esen et al. [3] compiled the dataset used here and reported 85.4% accuracy, with Vitamin D, CRP, total body water, and lean mass as the top predictors. Kothari et al. [4] compared a tuned XGBoost against RF and AdaBoost (test AUC=0.859) using SHAP and LIME, without repeated cross-validation or significance testing. Das et al. [5] proposed an SLOA-optimized CatBoost (5-fold CV accuracy 80.4%) using SHAP, LIME, and DiCE, again finding CRP and Vitamin D dominant. Akben and Yumrutas [6] used a stacked SVM/logistic regression/decision tree ensemble with nested cross-validation (82.3% accuracy, 85.7% AUC) and explicitly reported that strong multicollinearity (VIF > 100) destabilizes Vitamin D's SHAP direction, an independent parallel to the dependency-consistency issue documented in Section IV. None of these studies benchmarks the quality of counterfactual outputs or compares multiple counterfactual methods. Counterfactual explanations. Wachter et al. [7] introduced the foundational framework. DiCE [8] uses genetic search to generate diverse counterfactuals; PertCF [9] uses ablation-based feature importance with greedy median shifting at a much lower cost. Bayrak et al. [10] conducted a comparative benchmark of multiple counterfactual explanation methods across several classifiers in network-resilience classification, demonstrating that counterfactual methods can differ substantially in output quality and computational efficiency. The present study extends this comparative perspective to clinical tabular data by directly evaluating DiCE and PertCF on the gallstone prediction task.

Calibration and clinical utility. Calibration provides an additional, secondary check on a classifier's clinical relevance beyond discrimination [11]; this has not previously been reported for this dataset, though a full decision-analytic evaluation is beyond the scope of this paper.

III. METHODOLOGY

1. Dataset

The public gallstone dataset [3] contains 319 patients with 38 clinical and bioimpedance features and a binary gallstone-presence label: 161 negative (50.5%) and 158 positive (49.5%). Data were split 80/20 (stratified; n=255 train, n=64 test).

2. Preprocessing and Descriptive Comparison

Group comparisons (Table 1) used only the training set (n=255) and are strictly descriptive; they were not used for feature selection or model development, and all 38 features were entered into every model unchanged. Normality was assessed with the Shapiro-Wilk test; Welch's t-test or Mann-Whitney U was used accordingly, and chi-square/Fisher's exact test for categorical variables, with Benjamini-Hochberg FDR correction [12] across 38 features.

Table 1. Selected Features with The Strongest Group Differences (N=255)

Feature	**Test**	**p_FDR**	**Effect size**
C-Reactive Protein (CRP)	Mann-Whitney U	6.70e-19	r=0.582
Vitamin D	Mann-Whitney U	2.59e-10	r=-0.438
Aspartate Aminotransferase (AST)	Mann-Whitney U	3.01e-6	r=-0.334
BMI, Height, ALP	Welch t / MWU	n.s. (>0.05)	small

Table 2. Strongest Correlated Feature Pairs (Top 6 Of 19, |R|>=0.80)

Feature 1	**Feature 2**	r
Total Body Fat Ratio	Lean Mass	-0.998
Total Body Water	Muscle Mass	0.917
BMI	Total Fat Content	0.910
Total Body Water	Extracellular Water	0.897
Intracellular Water	Muscle Mass	0.888
Total Fat Content	Visceral Fat Area	0.885

3. Classification Models

Four tree-based models were compared: CatBoost [13], XGBoost [14], LightGBM [15], and Random Forest [16]. Hyperparameters were tuned with Optuna [17] (60 trials each, 5-fold CV, AUC objective) on the training set only.

4. AUC-Optimized Weighted Ensemble

The four models were combined by soft voting with weights optimized via differential evolution [18] on train-only out-of-fold predictions, maximizing AUC alone (no diversity objective). The single-run weights were CatBoost=0.485, XGBoost=0.497, LightGBM=0.000, RF=0.018. Their stability and the intercorrelation among the base models are assessed in Section IV-3.

5. Statistical Validation

Repeated stratified 5-fold x 10-repeat cross-validation was used for all models, with hyperparameters fixed as in Section III-C (base hyperparameters were selected once on the training set and were not re-tuned within each fold; only the ensemble weights were nested, below). Repeated-CV estimates should therefore not be interpreted as fully nested estimates of the complete model-selection pipeline; a full nested hyperparameter search was not computationally feasible within this conference paper timeline. A dedicated nested procedure tested whether the single-run weight optimization was optimistic: for each of 50 outer folds, weights were re-optimized on an inner 5-fold out-of-fold split of that fold's training portion only, the models were refitted on the full outer training data, and the models were evaluated on the held-out outer test fold. Because the 50 folds are not independent (the same 255 patients recur across repeats), confidence intervals were calculated using the Nadeau-Bengio correction [19], which adjusts the variance estimator for the train/test size ratio; the same correction was used for a paired t-test of the 4-model vs. 2-model difference on identical folds. McNemar's test [20] (accuracy) and DeLong's test [21] (AUC), with Holm-Bonferroni correction, assessed the ensemble's superiority over each base model on the held-out test set.

6. Calibration

Calibration intercept and slope were estimated by logistic recalibration of each model's logit-transformed probabilities against the outcomes, along with the Brier score, providing a secondary check on the classifier backbone's clinical relevance beyond discrimination [11].

7. Explainable AI

SHAP [22] values were computed per model using TreeExplainer as a secondary, supporting analysis; cross-model agreement was assessed using Spearman/Kendall correlations and top-5/top-10 Jaccard overlap.

The primary analysis compares two counterfactual methods: DiCE [8] (genetic search) and PertCF [9] (ablation-based greedy median-shifting), both run on all 31 test patients predicted gallstone-positive by the ensemble, with age, sex, height, and diagnosed comorbidities held constant. Laboratory values (e.g., CRP, Vitamin D) were left as mutable target biomarkers for the model's decision boundary, not as a prescription for direct clinical intervention; this distinction is revisited in Section V-3. DiCE's own validity claims were never trusted directly; every raw candidate was independently re-verified against the classifier. Both methods' raw outputs were passed through an identical backward-elimination step, reverting changes to features one at a time with re-verification after each step. Hence, the comparison reported below is DiCE+BE vs. PertCF+BE, not the raw outputs. Because DiCE can yield up to three candidates per patient, backward elimination was applied to each of the (up to three)

raw candidates, and only the resulting lowest post-elimination proximity candidate per patient was retained, yielding a genuinely matched 31-vs-31 sample for all paired tests. Metrics: coverage, sparsity, normalized-L1 proximity, and range feasibility (changed values within the observed training range). Each generated counterfactual was further checked against the 19 correlated pairs from Section III-2: changing exactly one member of a pair without the other is flagged as a dependency-consistency violation, a proxy for, not proof of, physiological implausibility, since a high correlation does not imply a deterministic per-patient dependency. Sparsity/proximity/runtime differences were tested with paired Wilcoxon signed-rank tests (Holm-Bonferroni corrected, matched-pairs rank-biserial effect size); the violation-rate difference was tested with matched McNemar.

IV. RESULTS

1. Classification Performance

Repeated CV AUC ranged 0.838-0.856 across base models; the naive (single-run) ensemble reached 0.863 (Table 3). On the held-out test set (n=64, Table 4), XGBoost outperformed the ensemble (90.6% vs. 85.9% accuracy) and also showed the most favorable calibration indices. This discrepancy with the CV ranking likely reflects small-sample test-set variability (n=64) rather than true model superiority; Section IV-3 addresses why a single fixed backbone was nonetheless used for the counterfactual comparison.

Table 3. Classification Performance (Repeated CV and Nested)

Model	Accuracy (%)	AUC
CatBoost	77.61	0.8559
XGBoost	77.41	0.8528
LightGBM	76.94	0.8422
Random Forest	75.92	0.8375
Ensemble (naive, single-run weights)	78.39	0.8628
Ensemble (nested, honest estimate)	77.57	0.8519
2-model average, CatBoost+XGBoost (nested)	78.35	0.8628

Table 4. Held-Out Test Set Results (N=64)

Model	Accuracy (%)	AUC	TN	FP	FN	TP
CatBoost	76.56	0.883	26	6	9	23
XGBoost	90.62	0.926	29	3	3	29
LightGBM	82.81	0.909	29	3	8	24
Random Forest	78.12	0.875	27	5	9	23
Ensemble	85.94	0.910	28	4	5	27

2. Statistical Significance vs. Base Models

After Holm-Bonferroni correction, the ensemble showed no significant superiority over any base model (Table 5, all p_Holm>0.05). This does not prove the absence of a true difference; given n=64, both limited power and a genuinely small/negligible difference remain plausible and cannot be distinguished here.

Table 5. Ensemble Vs. Base Models (Holm-Bonferroni Corrected)

Comparison	McNemar p_Holm	DeLong p_Holm
Ensemble vs CatBoost	0.125	0.085

Ensemble vs XGBoost	0.539	0.259
Ensemble vs LightGBM	0.688	0.938
Ensemble vs Random Forest	0.539	0.148

3. Ensemble Weight Instability and Nested Evaluation

Base-model predictions were highly correlated (Pearson r=0.90-0.94), and under nested evaluation (Section III-5), the optimized four-model ensemble did not significantly outperform the simple CatBoost-XGBoost average (AUC 0.852 vs. 0.863; Nadeau-Bengio corrected paired test, p=0.206). Ensemble weighting, therefore, provided no statistically established benefit for this dataset size. The ensemble was nevertheless retained as the pre-specified fixed backbone for the counterfactual comparison, since both DiCE and PertCF were evaluated against the same, unchanged backbone throughout; changing it post hoc based on a held-out test split would itself constitute the kind of small-sample overfitting this analysis warns against.

4. Calibration

XGBoost showed the most favorable calibration indices on the held-out sample (slope=0.953, Brier=0.098); all models showed a positive calibration intercept (0.107-0.207) in this test set, suggesting underprediction of absolute risk that may require external validation to generalize. Full calibration and decision-curve results are omitted here for brevity, as they are secondary to this paper's counterfactual comparison; the AUC values already summarize classification discrimination in Table 4.

5. Counterfactual Comparison: DiCE vs. PertCF

Both methods reached 100% coverage and 100% range feasibility (every changed value fell within the observed training range) on all 31 patients. DiCE's raw (pre-backward-elimination) output changed 27.8 features on average; backward elimination reduced this by 88.9% to 3.09. PertCF's raw output changed 8.90 features, reduced by 69.6% to 2.71 (Table 6), indicating that DiCE's raw genetic-search solutions contained substantially more removable feature changes under the common backward-elimination procedure.

Table 6. Raw Vs. Backward-Eliminated Sparsity

Method	**Raw sparsity**	**After BE**	**Reduction**
DiCE	27.78	3.09	88.9%
PertCF	8.90	2.71	69.6%

Table 7. Paired Wilcoxon Test (N=31)

Dimension	**DiCE (median)**	**PertCF (median)**	**p_Holm**	**Effect size**
Sparsity	2.0	2.0	0.313	-0.38
Proximity	0.932	0.977	0.544	0.127
Runtime (s)	3.80	0.625	<0.001	-1.00

Dependency-consistency (Table 8) showed PertCF violating at least one correlated pair in 54.8% of matched counterfactuals vs. 38.7% for DiCE (mean 2.74 vs. 1.71 violations per case); this difference was not significant (exact McNemar p=0.125, 7 discordant pairs). This is the primary result used for the dependency-consistency comparison.

Table 8. Dependency-Consistency Violations (Matched, N=31 Each)

Method	**Violation rate**	**Mean violations/case**
DiCE (best per-patient candidate)	38.7%	1.71

PertCF	54.8%	2.74

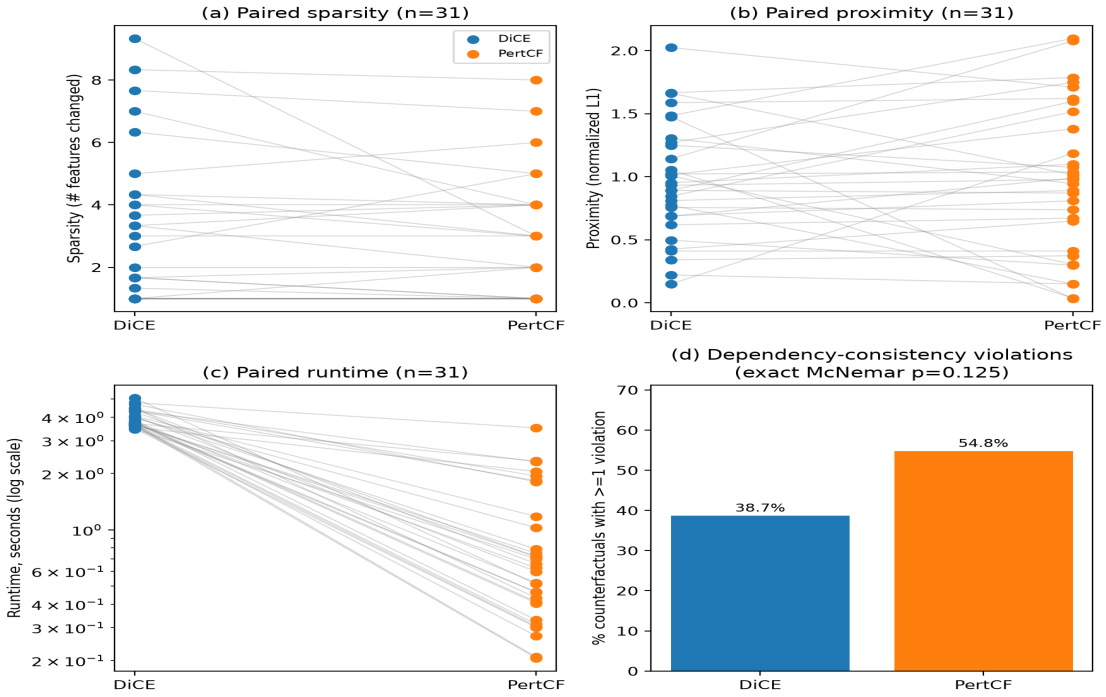

Figure 1. DiCE vs. PertCF, matched comparison: (a) sparsity, (b) proximity, (c) runtime (log scale), (d) dependency-consistency violation rate.

6. SHAP Cross-Model Agreement

SHAP values from the four models consistently ranked CRP and Vitamin D highest, associated with the model's output rather than implying a causal risk-increasing or risk-decreasing relationship. This convergence with Sections IV-B/E should be read as cross-method convergence rather than independent validation, since all four models share the same training data and yield highly correlated predictions. Given the strong correlations documented in Table 2, SHAP attribution may also be split across correlated body-composition features rather than assigned entirely to a single variable, a known limitation of Shapley-based attribution in the presence of multicollinearity. Cross-model SHAP rankings showed high agreement (Spearman rho=0.849-0.962), with CRP and Vitamin D consistently among the top-ranked variables across all four models.

V. DISCUSSION

1. Interpreting the Counterfactual Comparison

The similar post-elimination sparsity despite markedly different raw search behavior (Table 6) suggests that the common backward-elimination stage, rather than the native generator alone, substantially shapes the final counterfactual representation. DiCE's genetic search and PertCF's greedy ablation converge toward comparably sparse solutions once redundant changes are removed, even though their raw outputs differ by nearly an order of magnitude. This indicates partial agreement between the two strategies after post-processing, rather than proof that either has found the model's "true" decision boundary. PertCF's speed advantage converges with, though does not directly replicate, findings in a different domain [10]. No counterfactual method was uniformly superior

across all evaluated dimensions: PertCF was significantly faster, sparsity/proximity were statistically indistinguishable, and PertCF's numerically higher rate of dependency-consistency violations did not reach significance (Section IV-5).

2. Ensemble Finding

The ensemble backbone's modest CV advantage did not hold under nested evaluation or on the test set. High base-model correlation (0.90-0.94) plausibly contributes to this instability, though sample size and optimizer variance may also play a role. This is presented as an honest methodological finding, not as a limitation of the counterfactual comparison, which used a single fixed backbone throughout.

3. Clinical Interpretation and Limitations

Counterfactual outputs are model-derived changes to features, not causal or actionable clinical recommendations. CRP, for instance, is an acute-phase reactant rather than a directly controllable input. Calibration and decision-curve results are exploratory, single-center, and require external validation before any claim of clinical utility can be made. Because DiCE generated up to three candidates per patient and only the lowest-proximity one was retained, whereas PertCF produced a single deterministic solution, the paired comparison may be conservative with respect to PertCF on proximity; this selection rule was a deliberate design choice, disclosed here for transparency. Because DiCE uses unseeded stochastic (genetic) search, its output and any significance test built on it may vary between runs; future studies should quantify this run-to-run variability across multiple independent runs rather than relying on a single run, as done here for the main analysis. More broadly, dependency-consistency violations are a proxy for, not proof of, physiological implausibility, and neither method enforces joint updates for correlated features, a concrete direction for future work.

VI. CONCLUSION

This study compared DiCE and PertCF for gallstone risk prediction using matched, paired statistical tests. Neither method was uniformly superior: sparsity and proximity were statistically indistinguishable, PertCF was significantly faster, and PertCF showed a higher but non-significant rate of dependency-consistency violations. The ensemble classification backbone showed no significant advantage over a simple two-model average under nested cross-validation, consistent with high inter-model correlation. SHAP and univariate analysis consistently identified CRP and Vitamin D as the strongest predictors. Future work should develop counterfactual generation methods that jointly update correlated features and should quantify DiCE's run-to-run variability directly.

Abstract
In this study, a convolutional neural network-based approach was developed to automatically classify eight retinal conditions from retinal optical coherence tomography (OCT) images. The balanced dataset comprising AMD, CNV, CSR, DME, DR, DRUSEN, MH, and NORMAL classes is divided into training, validation, and test sets in an 80%/10%/10 % split. Images were resized to 224×224 pixels, and the CNN model, consisting of three convolutional blocks, was trained for 10 epochs. The model achieved 98.68% accuracy on the training set, 81.14% on the validation set, and 79.57% on the test set. The results show that the developed model can learn distinctive structural features in retinal OCT images and offers a feasible performance for multi-class classification. However, the difference between training and test performance indicates that the model's generalization capacity needs improvement.

Keywords: Retinal Diseases, Optical Coherence Tomography (OCT), CNN.

I. INTRODUCTION

Retinal diseases are significant ophthalmological problems that can affect visual function to varying degrees and, in some cases, lead to progressive vision loss [1]. Early diagnosis and accurate assessment of retinal structures are crucial for developing appropriate treatment plans and monitoring disease progression [2]. In this process, optical coherence tomography (OCT) is a widely used imaging method for clinical evaluation due to its ability to visualize the retina's cross-sectional structure at high resolution [3]. Distinguishing morphological changes caused by different retinal diseases in OCT images can be time-consuming, even for experienced specialists [4]. Furthermore, the increasing imaging volume has increased the need for computer-aided decision systems capable of automatically analyzing images. In recent years, the widespread use of deep learning-based methods in medical image analysis has enabled the direct learning of distinguishing features from OCT images.

Convolutional neural networks (CNNs) offer an effective approach to image classification problems by learning hierarchical representations of edges, textures, shapes, and more complex spatial patterns. While traditional methods require the predetermination of features and the design of a separate feature-extraction phase, CNN-based models can directly learn the necessary representations for image classification during training. This feature provides a significant advantage in evaluating retinal OCT images, where morphological differences can vary across classes. In this study, a specially designed CNN model was used to automatically classify retinal OCT images into 8 classes. The eight classes considered in the study were Age-related Macular Degeneration (AMD), Choroidal Neovascularization (CNV), Central Serous Retinopathy (CSR), Diabetic Macular Edema (DME), Diabetic Retinopathy (DR), DRUSEN, Macular Hole (MH), and NORMAL. The model's performance was evaluated using training, validation, and independent test subsets; the model's learning and generalization behavior was analyzed by examining changes in accuracy and loss during training.

II. LITERATURE REVIEW

The use of optical coherence tomography (OCT) images in the automated classification of retinal diseases has become a significant research area with the development of deep learning methods [5]. The ability of OCT images to reveal detailed structural changes in retinal layers makes this imaging method particularly prominent in the computer-aided diagnosis of macular diseases. A review of the literature reveals that research focuses not only on improving classification accuracy but also on issues such as noise tolerance, generalizability, explainability, and the integration of diverse data sources. Liew and Agaian, in a broad study of OCT-based ocular disease prediction methods, compared manual feature extraction methods used over the last two decades with deep learning-based approaches [6]. The study evaluated various disease groups, including glaucoma, diabetic retinopathy, cataracts, amblyopia, and macular degeneration; existing methods were examined for accuracy, sensitivity, specificity, and computational cost. The researchers also highlighted the importance of open-access OCT datasets in model development and discussed the security vulnerabilities of OCT-based diagnostic systems against adversarial attacks. In this respect, the study reveals that not only high accuracy but also model reliability and safety should be considered when classifying retinal disease. Redesigning network architectures to extract more distinctive features from OCT images is also widely discussed in the literature. Karthik and Mahadevappa proposed an approach that aims to make high-contrast regions, such as retinal layers, more prominent in feature maps by modifying residual connections in the standard ResNet architecture [7]. The developed structure increases the contrast in residual connections and enables the acquisition of sharper feature maps. In addition, the proposed activation function is designed to support smaller gradients while preserving negative weights. In experiments conducted on two different OCT datasets with four and eight classes, an increase in classification accuracy was reported compared to standard structures. In particular, an improvement of approximately 1.6% was observed when the initial accuracy was lower, and more significant gains were evident in the confusion matrix results when the class distribution was unbalanced, indicating that architectural improvements can be effective for classes with limited samples. Similarly, Peng, Lu, Zhuo, and Li focused on reducing the impact of speckle noise on classification performance in OCT images [8]. The researchers developed a model called the Multi-Scale Noise-Reducing Residual Convolutional Network (MS-DRCN). The proposed structure consists of Soft-Denoising Blocks to suppress speckle noise, Multi-Scale Context Blocks to capture contextual information at different scales, and Feature Fusion Blocks to combine high- and low-resolution features. The model achieved classification accuracy of 96.4% and 96.5% in the OCT2017 and OCT-C4 datasets, respectively. Furthermore, experiments adding different levels of Gaussian and speckle noise to the test data showed that the proposed method achieved 0.6% to 2.9% higher accuracy than ResNet. These findings demonstrate that noise-tolerant feature extraction is important for model performance in OCT classification systems. In addition to high classification success, the explainability of the models' decision processes is also a prominent issue in recent studies. Wang et al. investigated the use of explainable artificial intelligence methods for detecting age-related macular degeneration. The study considered various ophthalmic imaging modalities, including color fundus photography, OCT, ultra-wide-field fundus imaging, and fundus angiography [9]. The researchers aimed to optimize the deep learning model using insights from XAI methods and to make AMD diagnostic systems more reliable. The findings show that explainable artificial intelligence can contribute not only to making model decisions more understandable but also to improving model robustness. This approach is important for increasing confidence in AI-based decision support systems in clinical applications.

Multimodal approaches are being developed to evaluate retinal diseases, moving beyond models based solely on image data. The VisionTrack system proposed by Zedadra et al. has a hybrid structure that integrates multiple data sources [10]. The system uses a CNN for image feature extraction, a Graph Neural Network for modeling relationships among clinical risk factors, and a Large Language Model for processing patients' medical reports. Evaluated on the RetinalOCT and RFMID datasets, the system achieved an accuracy of 0.980, an F1 score of 0.979, a recall of 0.978, and a precision of 0.979 on the RetinalOCT dataset. Accuracy was reported as 0.989 on the RFMID dataset. The results of the study demonstrate that the combined evaluation of imaging, clinical

information, and patient-reported textual data can achieve strong classification performance in predicting retinal disease. Overall, the literature shows that CNN-based methods are effective for classifying retinal OCT images, but research is increasingly moving towards more complex, multi-component structures. Improvements in residual linkages, noise reduction mechanisms, multi-scale feature extraction, explainable artificial intelligence, and multimodal data integration are among the main approaches used to enhance performance and reliability. However, increased architectural complexity leads to higher computational costs and more model parameters. In this context, evaluating the performance of a relatively open CNN architecture that can directly distinguish eight retinal classes from OCT images is important for establishing a basic experimental framework for comparison with more complex methods.

III. MATERIAL AND METHODS

1. Dataset

Retinal OCT Image Classification - C8 dataset was used in this study [11]. The entire dataset consists of 24,000 retinal OCT images and includes eight classes: AMD, CNV, CSR, DME, DR, DRUSEN, MH, and NORMAL. Sample data is shown in Figure 1. In the original dataset structure, there are 3,000 images per class: 2,300 in the training folders, 350 in the validation folders, and 350 in the testing folders.

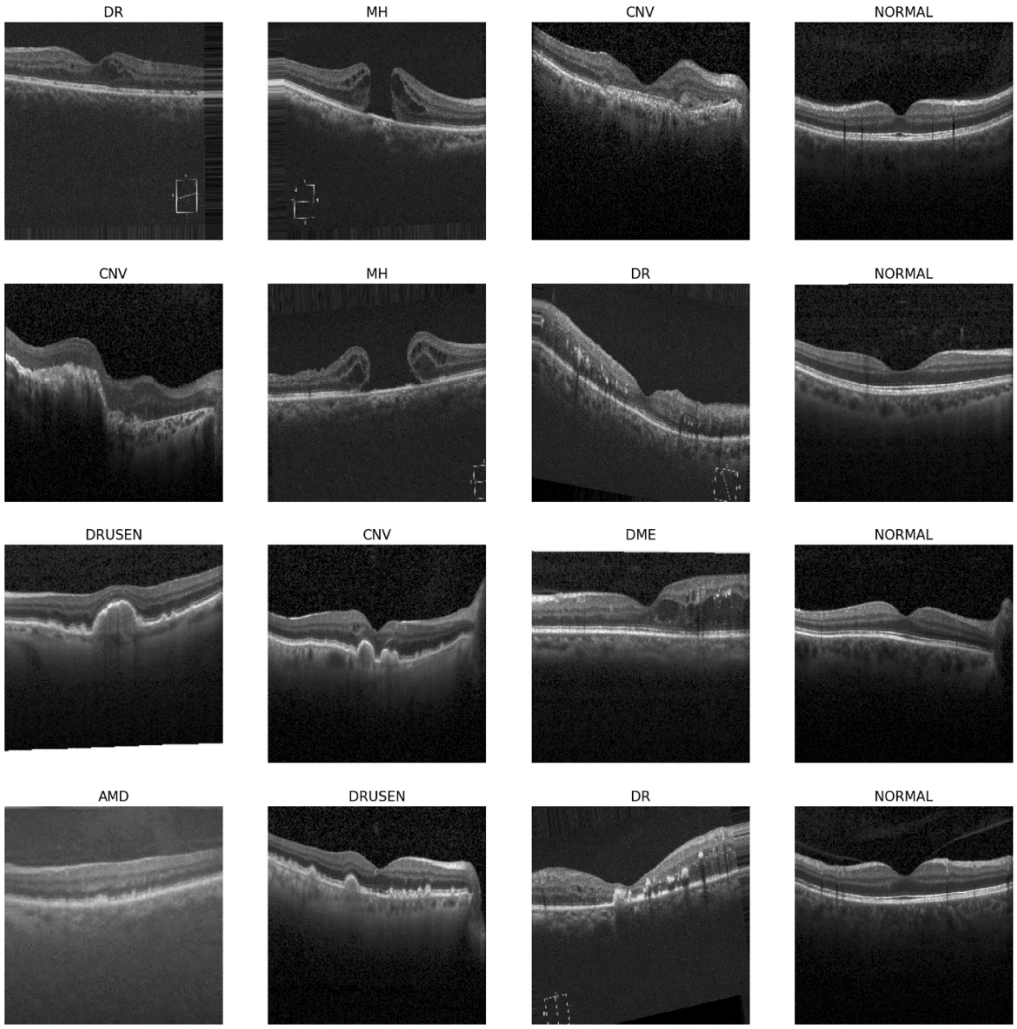

Figure 1. Sample data.

However, in this study, the dataset's pre-existing validation and test folders were not used directly. In the experimental design, only the 18,400 images found in the original train folder were used as the working data pool. Since each class contains 2,300 images, the dataset is perfectly balanced across classes. Stratified sampling was used to preserve the class distribution in dividing the data into training, validation, and test sets. In the first stage, 80% of the data was allocated to the training set, and the remaining 20% was split equally between the validation and test sets.

Table 1. Dataset ratios.

Dataset	**Image**	
Train	14.720	80%

Test	1.840	10%
Validation	1.840	10%
Total	18.400	100%

As a result of stratified division, each class was represented by 1,840 images in the training set, 230 in the validation set, and 230 in the test set. This ensured a balanced experimental structure, preventing the model performance from being affected by the numerical dominance of any single class. Since the original image sizes varied, all images were rescaled to 224 × 224 pixels and processed in three-channel RGB format before being fed into the model. The batch size was set to 16 for model training, and labels were created categorically, in accordance with the multi-class classification problem.

2. Convolutional Neural Networks

In this study, a custom convolutional neural network trained from scratch was developed to classify retinal OCT images. The model is constructed from three basic convolution blocks, each with increasing numbers of filters, to perform hierarchical feature extraction from low-level local features to more complex morphological structures in the images. The input layer of the model accepts RGB images with dimensions of 224 × 224 × 3. The first block contains two 3 × 3 Conv2D layers with 64 filters. The second block uses three Conv2D layers with 128 filters, and the third block uses four Conv2D layers with 256 filters. The same padding was used to preserve spatial dimensions across all convolution layers, and the Rectified Linear Unit (ReLU) activation function was used for nonlinear transformation. A 2 × 2 MaxPooling layer was applied after each convolution block. MaxPooling reduces the spatial dimensions of feature maps while preserving dominant features and reducing the computational load in subsequent layers. After the third convolution block, the resulting feature maps are converted into a one-dimensional feature vector via the Flatten layer. In the classification section, two fully connected layers with 256 and 64 neurons, respectively, are used, and ReLU activation is applied to each. The last layer consists of 8 neurons and uses the softmax activation function to produce class probability distributions. Based on the architecture defined in the code, the model has 53,870,600 trainable parameters. The general structure of the model architecture is shown in Figure 2.

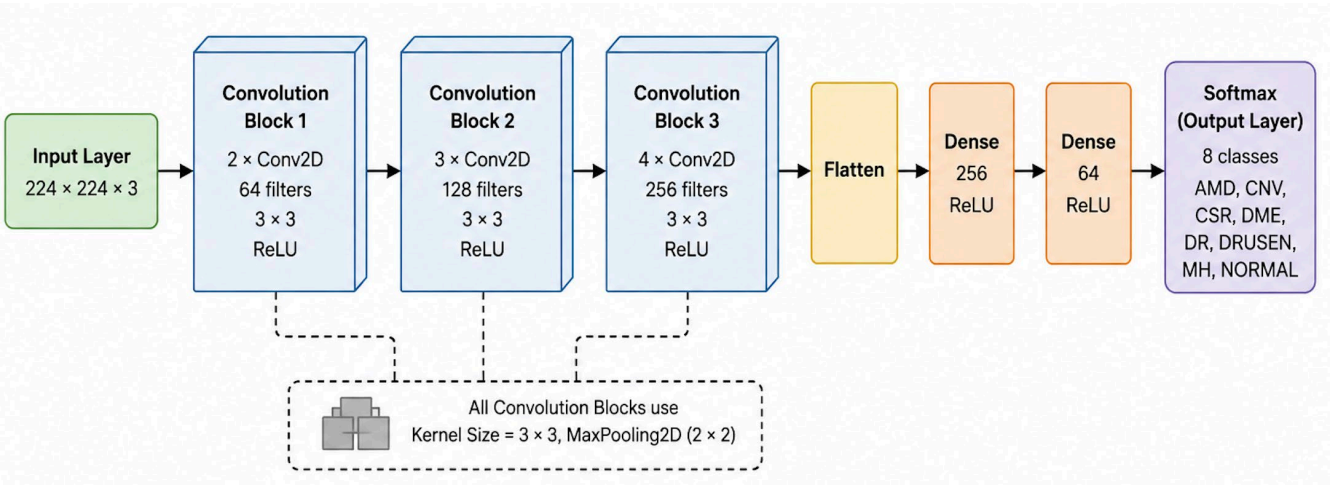

Figure 2. Model architecture.

IV. EXPERIMENT AND RESULTS

Experiments were conducted using the TensorFlow/Keras library. The training set used 14,720 images, while the validation and test sets each used 1,840 images. The batch size was set to 16, and the model was trained for 10 epochs. During training, at the end of each epoch, the accuracy and loss values on the validation set were calculated to monitor not only the model's learning on the training data but also its generalization to unseen data. As a result of training, the model achieved an accuracy of 0.9868 (98.68%) and a loss of 0.0380 on the training set. On the validation set, the accuracy was 0.8114 (81.14%) and the loss was 1.1539. On the test set, which was separate from the training process, the model showed an accuracy of 0.7957 (79.57%) and a test loss of 1.2704. The obtained values indicate that the model learned the patterns in the training data with a very high accuracy. However, the approximately 17.5 percentage-point difference between training and validation performance indicates that the model is becoming increasingly fit to the training data and that overlearning tendencies emerge as training progresses. The fact that test accuracy is close to validation accuracy is significant, as it shows that a similar level of generalization is achieved across both validation and test sets.

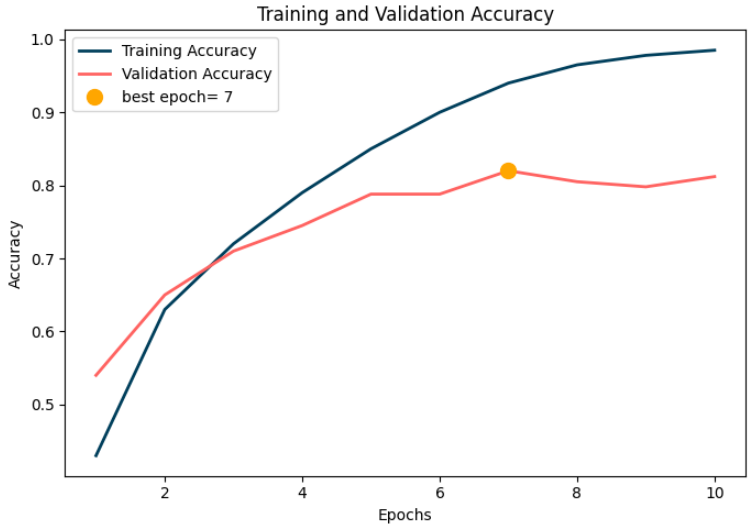

Figure 3. Accuracy curves.

As shown in Figure 3, training accuracy increased steadily from the first epoch and approached approximately 99% in the last epoch. Validation accuracy also increased significantly in the first part of training; however, the rate of increase decreased significantly after approximately the fifth epoch. The highest validation accuracy was achieved at approximately 82% in the 7th epoch. After this point, while training accuracy continued to increase, the fact that validation accuracy did not improve at the same rate indicates that training and validation performances began to diverge.

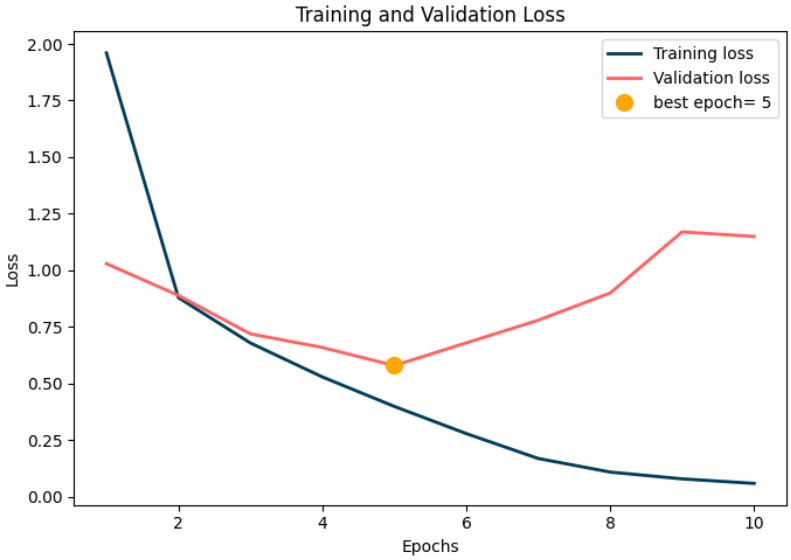

Figure 4. Loss curves.

A similar behavior is more clearly seen in the loss curves. Examining Figure 4, it can be seen that training loss steadily decreases throughout all epochs, approaching approximately zero. Validation loss also decreased during the first five epochs, reaching its lowest value around the 5th epoch. The fact that training loss continues to decrease while validation loss starts to rise again after the fifth epoch provides strong evidence that the model has begun overlearning. It is noteworthy that validation accuracy peaks around the 7th epoch, while validation loss reaches its minimum around the 5th epoch. While accuracy only considers the proportion of correctly classified samples, categorical cross-entropy also accounts for the model's predicted probabilities for correct and incorrect predictions. Therefore, even if the model continues to classify some images correctly, validation loss can increase as it begins producing higher-confidence values for incorrect predictions. Therefore, evaluating the training curves together is more informative than evaluating model behavior solely by accuracy. The overall test accuracy of 79.57% demonstrates that the developed CNN model can distinguish eight retinal OCT classes with reasonable generalization. However, despite training accuracy exceeding 98%, validation and test results remaining at around 80% indicate that the current architecture's high capacity leads to overfitting on the training data. The model's approximately 53.9 million trainable parameters are also consistent with this behavior; the fully coupled section, especially after the Flatten layer, constitutes a significant portion of the parameter count. These results suggest that methods such as early stopping, dropout, weight regularization, online data enhancement, or a lower-parameter classification header could be evaluated in future studies for stronger generalization performance. In particular, since validation loss begins to increase after the fifth epoch, saving the model weights at the best validation performance may yield more stable results than using the last-epoch model.

V. DISCUSSION

The findings show that the proposed CNN architecture achieves high training success on retinal OCT images, but validation and test performance decline significantly. Specifically, the fact that training loss continues to decrease while validation loss increases after the fifth epoch suggests that the model is overlearning. This may be related to the architecture's high capacity relative to the data volume, with approximately 53.9 million

trainable parameters. Nevertheless, the 79.57% test accuracy indicates that the model demonstrates strong classification performance on unseen OCT images. Future studies aim to improve generalization performance by increasing data volume, using dropout, early stopping, and employing fewer-parameter architectures.

ACKNOWLEDGEMENT

This study was conducted on a computer funded by the Gazi University Scientific Research Projects Coordination Unit under project number FPD-2025-9669.

Abstract

This study aims to identify students' recurring writing errors through AI-assisted analysis and use the findings to design a writing course syllabus. To define course objectives, it is essential to explore students' needs. To design the syllabus for a writing course, 50 essays written by engineering students are analyzed by using Gen-AI technology (GPT-5.6), and the errors are identified under a pre-defined 18-category taxonomy. The findings indicate that the major language knowledge flaw lies in lexico-grammatical accuracy, particularly in collocation and subject-verb agreement, rather than in surface-level writing mechanics such as spelling or punctuation. The study recommends that the suggested course syllabus focus primarily on vocabulary, with an emphasis on teaching and learning vocabulary in chunks.

Keywords: syllabus design, error analysis, error frequency, Artificial Intelligence

I. INTRODUCTION

In academia, writing skills are considered a basic requirement for university students to convey their scientific understanding and participate in academic discussions in writing. Some faculties at Gazi University, including Medicine, Architecture, and Engineering, offer English-medium instruction. At that point, writing skills gain importance for those majors. The current writing course content is becoming obsolete; therefore, it needs to be more motivating and to the point in terms of students' needs. The students from the engineering department, despite being outstanding, need to improve their writing skills. The students receive English-medium instruction in their departments, so they mostly need to express their ideas in writing. Therefore, the new writing syllabus must meet their needs. This study aims to revise the writing course syllabus based on the results of AI-assisted error analysis of students' essays. The dynamic nature of technology requires some revisions to the current syllabus content. There are numerous types of AI-assisted applications for writing academic texts. However, students are required to produce original work related to their majors, so they need to improve their writing skills. To tailor a syllabus to students' needs, it is essential to conduct an error analysis of their own work.

Given the current issue, the following research questions are posed to achieve the study's aim.

- What types of linguistic errors are found in university EFL students' essays?
- Which error types are most prevalent in terms of raw and normalized frequencies?
- What do these error patterns suggest for the design of academic writing instruction?

1. Significance of the study

This study presents results indicating that instructors should maintain more learner-centered courses to improve students' writing skills.

II. RELATED LITERATURE

Recent developments in Gen-AI technologies infuse every aspect of education, including language learning and teaching. AI-assisted applications can be used in a wide range of areas in language education. In a meta-analysis by Xu et al. [1], it was found that AI-assisted second-language learning has a positive effect on receptive skills, namely listening and reading, as well as on learners' vocabulary knowledge. In addition to studies on the effects of AI-assisted language learning, numerous studies examine the benefits of AI technologies in second-language teaching, including course preparation [2,3], learner assessment [4,5], and language-learning material development [6].

1. Error Analysis in Sylabus Design for Language Teaching

Error analysis is a systematic approach to understanding errors made by second-language learners. Error analysis is conducted to understand what is missing in learners' language knowledge. It involves categorizing errors and determining causes, such as flaws in understanding grammatical rules. To design a learner-centered syllabus for language courses, it is essential to acknowledge learners' language levels.

2. AI-Assisted Error Analysis

AI technologies are primarily used to detect language errors and provide users with feedback to improve their writing skills, according to recent related literature. As in Tseng and Lin [7], AI-assisted writing tasks enhance students' writing skills and improve writing quality. Pack et al. [8] claim that with the development of AI technologies, providing feedback on written work will no longer be time-consuming in the near future. On the contrary, in this study, the main task for Gen-AI is the identification and classification of errors in the essays using a fixed, researcher-controlled taxonomy. After reviewing the related literature, there is no similar use of AI for this purpose.

III. METHODOLOGY

1. Participants and Writing Corpus

In this study, a corpus of learners' written samples was compiled from 50 essays (25 males and 25 females). Students study on a full-time basis at the Engineering Faculty from six different departments, including Industrial Engineering, Mechanical Engineering, Civil Engineering, Electrical and Electronics Engineering, Computer Engineering, and Chemical Engineering. The students have been studying at different departments of the English-medium Engineering Faculty for two years. In their first year, they have a three-hour General English course during two semesters. In their second year, they have a three-hour Academic English writing course during two semesters. Engineering students must take the Prep school proficiency exam before starting their majors. Students who pass the proficiency exam begin their own majors. Students who fail the proficiency exam must take a one-year preparatory language program with a 24-hour weekly schedule. The preparatory school curriculum offers A1, A2, and B1-level English language education based on a skills-based curriculum. The ultimate purpose is for students to succeed in B1-level language education across all four language skills equally.

Consequently, the students who take language courses at their own faculty have diverse language backgrounds. At that point, it is essential to design a syllabus shaped by students' needs.

2. Error Analysis Framework

Engineering students have written different types of essays, ranging from a comparison essay to an argumentative essay, during their essay quiz. The corpus is generated from fifty randomly selected essays across over three hundred quizzes. The essays are anonymized and photographed for upload to the AI system. To analyze the errors, the error categories are defined as shown in the table below.

Table 1. Error Categories

Code	Error Category	Operational Definition
LEX	Lexical choice	Incorrect/inappropriate lexical item for the intended meaning
COLL	Collocation/phraseology	Words are individually possible, but form an unconventional combination
WF	Word form	Correct lexical family but incorrect morphological form/category
ART	Article/determiner	Omission, unnecessary use, or incorrect choice of article/determiner
PREP	Preposition	Incorrect, missing, or unnecessary preposition
SVA	Subject-verb agreement	The verb does not agree with the grammatical subject
COUNT	Countability/number	Incorrect singular/plural or count/non-count treatment

Code	Error Category	Operational Definition
VF	Verb form/pattern	Incorrect tense, aspect, infinitive, gerund, participle, auxiliary, or complementation pattern
SYN	Sentence structure/syntax	Malformed clause or sentence structure not adequately explained by a more specific category.
PRO	Pronoun/reference	Incorrect, ambiguous, missing, or unclear pronoun/reference
ADVADJ	Adjective/adverb modification	Incorrect adjective/adverb form or inappropriate modification
CONJ	Conjunction/linking expression	Grammatically or semantically inappropriate connective
WO	Word order	Constituents appear in an unacceptable/non-target order
OM	Missing element	A necessary grammatical element is absent and does not belong more specifically to ART/PREP/etc.
RED	Redundancy	Unnecessary repetition or grammatically redundant element
PUNC	Punctuation	Missing, incorrect, or unnecessary punctuation
CAP	Capitalization	Incorrect upper/lower case

Code	Error Category	Operational Definition
SPELL	Spelling	An orthographic error that does not create a legitimate different lexical item

The images of the essays are named as M1, M2, etc. for male students, and F1, F2, etc. for female students. The images are uploaded in groups of five to the AI system. It works on the essays to identify errors and count them, enabling error frequency analysis across the 18 error categories. The system provides two datasets, including raw frequency and normalized frequency per 100 words for each essay.

3. AI-Assisted Analysis Procedure

Fifty anonymized essays are randomly selected from three hundred papers written by engineering students from different departments. Each paper has two different tasks, one of which is chosen by the student. Students have to write a five-paragraph essay on the given topic, with a word limit of 200-300 words. The essays are uploaded as images to ChatGPT one by one. They are first transcribed from handwritten to a digital form.

In the first step, the following prompt is provided in the ChatGPT chat box, along with images of five essays.

Could you please first transcribe the handwritten texts in the images? Then apply error analysis to each essay separately. At last, generate a table including error types and their raw and normalized frequencies for each one.

The system executes the prompt and first transcribes the essay in the image without correcting any mistakes. Afterward, it presents a table showing raw and normalized frequencies. The following image is a sample of the results.

F2 error analysis

Representative examples include *"Everyone need"* (SVA), *"theirself"* (PRO), *"In that point"* (PREP), *"first prefer"* (WF), *"an information"* (COUNT), *"so many information"* (COUNT), *"which one of the acceptable"* (SYN), *"the some signs"* (ART), *"reliable informations"* (COUNT), and *"help you for reality"* (COLL).

Code	Error type	Raw frequency	Per 100 words
SYN	Sentence structure / syntax	6	2.50
COUNT	Countability / number	6	2.50
ART	Article / determiner	5	2.08
SPELL	Spelling	5	2.08
SVA	Subject–verb agreement	3	1.25
PREP	Preposition	3	1.25
WF	Word form	2	0.83

With the help of the table, it is easy to identify which kinds of errors each student makes most and least. Therefore, it is possible to give individualized feedback to each student easily.

All five essay groups have been analyzed using the same prompt by the AI system. Afterward, the following prompt is used, and the system combines the tables into one spreadsheet in two versions. In the first version, all participants' errors were listed according to their pre-coded taxonomy. Below are the results from the 50-participant corpus.

Participant	Lexical Choice		Collocation		Word Form		Article		
	Raw	Norm/100	Raw	Norm/100	Raw	Norm/100	Raw	Norm/100	…
F1	3	1.13	8	3.01	2	0.75	3	1.13	
F2	1	0.42	2	0.83	2	0.83	5	2.08	
F3	0	0.00	6	1.93	0	0.00	5	1.61	
F4	1	0.49	6	2.94	6	2.94	6	2.94	
⋮									

All the data is given in an Excel document. After error analysis is applied to the fifty essays and a table is produced showing the number of errors and the normalized frequencies per 100 words, the following prompt is given to the AI system to generate more compact data identifying which error types are more prevalent in terms of normalized frequency.

Can you make a bar chart that sorts the error types from most to least prevalent using the Excel page uploaded here?

Gen-AI can read different kinds of documents and interpret the data in them. It is very efficient to convert the data from one format to another.

IV. RESULTS

1. Error Frequencies

With the assistance of AI technology, the number of mistakes categorized under the 18-category taxonomy is visualized into a bar chart in Figure 1, and the normalized frequency of the errors is demonstrated in Figure 2.

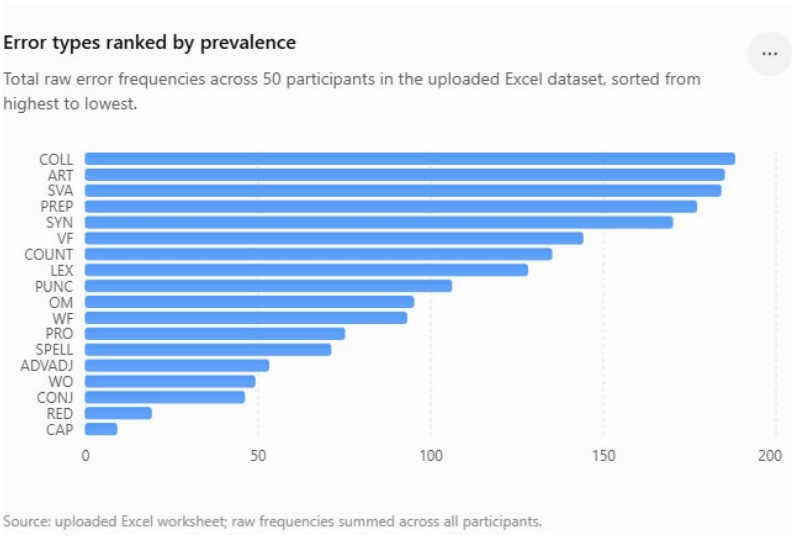

Figure 1. Raw error frequencies across the 18 error categories in the 50-participant corpus, ranked from highest to lowest.

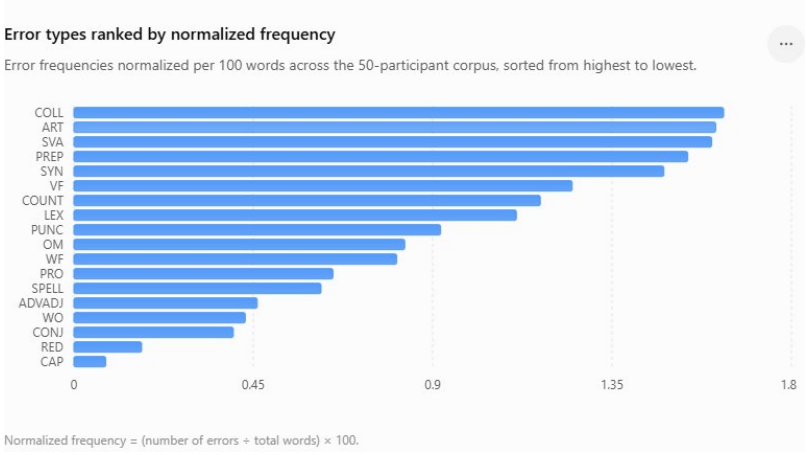

Figure 2. Normalized error frequencies (per 100 words) across the 18 error categories, ranked from highest to lowest.

As illustrated in Figures 1 and 2, the distribution of errors is not uniform across the 18 categories. Collocation errors were the most frequent (n = 188-1,63), closely followed by article/determiner (n = 185- 1,61), subject–verb agreement (n = 184-1,6), preposition (n = 177-1,54), and syntactic errors (n = 170-1,48). In contrast, redundancy (n = 19) and capitalization (n = 9) are relatively rare. The predominance of collocational, grammatical, and syntactic errors suggests that the learners' major difficulties lie in selecting contextually appropriate lexical combinations and controlling grammatical structures, rather than in surface-level writing conventions. The findings therefore indicate that EFL writing instruction may need to place greater emphasis on contextualized grammar and lexical patterning, particularly collocations, article use, agreement, and prepositions.

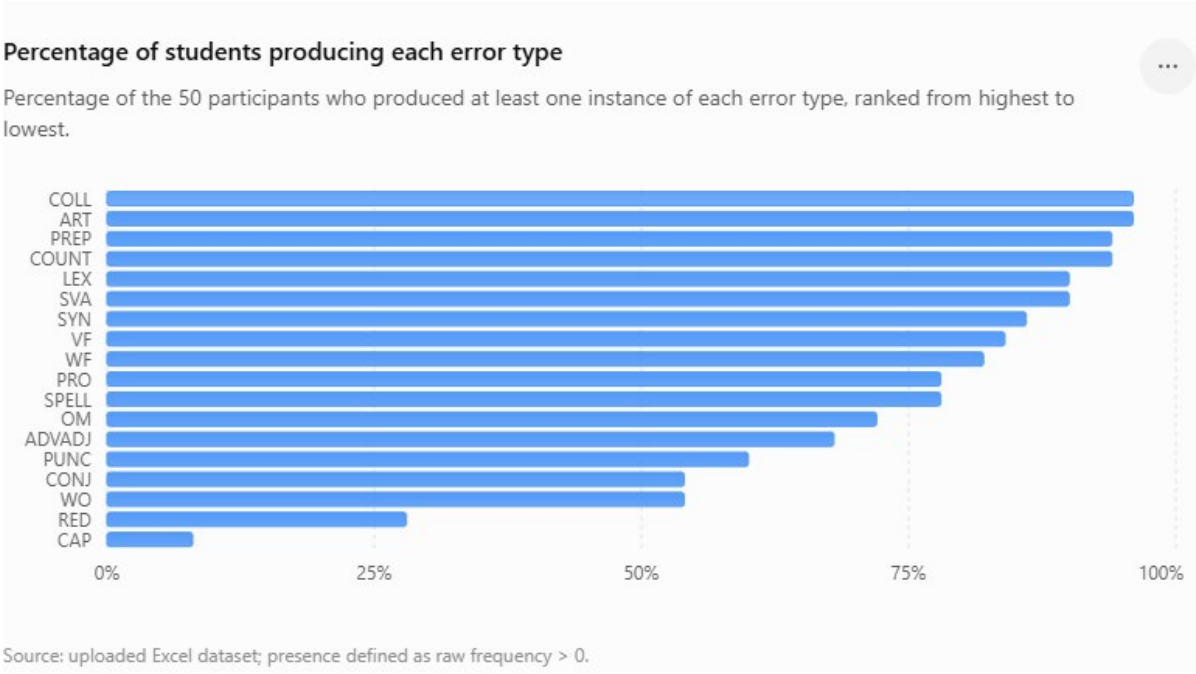

Figure 3. Percentage of the 50 participants producing at least one instance of each error type, ranked from highest to lowest.

Figure 3 shows that several error types were highly widespread across the 50 students. It indicates that they represent shared difficulties rather than problems restricted to a small number of learners. Collocation (COLL) and article (ART) errors are the most prevalent, occurring in 96% of the students, followed by preposition (PREP) and countability (COUNT) errors at 94**%**. Lexical (LEX) and subject–verb agreement (SVA) errors are also very common, each appearing in 90% of the participants. These findings suggest that difficulties involving both lexico-grammatical choice and grammatical accuracy are characteristic of the corpus as a whole.

A second group of errors is also broadly distributed. Syntax (SYN), verb form (VF), word form (WF), pronoun (PRO), and spelling (SPELL) errors occur in approximately 78–86% of the students. Thus, although their total raw frequencies may differ, these problems are experienced by a substantial majority of the learners.

In contrast, some error types are considerably less widespread. Punctuation (PUNC) occurs in 60%, while conjunction (CONJ) and word-order (WO) errors each occur in 54%. The least prevalent categories are redundancy (RED), found in 28% of students, and capitalization (CAP), found in only 8%.

V. DISCUSSION

The strongest learner need appears to be lexico-grammatical accuracy rather than writing mechanics alone**.** In particular, COLL, ART, PREP, and COUNT deserve the highest instructional priority because they combine high raw error frequencies with very high prevalence across students**.** This convergence is important: the errors are not simply repeated many times by a small group of weaker writers; almost the entire learner population shares them.

A second major need concerns sentence-level grammatical control, particularly subject–verb agreement, syntax, verb forms, and word formation. These results suggest that learners possess sufficient linguistic resources to produce extended written texts, yet still experience difficulty accurately combining them at the phrase and sentence levels.

Consequently, findings point toward three broader learner needs: **(**1) stronger phraseological and lexical competence, especially collocations; (2) greater control of grammatical form, particularly articles, countability, prepositions, agreement, and verb forms; and (3) improved self-editing and proofreading skills for spelling, omissions, punctuation, and other lower-frequency errors.

VI. CONCLUSION

With Gen-AI, large datasets can be easily and efficiently managed to provide a broad picture of the current situation across every aspect of education, from material development to the evaluation of learners' output. With this technology, time-consuming tasks are handled more efficiently in terms of time and human resources. Although some ethical issues related to Gen-AI exist, such as academic dishonesty [9] and data privacy [10], it facilitates big data management. It motivates teachers to improve the quality of their instruction. It helps reduce cognitive workload, enabling teachers to develop more creative ways to implement their courses.
